Foreword

VOLUME 53 of the TRANSACTIONS OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS contains 27 individual sections published during 1931 under the sponsorship of the Society's 15 professional divisions, as well as its annual Record and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections. Other papers published by the Society but not included in the Transactions may be located by means of the Record and Index which forms a part of this volume.

The papers published in this volume were issued originally in pamphlet form. These pamphlets appear in sections, each section being sponsored by one of the Society's professional divisions. A member of the Society may register in any three of the fifteen professional divisions, and receives in pamphlet form as they are issued the sections of Transactions sponsored by those divisions.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on page 97 of the Record and Index. Copies of the bound Transactions have also been set aside for sale.

At the end of Volume 53 will be found the Record and Index of the A.S.M.E. for 1931. This is the permanent record of the Society's activities for the year, and includes lists of committees, reports of meetings and committee activities, memorial notices of deceased members, as well as indexes of special A.S.M.E. publications and of *Mechanical Engineering*.

In this volume the papers of each section are grouped together and are numbered serially. The different sections follow each other alphabetically. Each paper is designated by a symbol composed of key letters followed by the volume number and paper number. The letters refer to the section of the Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS to the Iron and Steel section, etc. The arrangement of the index and designations for locating material are explained at the beginning of the index.

THE PUBLICATIONS COMMITTEE.

AER-53-1

Progress in Aeronautics

Contributed by the Aeronautic Division

Executive Committee: Charles H. Colvin, *Chairman*, Alexander Klemin, *Secretary*, Wm. F. Durand, Thurman H. Bane, Porter Adams, Wm. B. Mayo, and Edwin E. Aldrin

Aerodynamics[1]

WHILE the year 1930 has not been noteworthy for radical developments in applied aerodynamics, it may nevertheless be said that marked progress has been made in facilities for testing, in methods of obtaining and applying laboratory and flight test data, and in the further development of aerodynamic theory.

The construction of the world's first full-scale wind tunnel was started early this year at Langley Field by the National Advisory Committee for Aeronautics. This tunnel, with its 30-ft. × 60-ft. test section, will, when completed, easily accommodate airplanes of normal size.

In addition to its full-scale wind tunnel the N.A.C.A. has completed a new vertical type (with open throat), equipped with a continuous-rotation dynamometer for autorotation tests of airfoils and model airplanes.

Several new wind tunnels, among the most noteworthy being the large single-return type of California Institute of Technology, have been recently put into operation and are now busily engaged upon problems of fundamental importance. Furthermore two commercial firms have built complete aerodynamical laboratories, namely, the Sikorsky Aviation Corporation, with its vertical-jet wind tunnel, and the B/J Aircraft Corporation, of Baltimore, Md., with its open-jet double-return type.

A great deal of information for the future design of wind tunnels has been obtained from model tunnel experiments recently conducted by the N.A.C.A.

The research of Dryden and Kuethe, of the Bureau of Standards, has given us a clearer insight into the mechanism of turbulence, and has further emphasized the necessity of using it as a basis of standardization of wind tunnels.

The past successes of Karman, Polhausen, Prandtl, Bairstow, and others in solving certain fundamental problems in connection with the flow of viscous fluids, has more recently focused the attention of advanced students and physicists on many problems more directly related to aeronautics, such as the calculation of the drag of airship hulls, struts, airfoils, etc. In addition, however, many refinements have been made in the application of classical hydrodynamics to the solution of numerous practical problems involved in the design of airplanes, airships, propellers, helicopters, autogiros, etc.

The now classical theories of Prandtl and Munk have been applied with success to the determination of the rolling moment and hinge moment of conventional ailerons, the calculation of span and chord loadings of wings, the determination of stability and balance of airplanes, the calculation of the magnitude and distribution of load over tail surfaces during certain types of maneuvers, etc.

While the slotted wing has undergone more development in the laboratory than in theory, it may be stated that the calculation of the lift and moment of a multi-slot wing of elementary form by Tchapliguine, indicates that in certain cases we may expect increased inherent stability with a wing of this type. The recent development in England by Handley Page of the slot-and-aileron type of lateral control with an "interceptor" for increasing the effectiveness of the "up" aileron by spoiling the action of the slot on the wing to be depressed, has greatly minimized the dangers of the so-called "flat spin."

Paralleling the work of Handley Page is the further development of the floating aileron by the Curtiss Aeroplane and Motor Company. Also, this type of lateral control has been recently subjected to model tests by the N.A.C.A. in its vertical wind tunnel, and preliminary experiments have indicated in all cases either a marked reduction or absence of autorotative couple. Moreover, in addition to the laboratory studies of the floating aileron, investigators in England and in this country have subjected it to a thorough theoretical treatment in order to place its design on a rational basis.

During the past year or more, great progress has been made in coordinating the aerodynamical and structural phases of aircraft design. The Experimental Engineering Section (Matériel Division) of the Air Corps has carried out a large amount of research in connection with the vibration of wings and tail surfaces. In fact, the mathematical and experimental researches of Green at Wright Field, and of Frazer and Duncan at the National Physical Laboratory in England, have gone far toward placing the design of cantilever wings and tail surfaces on a sound basis.

In the realm of full-scale aerodynamic research—and apart from that already mentioned in connection with lateral control—we find the N.A.C.A. undertaking the most complete and systematic program of spinning research ever carried out up to the present time. It has been necessary to develop a number of special instruments for these and other tests, by means of which the committee is now able to determine among other things the forces and moments about the three axes of the airplane and the path of the center of gravity during a spin. By varying the mass distribution and aerodynamic arrangement of the airplane it will now be possible with these new facilities to ultimately obtain data whereby the designer will be able to predict the spinning characteristics of a proposed machine.

Commercial-aircraft concerns throughout the country have carried out an intensive development of the cowling of air-cooled engines, and this past year has witnessed the placing of venturi-type cowling and Townend ring design on a fairly sound engineering basis. The introduction of these improvements in the streamlining of aircraft with air-cooled engines has had a marked effect upon the design of commercial aircraft in this country.

Improvements in the autogiro have been noteworthy during 1930. The latest machines of the Pitcairn Autogiro Company are being equipped with a self-starter and a brake for the rotor. The former eliminates the necessity of ground taxiing in order to start the blades before take-off, and the latter enables the pilot to stop the rotor immediately upon landing. The latest autogiros are capable of a most satisfactory performance, and it is gratifying to note that Mr. Cierva, the inventor of this amazing craft, has developed the technique of design to such a high degree.

[1] Prepared by Wm. H. Miller, Assistant Chief Engineer, B/J Aircraft Corp., Baltimore, Md. Mem. A.S.M.E.

Propeller research during the past year is worthy of mention. There has been considerable progress in both theory and experiment. Notable contributions to design theory have been made by Roy in France and Pistolesi in Italy. The importance of the effect of peripheral speed on profile drag of the blades has been determined in a quantitative way by full-flight tests in England and by the staff of the Propeller Research Tunnel of the N.A.C.A in this country. It is of greatest importance to know that very serious losses in efficiency obtain at tip speeds in excess of 1000 ft. per sec., and valuable data are now available with which to estimate such losses.

The designer now has sufficient information to determine in any given case the advisability of using a geared propeller.

Progress in Airplane Design and Construction[1]

In spite of the depressed market for aircraft in 1930, the year seems to have been a most encouraging one when the progress made in airplane design and performance is considered.

Perhaps the increase of courage in design, and consequently of many new types—especially when we look back at the commercial plane of 1927 and 1928—might be said to be due to the increased competition brought about by poor business conditions. On the other hand, airplane designers have now a much wider choice with regard to selection of engines, and as a result, designs are becoming more varied all the time.

Similar in structural design to the Travel Airplane, developed in 1929, were the majority of the planes in the All-American Derby (for planes using Cirrus engines). These planes practically all have a low monoplane wing braced with wires to the landing gear, and to the upper portion of the fuselage.

However, the winner of the free-for-all speed contest at the 1930 National Air Racesin Chicago was a biplane—a Laird single seater with a fully cowled radial engine that governed the gap between the wings, these being tangent to the round fuselage, top and bottom.

Speed seems to have been the general aim this past year, and many designers have been willing to sacrifice a certain amount of pilot's vision in order to attain as much speed as possible.

Streamlining and close study of the aerodynamics of existing production types is evidenced by the new lines, fillets, and fairings on many types of the previous year—notable among these was the three-engine Ford. A number of excellent streamlined all-metal planes were developed, notably the low-wing Boeing Monomail, the Buhl mailplane, the metal Lockheed Vega, the Lockheed Sirius, and the further development of the all-metal Fleetster. The Monomail was an exceptionally modern design with cantilever wing and round fuselage, with ring-cowled engine. The landing gear retracted into the low wing.

Monoplanes seemed to be still increasing over the biplanes, with the number of externally and internally braced monoplanes almost equal. In England, where the biplane predominated for so many years, 1930 has found an increasing number of monoplanes from the De Haviland Moth series to the large Fairly and Short machines. The Bellanca sesquiplane type has continued in its development, and showed promise with the notable performance of the Bellanca Airbus.

A number of quite new experimental designs have been developed during the year such as the Northrup flying wing, the Emsco all-wing, the Waterman variable-incidence and variable-dihedral monoplane, and the McDonald Doodlebug, developed in 1929 for the Guggenheim Safe Aircraft Competition. Development of other new designs has continued, with the Curtiss Company experimentally applying a number of features of its Tanager to some of its other types, and with continuations of Furnic's and Locke-Wolf's experiments with the tail-first or Ente type. The Autogiro has been considerably improved by the Pitcairn Autogiro Company, which has developed a clutch-type starter as well as increased the performance of this promising plane.

Sliding and soaring planes have increased in remarkable numbers, and naturally their experience has been reflected in the development of many low-powered planes. These planes, which are produced very cheaply, are showing much promise for the private market.

During the year, the writer returned to America, and made a two months' tour of the centers of the aircraft industry. After having been abroad for some time, he was astounded at the progress made in metal development. Metal structures of all types had been brought to a high degree of perfection, with heat-treated chrome-molybdenum steel parts and sheet dural structures seeming to be the most in evidence. Welded and heat-treated steel spars, built-up sheet dural and alclad wings, and monocoque and semi-monocoque dural fuselages seemed to have appeared almost overnight. Manufacturers seemed to show confidence and experience in carrying out these designs. In England, the sheet-steel-strip type of spar construction was the most common, while most varied types of construction were to be found in Germany. Most firms were continuing with their work in dural and at the same time making tests and experimental airplanes from the magnesium alloy elektron. At the Ernst Heinkel Flugzeugwerke, in addition to the experimental work with dural and elektron structures, a series of all-steel spars (sheet-strip type) were developed to gain actual experience and knowledge of all of the types of construction and materials. The elektron structures seemed to be quite promising for inland usage where the air is dry, but at present the methods of preservation are not satisfactory enough to allow the material to be used in moist, salt air.

Hyblum, a comparatively new alloy claimed to have high resistance to corrosion, has come into use during the year, and seems to show much promise.

Stainless-steel sheet and strip for wing ribs and for use in floats subjected to severe corrosion conditions have been made during the year, and tried in service. The U. S. Navy and the British Air Ministry have sponsored a number of projects in stainless steel for use in sea water.

In detail design, a great deal of progress has been made in the standardization of parts and units, which will enable these to be marketed and produced much more efficiently and cheaply. Aluminum-alloy castings, especially in control systems and for complicated structural parts, have increased in usage. Metal ribs have come to be quite common, with most commercial ribs having specific strength-weight ratios of about 1400 to 1500. The Hall Aluminum Aircraft Co. claims to have developed ribs with ratios as high as 1800 to 3000.

In wing construction, especially in cantilever design, many interesting experimental structures have been made from the multi-spar to the monocoque type. The Fokker and Towle concerns developed interesting multi-spar dural wings having no ribs but depending on the skin and the number of longitudinal stringers to give the proper airfoil section. The Army Air Corps at Wright Field carried out an interesting series of experiments on monocoque-type wings.

Composite constructions (wood bracing and dural skin and gussets) for experimental or cheap construction have been developed to an increasing amount by Ireland and Aircraft Products, while Loening and Sikorsky, the best-known users of this type of structure, have shifted over to all-dural and they have standardized on their boat lines.

[1] Prepared by Richard M. Mock, an American aeronautical engineer at the time of writing. Now Consulting Engineer, Ernst Heinkel Flugzeugwerke, Warnemunde, Germany. Mem. A.S.M.E.

Balloon and semi-balloon tires have increased in use, and become standard equipment on many planes. However, on only the lightest planes or on racing types have they been used without shock absorbers. Hydraulic shock absorbers, both oil and spring and oil and air, have practically replaced the earlier rubber types.

Wheel brakes have been common on almost all commercial planes, and practically all of the Servo type. Sikorsky has developed a brake especially suited for amphibian use. It operates on the principle of a friction disk actuated by a hydraulic mechanism.

Floats and seaplane development have seemed to reflect Navy experience in the lines of seaplane floats and flying-boat hulls. By giving contracts to Martin, Douglas, Hall, and Keystone for building flying boats of the P. N. Type, the U. S. Navy has considerably aided flying-boat development in the United States. Sikorsky has developed his amphibian along larger lines, and is now working on a 32-passenger, four-engine plane of that type.

Ireland produced a light wire-braced monoplane amphibian flying boat, while Aeromarine Klemm and Edo have experimented with twin-float amphibians with wheels housed in the floats.

As in England, there seems to be some controversy as to the relative advantages of the twin-float seaplane versus the flying boat. The Ford plane and the English three-engined Short seaplane are examples of large twin-float designs.

In England, it is interesting to watch the development of seaplanes and flying boats. After considerable deliberation, service tests are being made on the twin-float seaplane, the flying boat with wing floats for lateral balance, and also the float boat with sponsons similar to those of Dornier except that they have a step across the bottom. Water rudders seem to be common on all flying boats and some seaplanes, especially the Italian.

Air Transport and Other Civil Flying[3]

The twelve-month period following that covered in the progress report for 1929 has been one of more or less continued development in air transport despite the effects of overexpansion in the manufacturing side and the general depression in business, both of which became very acute at this time. While flying schools felt this depression severely and while private flying did not continue the expansion of the previous period, the mail operators and the regularly operated passenger routes showed some substantial increases in traffic as well as some further extension of air lines.

TABLE 1 MILEAGE AND TRAFFIC STATISTICS FOR PRIVATELY OPERATED AIR-MAIL ROUTES WITHIN THE U. S. A. FOR YEAR ENDING JUNE 30, 1930[1]

Month	Number of routes	Length of routes, miles	Miles of service actually flown	Total weight of mails dispatched, pounds	Amount paid to contractors
July 1929....	25	13,928	1,260,980	645,653	$1,247,401
Aug. 1929....	25	13,928	1,308,186	701,538	1,361,619

[1] Compiled from Post Office Dept. statistics by Black & Bigelow, Inc., Air-Transport Engineers.

Manufacturing and Operating. The latter part of 1929 and the first several months of 1930 covered a period of drastic deflation in the aeronautical industry, particularly affecting operators of schools and manufacturers of aircraft and engines. The primary cause of this deflation was overproduction and overexpansion in the several months preceding. During that period, most manufacturers turned out more airplanes and engines than the market was able to absorb, while schools were increased in number and capacity considerably faster than applicants became available. Many companies directed their energies more toward obtaining additional financing than to the expanding of their markets. The effect of this overexpansion combined with the general business depression resulted in a serious drop in sales and school enrolment. As a consequence, many of the smaller airplane and engine builders have been eliminated and school operations have had to be curtailed.

Air Mail. Air-mail volume continued to grow more or less regularly throughout the earlier part of this period, but a peak was reached in October of 1929 and an appreciable drop followed, the bottom being reached about January, 1930, after which the volume began to climb back toward that of the previous peak. A large part of the 1929-30 winter slump may be charged against weather conditions, which always interfere with air-mail operations in the first few months of the year, and which early in 1930 were unusually bad for the maintenance of regular flying operations. It is evident, however, that the failure of the air mail to continue its growth is not fully explained by weather, and it seems probable that the general business depression was one of the underlying causes. In addition to this, some uncertainty existed on the part of the carriers (with some consequent slacking of their efforts) due to doubt on their part regarding the effect of contracts to be made under the Watres Bill. This bill was passed by Congress early this year and authorizes the Postmaster General to contract for the carriage of air mail by existing passenger air lines on the basis of a fixed rate per mile. In return for this compensation, carriers will be required to make available to the Post Office a certain definite volume and a certain cubic-footage capacity, which is to be paid for whether fully used or not. At the time of writing, bids have been recently opened and the first contract under this law has been awarded. Others are awaiting decision by the Postmaster General. It is encouraging to note that from February of 1930 to date, air-mail volume has been generally increasing, and with these new mail contracts approaching settlement, further growth may be looked for in the closing months of the year.

Fare Reductions. Early in 1930 several of the larger operators put into effect drastic reductions in passenger fares, bringing the cost of travel by air very close to that of travel by rail, and, in at least one case, the air-line fare was made slightly less than the rail fare for the same trip. Public response to these reduced rates was almost instantaneous, traffic on many lines doubling almost overnight, while the increase in some cases reached as high as 400 per cent in a comparatively short time. After operating for several months at the reduced rates, some of the lines put into effect new tariffs carrying a slight increase over the rates in effect for a few months previous. These increases, being comparatively small, appear to have had little or no effect upon the growth of passenger traffic, and while very few passenger lines are paying at this time, the volume of traffic has shown most encouraging growth, and the operating losses of many operators have been substantially decreased. Parallel with these changes in rates, operating economies were effected in many cases by the reduction of personnel and more intensive use of the flying equipment, both of which combined to appreciably reduce operating costs. Indeed, some operators have substantially reduced their operating forces while increasing their traffic volume.

Consolidations. While the consolidations referred to in the

[1] The figures in this table should be considered as being only approximate, as accurate records are not available in most cases. Compiled by Black & Bigelow, Inc., Air-Transport Engineers.

previous progress report were not continued through 1930, one combination of outstanding importance took place during this period. This was the consolidation of Pan-American Airways and the New York, Rio, and Buenos Aires Line, the former company having purchased the latter. Some realignments took place in other quarters, notably the absorption of National Air Transport by United Aircraft & Transport Corporation.

Accidents. The total number of accidents has been steadily increasing, but, on the other hand, the ratio between the total number of accidents and the total miles flown has been showing a steady improvement, the accident ratio decreasing more or less regularly in the past two years. A considerable amount of stunt flying is still being carried on, and this and reckless flying represent two important contributing causes of accidents at present. The Department of Commerce in 1930 began to apply its regulations with greater rigidity, and this effort to reduce accidents has been reflected in a substantial increase in violations of air-commerce regulations during the second and third quarters of 1930. Violations of these regulations dealing with acrobatic or dangerous flying headed the list of specific offenses. Other violations included flying without license, flying without navigation lights, or flying without identification numbering. The total number of violations charged was 278 in the third and 177 in the second, as compared with the total of 122 for the first quarter of the year. Accident statistics, for the preceding two years compare as follows:

	Jan.–June 1928	July–Dec. 1928	Jan.–June 1929	July–Dec. 1929
Total accidents, all services	430	692	774	924
Miles flown per accident, all services	38,337	78,308	72,612	85,433

Airports. The total number of airports and landing fields in use in this country during the period covered by this report increased from 1224 as of January 1, 1929, to 1527 at November 4, 1929, and 1655 at July 1, 1930. At the time of writing these airports are divided as follows: 500 municipal, 558 commercial privately owned, 79 army and navy, and 518 Department of Commerce and other intermediate or emergency fields and other Government fields. Considerable extension was made in line airways in this period, continuing the development program started a few years ago by the Department of Commerce Aeronautics Branch, and 583 airports and fields are now lighted. While considerable study has been given in various quarters to the design of airports, at present very little effort appears to have been made to apply this information in actual practice, due possibly to the tendency of many municipalities to place the entire design of their airports in the hands of the existing city engineer's staff without calling for aid from the aviation industry.

Progress of Naval Aviation[4]

Satisfactory progress is being made toward the completion of the five-year building program for naval aviation as authorized by Act of Congress, approved June 24, 1926. This act authorized an increase in useful airplanes to 1000 in five yearly increments. The last appropriating year contemplated by the act is the one ending June 30, 1931. It is expected that the aircraft to be procured under the 1930 and 1931 authorizations will raise the number of naval airplanes on hand to 1000 during the fiscal year 1932.

In the interest of improvement in safety in flying, the Bureau of Aeronautics maintains a detailed record of all failures of material and of all accidents. Each such occurrence is analyzed on the spot by a board of three officers, who submit findings of fact, express their opinions as to the cause, and make pertinent recommendations. These reports and records enable the Bureau to take such steps toward the elimination of material faults and make such recommendations for the control of improper flying and personnel derelictions as will best contribute to safety in aviation, and yet not restrict the employment of aircraft in the proper development of this new art of naval warfare. During the past year a total of 266,984 hours were flown by naval airplanes with but 14 fatal accidents and 18 fatalities. For every fatality there were thus flown a new record total of 14,832 hours, and for each fatal accident, 19,070 hours. These figures compare with the previous best records in 1929 of 6773 and 11,289 hours, respectively. This new record may also be expressed by stating that in a total of 252,095 flights during the past year only 14 resulted in fatal injuries to occupants of the aircraft, or in other words, flights were 99.9945 per cent safe from fatalities.

The past year has witnessed progress in the elimination of wood from aircraft structures. No new construction for several years has used wooden fuselages, and the passing of the fiscal year 1930 carried with it the last of the wooden-fuselage airplanes of the Navy. Wooden wing ribs and wooden tail structures have been entirely replaced by metal construction in new designs, while almost all new experimental types and new-production aircraft have metal wing beams as well.

One of the recent interesting material investigations has been in the field of corrosion-resisting steels. Streamline tie rods made of various steel compositions are being service tested; seaplane floats of stainless steel are under construction. Wing ribs constructed of spot-welded strip stainless steel are being incorporated in certain wings for service tests. Sources of supply for this material in sheet, bar, and seamless tubing, and methods of handling and working it, are under development.

A step in the solution of our difficulties in the use of aluminum alloys in the construction of hulls and floats has been the discovery that incorrect heat treatment has been responsible for much of the rivet corrosion. Tests indicate that improved methods, which will insure all rivets of obtaining correct and uniform heat treatment, will largely eliminate this trouble. After experiment and service tests the anodic treatment, whereby aluminum and aluminum alloys are given electrolytically a coating of aluminum oxide, has been adopted as the standard method of preparing these materials to receive paint finishes. This treatment not only provides a surface to which finishes adhere readily, but one which has also considerable corrosion resistance in itself.

Because of their advantages in weight, reliability, cost, durability, ease of maintenance, and performance at altitude, the policy has been continued of using radial air-cooled engines

[4] Prepared by Rear-Admiral William A. Moffett, U.S.N., Chief of the Bureau of Aeronautics, Washington, D. C.

in all service airplanes. The Bureau has kept touch with all lines of engine development by awarding experimental contracts for liquid-cooled, air-cooled in line, Diesel (radial), and several types of foreign engines, but at present the American radial air-cooled seems the best for naval uses. Definite progress has been made in increasing the power of these engines by better cylinder and crankshaft design, and by the use of higher compression ratios and intake pressures.

The chief requirements of an airship engine are durability and fuel economy. The Maybach engines, which are to be used by the Navy in the *ZRS-4*, possess these requirements to a marked degree. The Bureau looks to the compression-ignition heavy-oil engine, however, as the airship engine of the future, and has been concentrating its efforts and experimental fund on its development. Two such experimental engines are now under contract, and both are scheduled for delivery within the present fiscal year.

Good progress has been made by the Goodyear-Zeppelin Corporation in the construction of the airship *ZRS-4* (U.S.S. *Akron*). The contractor's shed was ready for occupancy in October, 1929, and shortly thereafter, with appropriate ceremonies, the keel of the airship was laid. The contractor is working to a schedule which calls for completion of the airship in June, 1931, and it is believed this date can be met. A number of developments have been incorporated in the design as the work proceeded; however, there have been only a few minor changes involving modification of the contract requirements.

Rigid-airship operations throughout the year have shown definite progress toward the solution of the problem of handling large airships. The mobile mooring mast has become a regular part of the handling equipment. Other mechanical appliances which play necessary roles in a complete mechanical-handling system, have been developed and are now in habitual use. Improvements are necessary, but an adequate system for handling airships mechanically is definitely visualized, and requires only time and effort for its realization.

Operations in the Fleet have shown the necessity for the modification to a certain extent of previous ideas as to the proper types and models of airplanes suitable for use in naval aviation. Patrol flying boats used in the Fleet and at air stations were originally developed by the United States Navy. Smaller aircraft assigned to cruising vessels were originally adapted from models similar to those used in military operations on shore. It is interesting to note that practically all changes that have been made in naval aircraft in the last few years, except such as have been due to the development of the art, have been in the line of introducing features that fit them to operate from ships. Ship-based landplanes have emergency flotation gear for keeping them afloat in a forced landing at sea, and have carrier arresting gear and low stalling speeds to permit satisfactory operation from the decks of carriers. Most naval planes have radio in order to maintain touch with their moving bases. Observation planes have sturdy float-type landing gear to permit landing in rough water, and the use of the carriers has emphasized the need for a satisfactory but light amphibian landing gear. The size of fleet airplanes must be kept at a minimum in order that the limited space on board ship may be utilized to the best advantage. The differences in coordinate types of aircraft as used by the Army and Navy have arisen not because the airplanes are produced by different organizations, but because the peculiar conditions under which they operate must be taken into consideration from the inception of their design. Although it is considered sound policy to build as few different kinds of naval airplanes as possible for meeting the needs of the service, recent actual operation of naval aircraft in the Fleet has indicated that greater differentiation than now exists may be desirable if naval aircraft are to perform satisfactorily the service required. The Bureau constantly endeavors to keep in the closest touch with Fleet operations, and with the latest ideas that have been evolved in the Fleet, in order that airplane types entirely suitable for the purpose may be produced without delay.

Naval operations of the fiscal year have served further to emphasize the great value of aircraft carriers to the Fleet, and to indicate the urgent necessity of continuing our progress along these lines by building up to the carrier tonnage allowed under the London Limitation of Armament Treaty. This is considered the most vital need of naval aviation at the present time.

Development of Military Aeronautical Equipment in 1930[5]

Development of military aeronautical equipment during 1930 has been carried on under the direction of the Chief of the Air Corps by the Matériel Division, located at Wright Field, Dayton, Ohio. The five-year program, calling as it does for a greater number of up-to-date airplanes in the hands of service squadrons, has stimulated interest in new equipment. It is not the desire of the Air Corps to darken the skies with military aircraft, nor to spend vast sums of money on purely military flying, but it is the duty of the Air Corps to the nation to thoroughly and painstakingly investigate and test a large amount of promising experimental equipment. The value of governmental researches and development to the commercial-aircraft industry, as well as providing satisfactory equipment for national-defense purposes, has justified the soundness of continuing an experimental program. Closer cooperation with aircraft manufacturers and an increasing willingness to try out less conventional equipment is resulting in machines of increased performance and greater effectiveness. The lessons learned from joint Army and Navy maneuvers, the extensive Air Corps maneuvers held last spring in the vicinity of Sacramento, California, and the trend of high-performance commercial aircraft as well as the 36,000,000 airplane-miles actually flown last year by the Air Corps, are being applied directly to the new designs now in embryonic stages.

During the year two new designations of airplanes have been added—"Photographic" and "Basic Training," bringing the number of types to eight, i.e., Attack (symbol A), Bombardment (B), Transport (C), Observation (O), Pursuit (P), Photographic (F), Primary Training (PT), and Basic Training (BT). The symbol prefixed by "X" denotes that the airplane is "Experimental" and when prefixed by "Y" denotes a "Service Test" (in the hands of operating squadrons) status. Increased performance in all types except training has been attained by reduction of resistance through refinement of detail, installation of engines of increased horsepower, new methods of construction, and the use of accessories such as ring cowls for air-cooled engines, wheel streamlines, etc.

Engine development, upon which so much of the effectiveness of aircraft as a military weapon depends, has been carried on unceasingly along two general lines: direct air cooling and liquid cooling. While air-cooled engines dominated the field in commercial and naval operations and took a most important part in Air Corps activities, yet water cooling was still much in evidence. With the increasing of the power plants of observation airplanes from 425 hp. to 600 hp. the geared water-cooled Curtiss Conqueror was generally employed. The substitution of ethylene-glycol for water as a cooling liquid so successfully employed during 1929 in 12-cylinder 425-hp. engines, met certain problems when applied to engines of 500 hp. or greater. Recent design changes in larger engines appear to have overcome the diffi-

[5] Prepared by Lieut. S. P. Mills, Matériel Division, Air Corps, U. S. A., Wright Field, Dayton, Ohio.

culties encountered and promise to provide a high-powered liquid-cooled power plant whose total installed resistance will be a joy to the airplane designer. It should be remembered that the cooling liquid in such installations is delivered to the radiator at 300 deg. fahr. instead of 180 deg. fahr., giving twice the temperature difference attained with water under normal flying conditions. A radiator of one-fourth to one-third the size formerly used with the attendant saving in amount of liquid used effects a substantial saving in frontal area and total weight. Greater fuel economy with only about 2 per cent decrease in maximum engine power is also a highly desirable result.

CURTISS B-2 BOMBER POWERED WITH TWO 600-HP. WATER-COOLED CURTISS ENGINES

(Used in limited numbers by the Air Corps. Has on several occasions carried a 4000-lb. bomb.)

KEYSTONE BOMBER POWERED WITH TWO 525-HP. HORNET AIR-COOLED ENGINES

(Standard equipment for Air Corps. Carries crew of four and is capable of carrying 2000-lb. load.)

Development of air-cooled radial engines has been carried on vigorously, centering about the Pratt-Whitney Hornet and Wright Cyclone, each rated at 525 hp., which have been used extensively in bombardment airplanes. Models of these engines with cylinder displacements of 1850 cu. in. will develop 575 hp. The coming year will undoubtedly witness the more extensive use of other higher-powered types, some of which will be geared. The Wright V-1460, an inverted air-cooled 12-cylinder V-type of engine rated at 600 hp., has been tested in flight as well as on the dynamometer stand, showing good progress in this development.

TWO VERY INTERESTING SINGLE-ENGINE TRANSPORT MONOPLANES, THE FOKKER C-14 AND THE BOEING ALL-METAL PLANE

(The high-wing plane shown above is a Fokker C-14 with plywood wing and steel-tube fuselage, powered with a Pratt & Whitney Hornet engine. Below is shown the Boeing all-metal monomail low-wing transport plane. Each plane has high speeds above 140 m.p.h.)

The testing of a 1400-hp. (at 2000 r.p.m.) air-cooled 24-cylinder "X" type of engine for securing engineering data has proved interesting. This engine has four rows of six cylinders, each with a $5^3/_4$-in. bore and $7^1/_4$-in. stroke, set at 90-deg. intervals about a 6-cylinder-type crankshaft. When tests are completed upon this 4520-cu. in. engine, excellent data on the behavior of air-cooled cylinders in large sizes should be available.

With the advent of fuels of improved anti-detonating properties it has been possible to increase the compression, securing as a result an even better power-weight ratio and a lower fuel consumption. The 425-hp. Pratt-Whitney Wasp air-cooled engine as used in the late Boeing pursuit airplanes is now equipped with supercharger blowers geared 10 to 1, increasing the performance at altitude to a marked degree.

Three Diesel engines purchased from the Packard Company are now being tested in the dynamometer laboratory and in flight. This interesting engine of 240 hp., America's first Diesel-type aircraft engine, uses as fuel furnace oil instead of gasoline and eliminates the electrical ignition system. When supplied with fuel for several hours' operation, the overall power-weight ratio is very favorable. An apparent advantage arising from the use of this compression-ignition type of engine is the greatly reduced fire hazard due to the less inflammable fuel carried. Economical operation costs plus freedom from radio interference experienced in the presence of conventional ignition systems constitute additional advantages.

Less spectacular, but of far-reaching importance, is the development work on fuels making possible the use of higher compression and greater supercharging, with the attendant fuel economy. Studies in the torsional vibration of engine crankshafts by means of a newly designed torsiometer have resulted in correct counterbalancing and the determination of certain speeds which should be avoided in regular operation. A graphic record showing distortion or twist of crankshaft is easily obtainable at any desired speed.

Two other developments include the automatic supercharger regulator whose operation is governed by the change of barometric pressures due to altitude, and the solid-fuel-injection system using a fuel pump and spray jets for improving the fuel distribution.

During the coming year radial air-cooled and V-type liquid-cooled engines of over 500 hp. will be used in numbers, with the air-cooled "V" and "in-line" struggling for a foothold. The tendency of the times seems to indicate a material increase in m.e.p. due to increased supercharging coupled with the use of new and improved fuels. The use of gearing will probably increase, and controllable-pitch propellers will undoubtedly make their appearance on commercial as well as military aircraft.

Progress in the development of the airplane proper has continued along certain very definite lines. A marked tendency toward the use of monoplanes is noted in the experimental programs, although the biplane is very much in the majority in the hands of service organizations. Monoplanes have been or will be tried out in each one of the eight different types of aircraft used by the Army. In construction the tendency appears to be toward the all-metal machines incorporating the smooth-

surface monocoque type of fuselage and wings whose structure and covering are metal. The use of duralumin construction is undoubtedly growing, although again the majority of machines in actual use today are of the steel-tube, welded-joint type. Many studies have been carried on with a view to reducing the resistance and the weight of structures of a given strength in order to increase the performance. A short discussion of the airplanes in present use, and a word about the tendency of design in each of the basic types, may prove of interest here.

The present attack type of airplane, designed for exceptionally low-altitude flying and surprise attacks with machine guns and small bombs, is a biplane built by Curtiss and known as the A-3B. This two-place airplane mounts M-2 machine guns in the wings just outside of the propeller disk and is equipped with a Browning M-2, .30 caliber, flexible machine gun in the rear seat. The power plant consists of a Curtiss D-12 engine of 450 hp. giving a high speed of over 140 m.p.h. Low-wing monoplanes have been suggested, but as yet none have been tested. Such planes equipped with powerful water-cooled engines should add materially to the effectiveness of this type.

In the bombardment class the Keystone B-3A biplane powered by two 525-hp. Pratt & Whitney Hornet engines is now standard equipment. A new contract for 60 of these airplanes has been placed, deliveries of which have already commenced. This type of airplane may also come equipped with 525-hp. Wright Cyclone engines. Geared air-cooled engines have not as yet been used extensively in bombing airplanes, but may make their appearance at some future time. The gear ratios generally employed are 2:1 or 3:2.

The Curtiss B-2 biplane with two 600-hp. geared Curtiss Conqueror water-cooled engines is used in smaller quantities. Gearing may be expected in several of the new bombers as it affords a substantial increase in speed and climb. Late improvements in the Keystone bombers include greatly improved instrument boards, engine shutter controls for altitude and winter flying, and suitable tail wheels as a replacement for skids.

During the past year many commercial companies have submitted transport airplanes for Air Corps inspection. While the Ford and Fokker tri-engined transports have been continued as standard, yet there is a tendency toward single-engined lighter machines. A new type which will be used by the Service this coming year in limited numbers is the Fokker high-wing C-14. With its plywood wing raised 18 in. above the fuselage and the pilot mounted in an open cockpit aft, it should prove useful for transporting supplies, spare engines, etc. For many military

(Note smooth-surface duralumin monocoque fuselage.)

requirements the lighter single-engined transport appears more practicable.

Marked progress in observation aircraft performance has been effected by increasing the power from 425 (Standard Liberty or Curtiss D-12) to 600 hp., which brings this class of machine definitely in the 150-m.p.h. class. Fifty Douglas O-25 A planes each powered with a water-cooled geared Curtiss Conqueror engine and mounting the new Browning .30 caliber machine guns, have been placed in the hands of the Service. Rate of climb and ceiling with a very quick take-off feature the model. The steel-tube fuselage and wood wing structure follow standard practice. A new rear gun mount eliminating the familiar ring mount and improved brakes add much to the safety of this machine. The Curtiss O-1E with a 425-hp. Curtiss D-12E engine is standard equipment. The Thomas Morse O-19B powered with a Pratt & Whitney Wasp air-cooled engine is also being used quite extensively. A new series of Douglas observation airplanes (O-38) powered with a Pratt & Whitney Hornet or Wright Cyclone engine of 525 hp. promises to contribute this year. In spite of the fact that all standard planes in this class are now of biplane construction, new types of construction in high-performance, cantilever, monoplane wings may bring about radical changes.

"The Longest Shot"—Aerial View of Mt. Rainier From a Distance of 266 Miles
(Photograph made possible by use of infra-red filters. Mt. Rainier is invisible to the eye at a much shorter distance than 266 miles.)

In the experimental field in this class the Fokker O-27 provides a most interesting exhibit, combining a cantilever wood wing in which two Prestone-cooled Curtiss Conqueror engines are streamlined, a small-section steel-tube fuselage, and a retractable landing chassis. The pilot and two observers sit in open tandem cockpits. Performance trials are now under way to determine its suitability for Service use. To the casual observer on the ground watching it pass, its two 600-hp. engines wide open and its landing chassis drawn up into the engine nacelles, it seems like a step in advance. Speeds in the 1929 pursuit class are hoped for but only time will tell.

That the pursuit plane must look to its laurels if it is to maintain a liberal margin of high speed over certain larger and heavier types, seems to have been demonstrated in British maneuvers in the defense of London. Light bombardment planes of the two-place class powered with water-cooled engines made a splendid showing, and did not appear to be particularly worried by the pursuit machines.

In our Service the Curtiss Hawk P-1C and the Boeing P-12C are the two standard types of pursuit. The P-12C incorporates certain improvements, among which is a ring cowl about the supercharged Wasp engine. With the cowl only about 12 in. wide, the visibility is not materially reduced. In order to gain increased performance at higher altitudes, the supercharger blower is geared 10:1. By careful handling of the throttle and not overloading the engine at ground levels, reasonably satisfactory maintenance may be expected. Full-capacity operation should take place only at altitudes above 8000 ft. With its short span and compact weight arrangement, it is a very maneuverable machine. The fuselage construction is of the square-tube, rounded-corner duralumin longeron type, riveted and bolted.

The Curtiss P-1C has been improved from time to time, but is still powered with a water-cooled Curtiss D-12E engine of 425 hp. It is probable that water-cooled pursuit airplanes will be generally of a higher horsepower than the P-1C.

Among the experimental airplanes being performance-tested at this time which may affect pursuit design, should be mentioned the two-place Berliner-Joyce, the Curtiss XP-10, the Boeing XP-9, and the Curtiss XP-17. The two-place Berliner-Joyce airplane is powered with a 600-hp. Prestone-cooled Curtiss Conqueror engine. This plane with the gull-wing type of construction in the upper wing has every appearance of a pursuit airplane, but the presence of a gunner immediately back of the pilot will afford a great protection from the pursuit pilot's weakness—vulnerability in case of an attack from the rear and above. The pilot's visibility in this plane during a dive should be excellent. Speeds comparable with last year's single-place pursuit airplane are hoped for in the tryouts to follow. A steel-tube fuselage and fabric-covered metal wing are used.

The Curtiss XP-10 pursuit airplane is built around the Prestone-cooled Curtiss Conqueror engine and incorporates the gull-wing construction in the upper wing. In order to attain the maximum speed, an improved type of wing-surface radiator has been applied to the upper wing extending about 5 ft. on each side. As in the Berliner-Joyce, a direct-drive engine is used. The airplane has been designed with a view toward securing a satisfactory high-speed performance, particularly at altitude, and a rapid climb. Performance tests on this machine will be completed by the end of the year.

The latest pursuit airplane produced by Boeing, known as the

XP-9, is of the externally braced monoplane type powered with a Prestone-cooled Curtiss Conqueror 600-hp. engine. The XP-9 is of unusual interest in that its fuselage is of the all-duralumin smooth-surface monocoque type and its wing construction entirely of metal. An axle type of landing gear, flat-nose-type radiator, and synchronized Browning M-2 machine gun are used.

The Curtiss XP-17 pursuit airplane powered with an inverted 12-cylinder air-cooled Wright engine of 575 hp. is now being experimented with. In the early stages of development this airplane is interesting due to the exceptionally good visibility afforded the pilot. Due to the inverted position of the engine a considerable amount of noise, dirt, and vibration appear less noticeable to the pilot. A considerable number of experiments have been conducted with modified forms of equipment. One such experiment is the use of a Heinrich low-resistance flat-tube radiator used in connection with a Prestone-cooled Curtiss D-12 engine whose compression ratio is above 7:1. A marked increase in high speed coupled with increased rapidity of climb resulted from this installation.

The Curtiss P-6 pursuit airplane powered with a 600-hp. Prestone-cooled Curtiss engine will soon be equipped with the new improved Conqueror engine designed especially for Prestone cooling and will then be given additional service tests.

The present tendency in pursuit development is to increase the high-speed performance, particularly at altitude, by the use of engines of greatly increased horsepower which are more highly supercharged. In all probability, future development in this type of machine will swing toward the smooth-surface all-metal fuselage and metal-covered wings. Duralumin construction will undoubtedly play a most important part in this development. The surprising increase in speeds of larger and heavier machines is forcing the pursuit to reduce resistance to the minimum and to use overpowered engines. The use of retractable landing gears, and even an inclosure for the pilot, have been suggested in the past and may be given more serious attention than heretofore.

The progress in aerial photography and mapping has been steady, although not particularly sensational. Many excellent photographs have been taken from points 30,000 to 40,000 ft. above the earth. One photograph taken with the aid of infrared filters shows the summit of Mt. Rainier at a distance of over 266 miles. The type of airplane now in the hands of the Service for photographic use is the Fairchild YF-1, which is undergoing extensive service tests. This externally braced monoplane powered with an air-cooled Wasp engine provides a roomy cabin for operation of the cameras and developing or printing, if desired. The high-wing type of monoplane affords the photographer good visibility for the taking of oblique photographs through the door, as well as for the usual verticals taken through the floor. Among the characteristics necessary in a photographic plane should be mentioned stable flying qualities and the ability to reach 15,000 ft. with the required load.

The past year has witnessed an investigation as to the primary training plane best suited to Air Corps needs. During the past 20 years we have watched the Army pilots being trained on the 30-hp. Wright engines, then the 75-hp. Curtiss, then the famous 90-hp. Curtiss OX-5 of the "Jenny era." Following the war period the power of training airplanes was increased to 150 and then to 180 hp. by adopting the Wright Hispano engines. With the coming of successful air-cooled engines, the power was again raised, until at present the power of training airplanes in service is 225, using the Wright J-5B Whirlwind engine. In view of improvements in airplane construction it is now believed unnecessary to use so great an amount of power. Exhaustive service tests are now under way to determine if the small airplane, such as the "Fleet" PT-6, powered with a 100-hp. Kinner engine or higher-powered planes such as Stearman, Verville, and others, will more satisfactorily meet A.C. requirements. There is naturally a considerable difference of opinion regarding this point. Some pilots believe that a medium-heavy plane using 150-hp. would be satisfactory. The tendency, however, seems to be toward a reduction in weight and horsepower and the use of a machine whose flying qualities are comparable with those of the more powerful service aircraft.

As a transition airplane to be used by newly trained pilots between their primary training and training on service-type airplanes, a new type known as "basic training" has been adopted by the Air Corps. At present this type is being supplied by the Douglas Company in a model known as the BT-2 series. The construction of this plane is similar to that of the Douglas O-2H

DOUGLAS BT-2B BASIC TRAINING PLANE POWERED WITH WASP 425-HP. AIR-COOLED ENGINE
(Note ring cowl, which increases speed about 5 m.p.h.)

A TYPICAL LIGHT TYPE OF TRAINING PLANE—THE "FLEET" XPT-6, POWERED WITH 100-HP. KINNER ENGINE—NOW ON SERVICE TEST

and O-2K observation, but its power plant is the 425-hp. Wasp air-cooled engine instead of the Liberty engine. The use of airplanes of this type is a very important step in the training of new pilots, and will undoubtedly fully justify its cost in the conservation of fully equipped and more expensive service airplanes.

Although little of a revolutionary nature has been advanced in the progress of military aeronautical equipment during the past year, yet the steady advance in airplane construction marked by the wider use of metal and cleaner designs together with corresponding advancement in power plant, higher compression, greater supercharging, and perfection of liquid cooling, has paved the way for a material advancement in performance.

AIRSHIPS[6]

The year 1930 was marked by one spectacular airship disaster, and by comparatively little progress of the sort that fills the public eye. Nevertheless very real progress was made in improving methods of airship mooring and ground handling, which have long been among the most important and intractable of airship problems. An intensive practical and theoretical investigation

[6] Prepared by C. P. Burgess, Bureau of Aeronautics, Navy Department, Washington, D. C.

of mooring and ground-handling methods has been carried out by the U. S. Navy, and the results have been tested and demonstrated in the handling of the U.S.S. *Los Angeles*.

The low, or stub, mooring mast developed at Lakehurst has now been in successful use for several years. With this mast the airship rides close to the ground, its stern resting upon a car running on a circular track, concentric with the mast. The airship is free to turn like a weather cock, always pointing into the wind; but all vertical motion is eliminated and the airship is conveniently accessible for servicing from the ground. An objection to the low mast was that, until recently, it was necessary to land the airship upon the ground by man power, in the old-fashioned way, and walk her to the mast. In the past year, the technique of mooring has been so improved that direct-flying moors to the low mast have become standard practice.

A very important development in ground handling has been the use of the mobile stub mooring mast at Lakehurst. This mast is mounted at three points on Athey truss wheels, which are a modification of the caterpillar-tread principle. The mast, with the bow of the *Los Angeles* attached to it, is towed by a tractor into and out of the hangar. It was also used for handling the *Graf Zeppelin* when she visited Lakehurst in June. A new system of side handling lines, attached to the ship and docking trolleys, has been developed to hold the ship parallel to the hangar when being taken in or out by means of the mobile mast. These handling lines are arranged to distribute the side force evenly over a large part of the ship's structure.

The *Graf Zeppelin* has continued in successful service throughout the year. Her numerous voyages in and across Europe, extending from Spain to Asia Minor, and from Africa to the North Cape, have become so common as to attract almost no notice in the daily press. She also made one notable voyage to North and South America, including a visit to Lakehurst, in June. This airship has now crossed the Atlantic Ocean seven times, and the Pacific once. Her South American voyage demonstrated the ability of a well-found and handled airship to encounter successfully the torrential rains of the equatorial region.

The British airship *R-100* made a round-trip voyage from England to Canada and back in July and August. She remained in Canada about two weeks; and during that time was based on the mooring mast at St. Hubert, Montreal, without the protection of a hangar. While coming up the St. Lawrence valley, the *R-100* was struck by a severe squall which partially ripped the fabric from both her horizontal fins. The accident was strikingly similar to that which happened to the *Graf Zeppelin* on her first voyage to America in October, 1928. The lessons of the two accidents were the same: a modern rigid airship can continue her voyage, even with badly damaged fins; and the fabric covering of the fins should be supported at closer intervals than had become standard practice in the slower airships of an earlier day. In neither the *Graf Zeppelin* nor the *R-100* did any weakness develop in the primary structure of the fins or hull. Repairing the damaged fins while the airship was riding to the high mooring mast at Montreal was a praiseworthy accomplishment.

This report is written immediately after the crash of the *R-101*. The thorough investigation into this disaster, which will undoubtedly be made by the British Government, may reveal some causes unsuspected at present; but it appears to be fairly obvious that the crash was the result of flying too low in bad weather. The low altitude was probably forced upon the commanding officer by the ship's being nearly 100 per cent full of gas, so that her pressure height was very low; and because of insufficiency of ballast, the altitude could not be increased without dropping fuel and valving gas. Owing to the small fuel capacity of the *R-101*, such procedure might have necessitated abandoning the attempt to reach India, and returning to Cardington. As many another commander would do, he chose to take a risk, rather than to play safe and admit failure of the task assigned to him. If the ship had been inflated with helium there would have been no fire, and probably no loss of life.

The moral of the catastrophe is that airships should be inflated with helium, should not be so filled with gas that their pressure height is less than a thousand feet above the terrain which they are crossing, and should have plenty of disposable ballast. All of these operating features are standard practice in the operation of the U.S.S. *Los Angeles*, which is the only rigid airship now in commission in America. The disaster points also to the great gain in safety resulting from the use of apparatus to recover water ballast from the engine exhaust. This is a feature which has been used only in the helium-filled airships of the United States.

Rapid progress has been made during the year in erecting the Navy's new rigid airship, the U.S.S. *Akron*, of 6,500,000 cu. ft. gas capacity. Already (October, 1930) over 500 ft. of the framing has been erected, and the vast structure is most imposing in appearance. In June, a successful test was made in inflating a gas cell in the midship main bay of the ship. This one cell has a volume of nearly a million cubic feet.

The Navy Department's Board of Inspection and Survey conducted a thorough material inspection of the U.S.S. *Los Angeles* in the spring of this year. The *Los Angeles* is now over six years old; she has been under way over 2500 hours, and has flown in that time over 110,000 air-miles. She has also operated about 1200 hours at mooring masts. No other rigid airship has had such a long and continuous useful life. The Board found the present condition of the *Los Angeles* to be good; and found no reason why she should not be continued in service from two to four years longer, provided she is operated in the same careful manner as in the past, with frequent inspections, and renewals of worn or deteriorated parts when necessary.

The Board recommended that when the *Los Angeles* is no longer fit for service she should be subjected to destruction tests in ground handling in heavy weather. Such tests would be of great service to the arts of airship design and operation.

American Airways Practice in 1930[7]

For the purpose of surrounding air lines engaged in the scheduled transportation of passengers in interstate commerce with all possible safeguards and with a view of providing air transportation with virtually the same uniformity of operation as is now obtained by other major transportation systems, the Department of Commerce has revised its Air Commerce Regulations to include a certificate of authority to operate such air transportation service, these regulations constituting a code of minimum requirements to govern the operation of the scheduled interstate air passenger routes. The issuance of a certificate of authority will assure the public that aircraft are reliable and suitable when provided with instruments and equipment properly adaptable to the nature of the service and conditions involved, together with an adequate number of qualified airmen fully competent in all phases of the particular operation. It furthermore assures the proper maintenance of aircraft, including engines and equipment, to the highest degree of operating efficiency, with inspection, repair, and overhaul at proper intervals. Under the certificate of authority, the air-transport line must operate over airways or routes provided with proper air-navigation facilities in the interest of safe and reliable operation with a proper

[7] Prepared by F. C. Hingsburg, Chief Engineer, Airways Division, U. S. Department of Commerce, Washington, D. C.

ground organization to administer efficiently all phases of ground operation. Each scheduled flight shall be authorized, delayed, suspended, or canceled by competent officials designated by the holder of the certificate of authority. Uniform instructions pertaining to the operations of the line will be issued, and these instructions will be made conveniently available for the information of all passengers by the holder of the certificate.

The principal airports along the routes are provided and operated by municipalities or commercial concerns. Under the Air Commerce Act, the airports are rated on general facilities, size of effective landing area, and night-flying equipment. An A-1-A rating indicates an adequate airport equipped with full facilities of the highest standard. Airports rated D-4-D or better will meet the minimum requirements set up for intermediate or emergency landing fields. The Airport Construction Bulletin and Airport Rating Regulations of the Department of Commerce cover the minimum requirements of airports. To meet the demand for a more powerful and distinctive beacon for airports, the Aeronautics Branch has designed a new type of 36-in. beacon. This design is based on optical principles which have been found satisfactory for aeronautical beacons and lighthouses, and shows alternate green and white flashes at 5-second intervals, using 1000-watt aviation lamps. The candlepower of the new unit is about two and one-half times that of the present 24-in. revolving beacon using the same size and type of lamps. The beacon is double ended, using but one standard 1000-watt airways lamp with lamp exchanger. The doublets are 15 in. in diameter and the optical lenses 36 in. in diameter, made in 13 pieces. The center bull's-eye of the lens is 20 in. in diameter. The beams of light are elevated by lowering the lamp, this principle having been proved practical and efficient in the present course lights and acetylene range-light units. The simplicity of design and workmanship is the outstanding feature of this unit. The 36-in. drum is mounted on a standard base of the type used with the 24-in. revolving beacon. The vertical shaft is mounted in ball bearings with a gear wheel and clutch mounted on the shaft. The beacon is driven by a fractional-horsepower motor with a case-hardened and polished steel worm engaging the gear wheel.

Air-navigation facilities on civil airways, according to revised regulations, require landing fields approximately 50 miles apart along the route to provide suitable landing places for aircraft under conditions of stress of weather, with additional intervening fields where hazardous and mountainous terrain is encountered. Where airports are not available to serve the purpose, the Federal Government establishes and maintains intermediate landing fields. The intermediate landing fields are located as close to the air line as possible, preferably on a main highway or at least accessible to a good road to provide for an emergency transportation and for maintenance of equipment. The location should be accessible to electric power and telephone lines wherever practicable. The ideal shape for the intermediate landing field is square as it permits landing in any direction against the wind. Such fields are not available in most locations, and therefore intermediate landing fields having at least two runways forming "L," "T," or "X"-shaped fields are selected. The runways vary between 2000 to 3000 ft. in length at sea level, increasing at higher altitudes, and are not less than 500 ft. wide. The intermediate landing fields should preferably have clear approaches on all sides. It is considered that an obstruction to the approaches cuts down the effective length of the runway approximately 7 ft. for each foot of height of the obstruction. The obstructions should be adequately marked and lighted unless arrangements can be made for their removal.

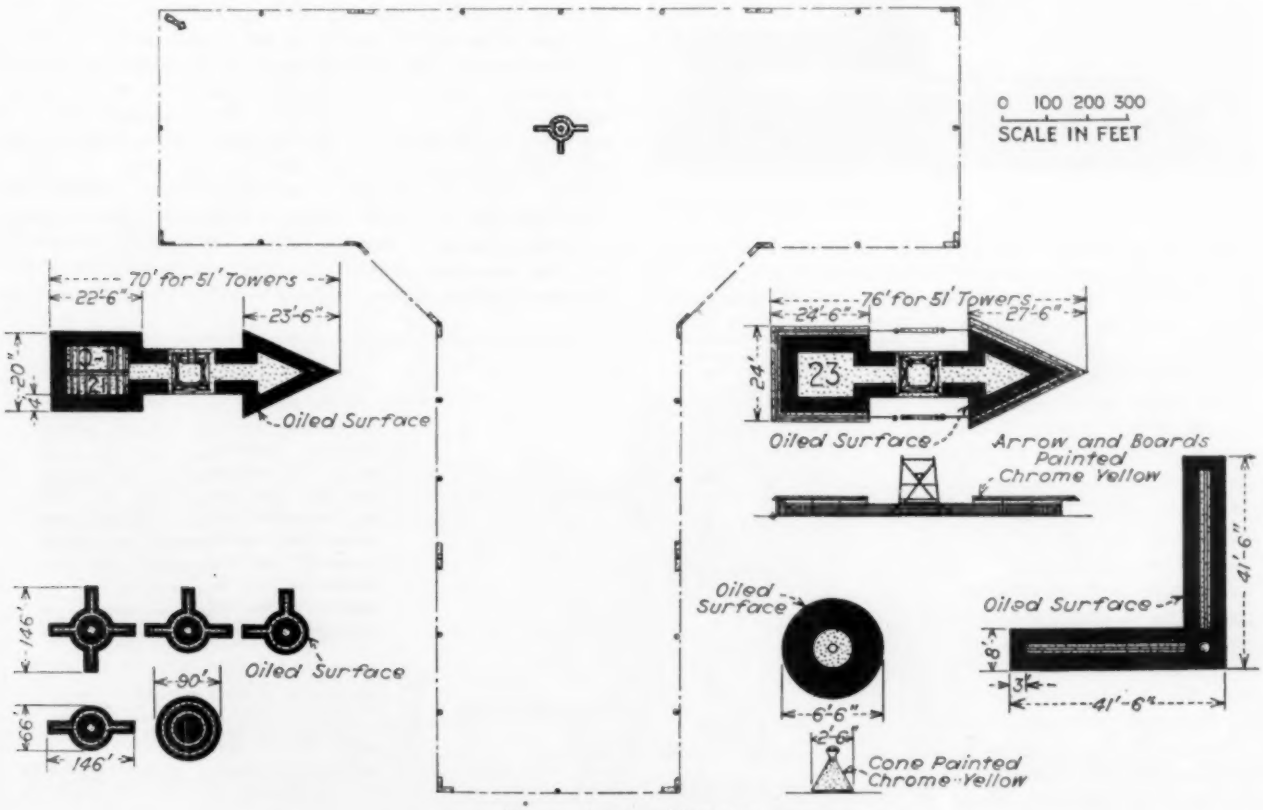

FIG. 1 AIRWAY MARKERS

FIG. 2 AIRWAY BEACON MOUNTED ON A 51-FT. SKELETON TOWER

Intermediate landing fields should be as nearly level as practicable, and of uniform surface without abrupt changes. The field should be free from ditches, rocks, or any irregularities which would be hazardous to aircraft in landing. Natural drainage is of vital importance to prevent softening of the surface in wet weather. To a limited extent, tile or artificial drainage is provided on the intermediate fields. The fields are conditioned and planted with crops of a variety suitable to the locality and growing not over 12 in. in height, the interlaced roots preventing erosion of the top soil. The crops are cut from time to time to keep the field in proper condition.

For day flying, intermediate landing fields are marked with boundary markers and a ground marker placed at the intersection of the runways as shown in Fig. 1. The boundary markers are placed on the corners and along the sides so as to outline the intermediate landing fields from the air and show the landing area. The corner and side markers consist of wooden planks attached to triangular skeleton steel frames supported by vertical posts about 30 in. high, the wooden planks being sloped so as to shed snow. They are high enough to prevent being obscured by vegetation, and are painted chrome yellow to provide maximum visibility. The ground under the marker is oiled with road oil showing a strip 8 ft. in width in contrast to the yellow color of the marker, the oil also preventing the growth of vegetation. A circle with runway indicators is placed at the intersection of the center lines of the runways, indicating the general shape of the landing strips. Where runway indicators are used in conjunction with the circle, the overall dimension of the marker is 130 ft. and the circle 50 ft. in diameter, while for square fields the circles are 90 ft. in diameter. In addition, a directional arrow is placed at the base of the airways beacon tower and points the direction of the route from south to north and west to east. Beacons are assigned mileage numbers by dropping the unit digit. The pilot can ascertain his location along the route by adding a digit to the beacon number.

A wind cone showing the direction of the ground wind is usually mounted on a bracket on the side of the beacon tower. At night, the wind cone is lighted internally, the light showing through the fabric. Intermediate landing fields are marked for use at night with a standard type of airways beacon usually mounted on a 51-ft. skeleton tower as shown in Fig. 2. The boundary of the field is marked by white lights on low boundary standards spaced 200 or 300 ft. apart and so located as to show the pattern of the field from the air at night. Green lights are mounted to show the best approaches to the landing field, and red lights in the boundary lighting circuit indicate that there is no clear approach from that side of the boundary. Red lights burning fixed are shown on all obstructions. Fifteen-watt lamps are used for white boundary lights, and 25-watt lamps for colored lights. Refractive globes are used in connection with the boundary lights to increase the effectiveness of the boundary lighting system. Metal boundary cones are used in

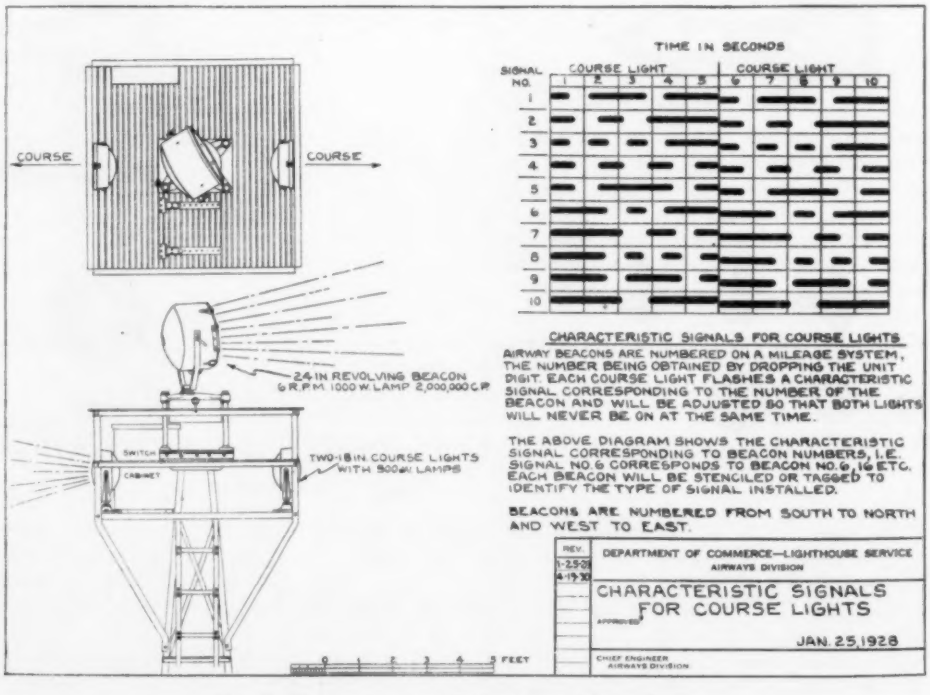

FIG. 3 CHARACTERISTIC SIGNALS FOR COURSE LIGHTS

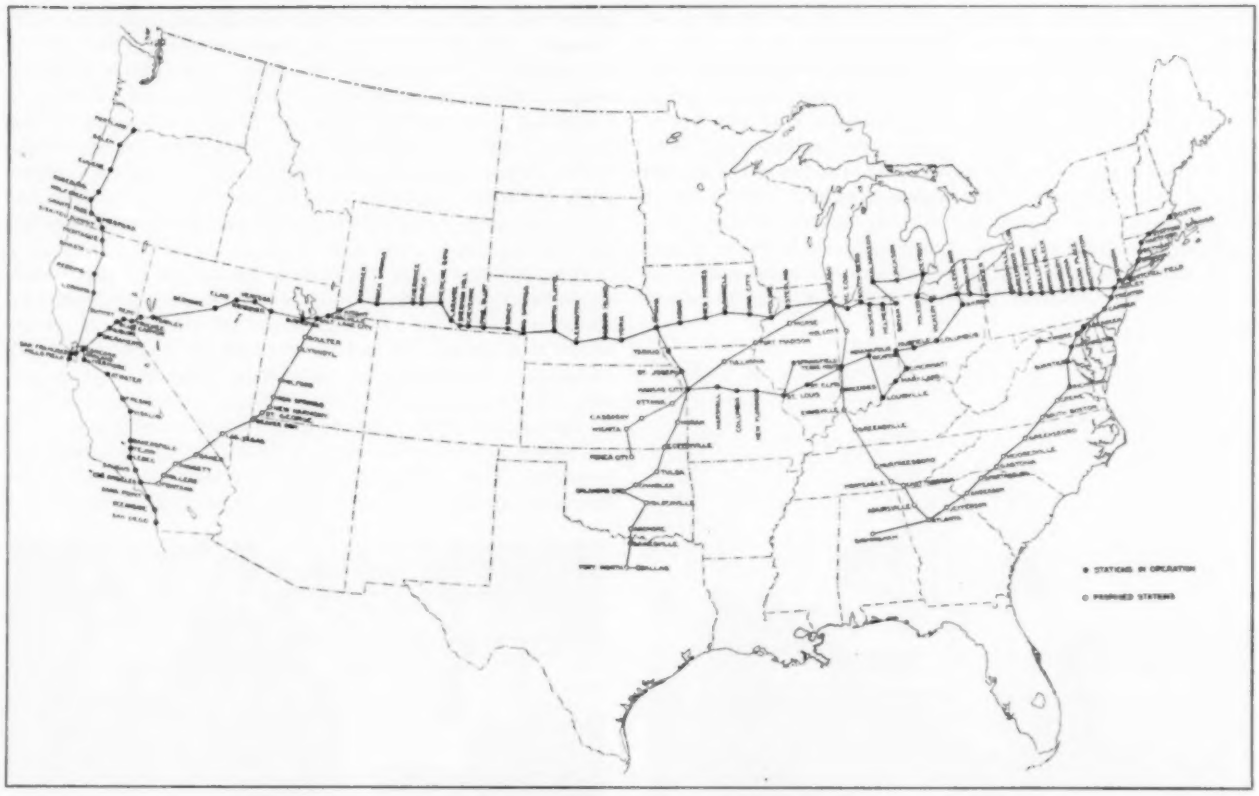

FIG. 4 AERONAUTICAL TELETYPE STATIONS, U. S. DEPARTMENT OF COMMERCE

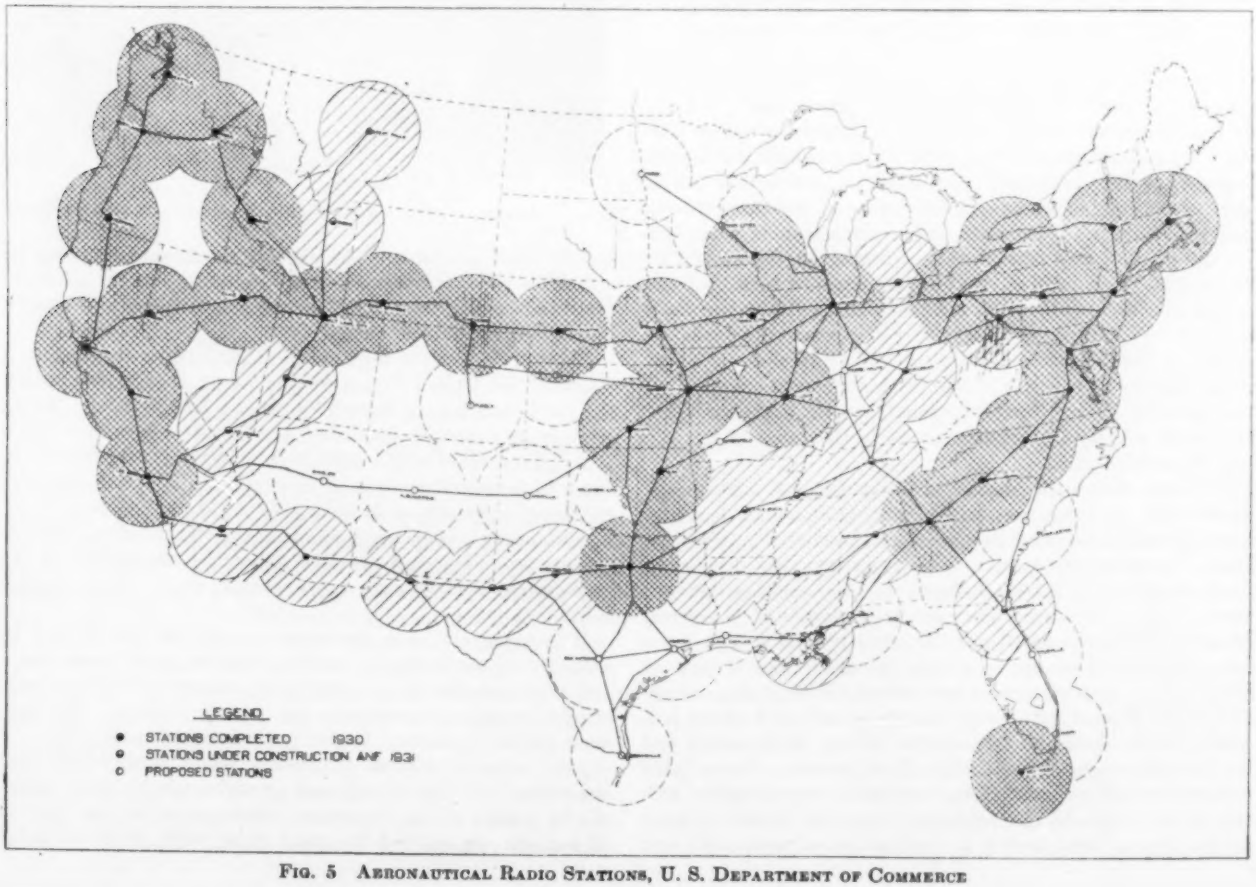

FIG. 5 AERONAUTICAL RADIO STATIONS, U. S. DEPARTMENT OF COMMERCE

conjunction with the boundary standards so as to minimize chances of collision and serve as markers for day use.

The Department of Commerce has established approximately 327 intermediate landing fields, the total area employed for landing-field purposes totaling approximately 27,000 acres. This represents an average of 70 acres per landing field. The rental paid for landing fields is over $115,000, the average price per acre being about $5. The total number of boundary lights maintained at the intermediate landing fields is about 7500, which is an average of about 24 lights for every field. There are on the average 5 red lights marking obstructions on or in the vicinity of intermediate fields, making a total of about 1500 obstruction lights.

FIG. 6 STANDARD AIRWAYS RADIO STATION OF AIRWAYS

Intermediate landing fields are available for the free use of the aeronautical public on condition that all aircraft pilots and the aeronautical public comply with the Air Commerce Regulations and the Intermediate Landing Field Rules promulgated by the Department of Commerce. Exclusive or preferential privileges are not granted, and commercialization of any intermediate landing field is not permitted. An airplane making a landing has the right of way over airplanes moving on the ground or taking off. Upon landing, the airplane must be taxied off the landing area to a location that will not interfere with or become a hazard to an airplane that may find it necessary to make an emergency landing without warning. The caretaker employed at the intermediate landing field renders reports covering all landings, and visiting ships are required to report to the caretaker to register and furnish information as to the cause of landing and the use of the field.

Airways beacons are established along the civil airways approximately 10 miles apart. The airways beacon is a 24-in. searchlight with a parabolic mirror and a 110-volt, 1000-watt Mazda lamp equipped with lamp exchanger and developing approximately 1,000,000 candlepower. The airways beacons rotate 6 r.p.m. showing a flash every 10 seconds of $^1/_{10}$-second duration, visible 20 to 40 miles in clear weather. The beam from the airways beacon is a high-intensity pencil of light of about 6 deg. beam divergence and clearly visible at close range. The cover glass is fitted with prisms to refract a small percentage of the light upward to within 55 deg. of the zenith and thus provide close-range visibility of the beacon. Course lights flashing definite mileage characteristics in synchronism with the airways beacons are projected along the course, showing to the pilot a light having a combination of short and long flashes with a luminous period of about 35 per cent and a color contrast. The beacon number characteristics of the course-light signals are shown in Fig. 3. Red course lights are used on beacons located where landings cannot be made, and green course lights are used at the intermediate landing fields. This system of lighting combines in the airways beacon all the desirable characteristics of high-intensity quick flashes for off-airways indication, and also long flash periods developing the full luminous value of the light source for on-course indication together with color contrast of light.

About 60 per cent of the airways beacons are operated automatically on commercial power, this source of supply being used wherever obtainable. The lights are turned on by a motor-wound astronomic clock, and burn from sunset to sunrise. Lamp exchangers are provided for all airways beacons so as to substitute a spare lamp in the focus of the reflector should the lamp in service burn out. Caretakers are hired at all beacon sites and paid a nominal consideration to look after the equipment and property. The principal work of servicing beacons is performed by an airways mechanician, who visits each site approxi-

FIG. 7 INTERIOR OF AIRWAYS RADIO STATION, CLEVELAND, OHIO

mately twice a month. The airways mechanicians use motor trucks for transportation which are equipped with all necessary tools and spare parts to make emergency repairs and replace burned-out and broken parts.

There are about 156 private aeronautical lights established in cities in the United States serving as landmarks from which the pilots can take a bearing to reach a landing field. Where a revolving beacon is established as a private aeronautical light, it is supplemented with a fixed 24-in. directional projector showing a high-intensity pencil of light pointed in the direction of the nearest airport or landing field to show the pilot where a safe landing may be made should he fly over the city. Private aeronautical lights are operated under the certification of the Department of Commerce as provided for in the Air Commerce Act.

It is important that obstructions along the routes such as radio towers, smokestacks, and those such as power-transmission and telephone lines in the vicinity of airports and landing fields should be marked to minimize the hazards to flying. For daytime visibility, skeleton towers are painted alternate bands of chrome yellow and black, the chrome yellow bands being twice the width of the black bands and approximately $^1/_7$ of the height of the height of the structure. Obstructions in the vicinity of airports are marked for night flying with fixed red lights

mounted at the height of the obstruction, using 100-watt lamps in high-transmission red waterproof globes. Radio towers are marked in the same manner, but in addition have fixed red lights consisting of 50-watt lamps in waterproof globes mounted on the diagonal corners at their $^1/_3$ and $^2/_3$ height so as to be visible from any angle of approach.

The supporting towers of transmission lines crossing navigable waters are painted as hereinbefore mentioned for daytime visibility, and are marked with red lights consisting of two 200-watt lamps mounted in 300-MM fresnel lanterns with red color screens visible in all directions. In addition red lights consisting of 100-watt lamps are mounted in waterproof globes so as to envelop an outline of the area over which flying is a hazard. The projected beams of lights are elevated so as to intersect at the height of the obstruction to be cleared. One or more red electric-code beacons showing flashing lights are installed on the corners of the hazardous area so as to give the pilot the proper warning at long range.

Weather is one of the uncontrollable factors that affect the reliability and safety of air transportation, and therefore an adequate weather-service and communication system in addition to other aids to navigation along the airways is essential for maintaining dependable schedules. Current weather information is collected on an hourly basis from the principal

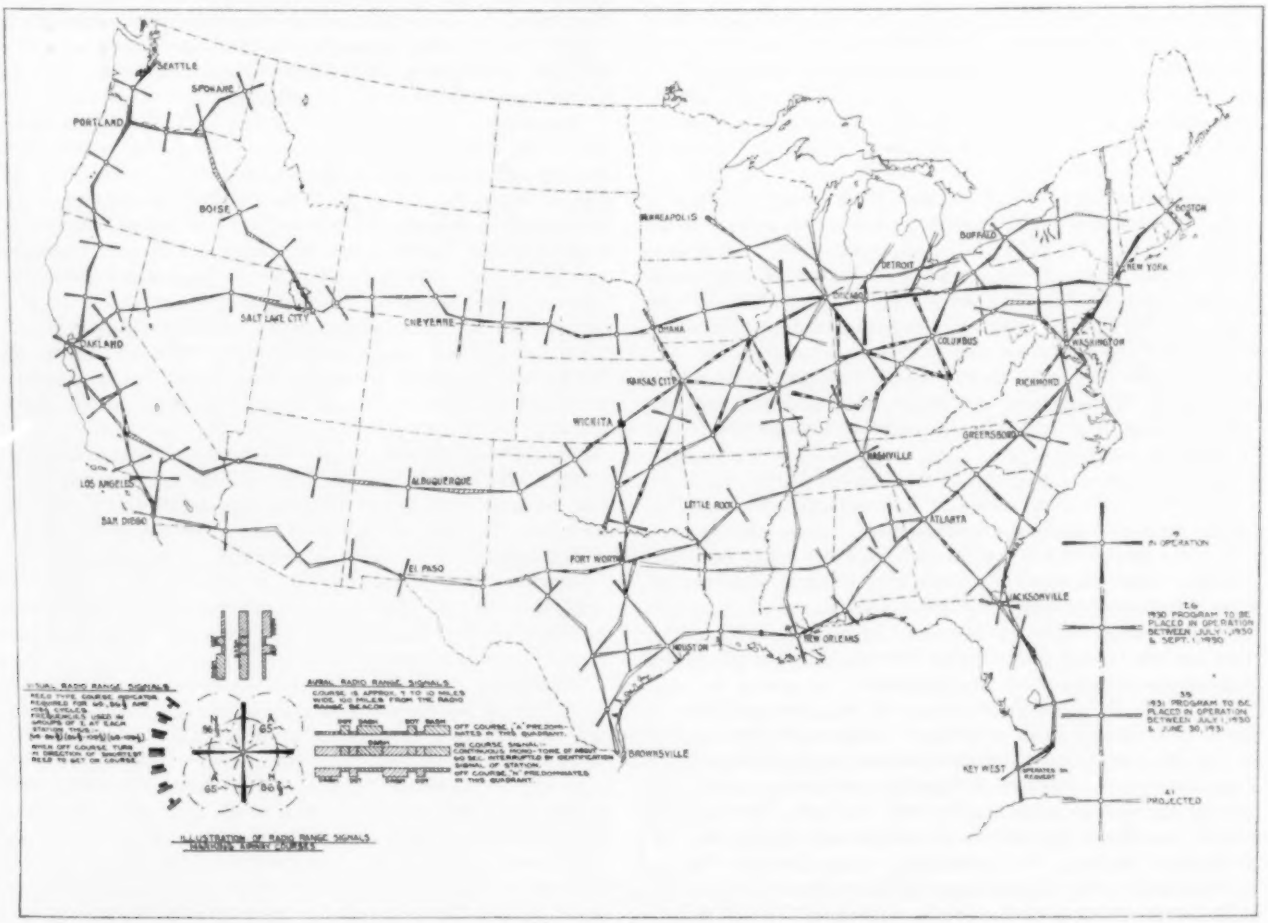

FIG. 8 AERONAUTICAL RADIO RANGE BEACON SYSTEM

at the $^1/_3$ and $^2/_3$ heights of the tower. The catenary of transmission lines crossing navigable waters is illuminated from the towers by 24-in. parabolic directional projectors showing a light of sufficient intensity to mark the crossing by the indirect illumination of the beam. Bridges are marked with 300 MM code lanterns having two 200-watt lamps mounted on the tops of the towers. For marking areas which may present a hazard to flying along a civil airway, a 24-in. standard revolving beacon equipped with a 1000-watt lamp and lamp exchanger and with red cover glass is used at a prominent point to indicate the existence of the hazardous area. Pilots are warned to give red revolving beacons a wide berth or fly over the area marked by such beacon at an altitude not less than 1000 ft. An alternative method of marking the hazardous flying area is the use of a high-intensity fixed projector pointed along the boundary of the area

intermediate landing fields and critical points along the route. Teletype communications are used in collecting weather information and for making aircraft-position reports and keeping track of airplanes flying over the route. The teletype system now in operation and the weather-reporting points are shown on the map in Fig. 4. Weather information is collected in sequence from each reporting station at the scheduled period set for each circuit, the collection taking from four to five minutes. At terminal points where a number of airways converge, the collections from the respective circuits are made just prior to the quarter-hour periods. There are at present 5650 miles of teletype in operation along the civil airways, and this mileage will be increased to 8600 miles during the next year. The teletype service utilizes a leased telephone circuit over which signals are transmitted by an automatic typewriter, leaving a type-

written record on all the teletype machines in the circuit. The transmission is at a rate of 40 words per minute. The weather information collected along the route is communicated by teletype to the Weather Bureau for interpretation and used in connection with weather maps. Weather information is disseminated by radio to airplanes in flight and to airports equipped with receiving apparatus. There are at present 35 airways radio stations in operation as shown on the map in Fig. 5. When the airways radio stations are completed in accordance with the program, there will be no area in any part the United States where flying takes place that will not be equipped with proper weather service, which may be received by the pilot in the air by tuning in.

In addition the Weather Bureau collects weather information from the primary net twice daily and from the secondary net every three hours, from which data weather maps are prepared for the interpretation of weather and the planning of schedules. A special broadcast is made every three hours for the use of airports covering the secondary net area. Upper air conditions are broadcast each 6 hours.

The standard airways radio station of the Airways Division is shown in Figs. 6 and 7. The equipment of the airways radio station consists of a 2-kw. intermediate-frequency transmitter for broadcasting weather information and messages to airplanes for the safety of flight on frequencies between 237 and 350 kilocycles (kc.) This band is divided into channels with 6 kc. separation, and the same frequencies are shared by stations approximately 700 miles apart. In addition to the broadcast transmitter, the station is equipped with a 500-watt high-frequency transmitter for point-to-point communications. This transmitter can be operated from a gasoline-driven generator in the event the station is cut off from power due to the failure of electrical transmission lines. The airways radio stations are operated in conjunction with the radio range-beacon service now being established along the airways sharing the same frequencies. The radio range beacon is stopped on the quarter-hour periods and identified by station announcement followed by correct time and voice broadcast of weather information. This concise statement of weather information along any sector of the route occupies about two minutes.

The system of radio range beacons to mark the civil airways in the United States is shown in Fig. 8. Nine radio range beacons of the aural type have been in operation during the past two years, and the 26 additional beacons now under construction will be placed in operation early next summer. The program for the fiscal year 1931 covers the installation of 33 additional radio range beacons. Consideration is being given to the use of visual-type radio range beacons for the 1931 program. Seven radio range beacons of the visual type have been manufactured by the Airways Division at the Detroit shops and are now being flight tested. The transmitter for the radio range beacon is a 2-kw. one and transmits signals on two-directional loops. The interlocking along the equisignal zone marks the airways course and coincides with the lighted route. The most important function of the radio range beacon is its homing feature, and therefore the radio range beacons are installed in the vicinity of landing fields so as to direct the pilot to a safe landing field under conditions of poor visibility.

Marker beacons are located at the intersection of two radio range courses and transmit identification signals on dual frequencies of the adjacent radio beacons. The marker beacons serve as mile posts along the route. The marker-beacon transmitters are equipped for transmitting voice in addition to the characteristic signals, and are used in acknowledging messages from airplanes and reporting their flight over the intermediate fields. The position reports from airplanes passing over the principal intermediate fields are transmitted by the airways keepers on the teletype to the terminals.

The airways keepers stationed at the principal intermediate fields from which weather reports and "plane over" reports are received will be equipped with radio receivers to stand a loud-speaker watch on the national calling and distress frequency for emergency messages from aircraft. The national frequency adopted in the United States for calling and distress messages from aircraft is 3106 kc. The airways keepers are instructed to keep a sharp lookout for airplanes flying over the route and transmit on the teletype the "plane over" movements of aircraft that are not equipped with radio. Airways keepers set flares for the landing of aircraft under conditions of stress of weather when instructed by a proper responsible official of the operating company.

In the United States a national frequency of 278 kc. has been set up for the use of airports to communicate to aircraft in flight. The power is limited to 10 watts and transmits to the airplane by voice. The airports are requested to be equipped with receiving sets having a loud speaker tuned to the national calling frequency of 3106 kc. for receiving messages from aircraft, thus permitting the airport manager to communicate with airplanes for such landing instructions or emergency communications as may be found necessary.

The Federal Radio Commission has adopted an aviation plan for the use of the air-transport companies so as to provide two-way radio communications. A number of frequencies in the 1500-6000-kc. band have been reserved for aviation purposes to be used by aeronautical or aircraft stations on a chain basis for communication purposes. Under this plan the air-transport operators will establish ground stations along the routes on which scheduled operations take place and keep a constant contact with aircraft while in flight. This system permits the air-transport operators to provide for themselves a two-way system of radio communication for safeguarding the lives of passengers and maintaining proper schedules.

Trend in Aircraft-Engine Development

By HAROLD CAMINEZ,[1] INDIANAPOLIS, IND.

It is difficult to ascertain the extent to which various improvements in aircraft engines will be adopted, and it is unwise to predict what the eventual types of aircraft power plants will be. However, a discussion of present-day aircraft engines with their possibilities and shortcomings is helpful in establishing some of the trends in engine development.

The author discusses general features of aircraft engines, such as in-line versus radial types and water-cooled versus air-cooled types, and shows their limitations and advantages.

THE TREND of aircraft-engine development is a subject over which there is always considerable controversy. Each engine manufacturer likes to believe that his developments are along present tendencies and that his latest product demonstrates the latest trend.

All developments in engines are for the purpose of eventually meeting the requirements of the aircraft builders. These requirements continually grow more exacting, and often necessitate changes in basic engine designs. In studying the trend in engine construction, improvements must be reviewed that will be made in aircraft and which will influence engine requirements.

To obtain any great increase in the market for commercial aircraft, airplanes must be made safer, more comfortable, more useful, and more economical. Improved safety requires not only increased engine reliability, but more especially superior airplane performance. As demonstrated in the recent Guggenheim safe-aircraft competition, airplanes will have lower minimum flying speeds, higher maximum speeds, and much steeper angles of climb. Such performance characteristics make flying safer and more simple, and will encourage more widespread use of airplanes. However, they introduce additional problems for the engine designers, since with such airplanes there will be steep climbing angles at full engine throttle with low air-speed velocity, and it will be necessary to cool the engine satisfactorily under such conditions. High propeller efficiency, not only at maximum speed, but also during climb, will be important in these airplanes, so that the need for low propeller r.p.m. will be more pronounced. These more difficult cooling conditions will have to be provided for, and lower propeller speeds will have to be obtained with no material increase in present total power-plant weight. These requirements will tax the ingenuity of the designer.

Increased comfort during flight is essential before air travel becomes truly popular with the general public. This necessitates the reduction of the noise and the vibration that are so prevalent in present-day airplanes. The worse offenses as regards noise are due to the propeller and to the engine exhaust. The requirements of comfort seem to suggest the necessity of propeller reduction gea ng to obtain quieter slow-turning propellers, together with the f efficient exhaust silencers to reduce exhaust noises. Whe these noises are diminished, it may also be necessary to investigate means of reducing some of the other engine noises, especially those due to high piston side clearances and to too large variations in valve-tappet clearances. Together with the reduction of noise, a serious investigation will be necessary toward the complete elimination of vibration, for not only is vibration disquieting to the nerves, but it is also a contributing cause to numerous airplane and engine failures. Elimination of vibration will mean not only complete inertia balance of the engine, but also low engine-torque variation throughout the cycle, and the complete elimination of all critical speeds of crankshafts and other fast-moving parts. It will also be necessary to get this quietness of operation and freedom of vibration without any increase in engine weight. There must be considerable divergence of opinion as to the best method to obtain these ends.

Greater Pay Loads Needed

The commercial usefulness of aviation will be increased when higher flying speeds are obtained along with increased flying radius and greater operating economy. Economy will require carrying greater pay loads without increasing power-plant sizes, as well as a reduction in engine cost and in fuel consumption. Reduced fuel consumption will also result in increased flying radius. Therefore higher flying speeds with increased radius and economy will be obtained not merely by increasing the power in a given airplane, but by refinements in design and aerodynamic qualities. This will result in more careful consideration of the parasite drag or head resistance of the power plant and cooling system, as well as in improvements of propulsive efficiency. The air-transport operator will also seriously consider the economy in operation that will be effected by longer engine life and lower maintenance cost. It is possible that this increased engine life and lower maintenance cost may be obtained by improving airplane performance to such an extent that reasonably large pay loads can be carried with satisfactory performance when operating the engine at only part throttle for most all flying conditions. However, it is more reasonable to expect that the engine builder will so improve his product that adequate life and reliability will be obtained at full-throttle as well as at part-throttle engine operation. In small airplanes operated by private fliers it is also essential that adequate reliability be obtained under all conditions of operation. It is difficult to visualize any real widespread popularity of private flying as long as there are any "don'ts" in connection with engine operation. Signs on airplane instrument boards saying "do not climb at air speeds less than—m.p.h." and instructions in engine books saying "do not run engine unnecessarily at full throttle" must be eliminated. One of the joys of flying is the absence of traffic and the needlessness of speed laws. There should be no engine requirements that will diminish the full appreciation of these joys.

---

[1] Engineer in Charge, Aircraft Engine Department, Allison Engineering Company. Mr. Caminez was educated at Cornell University, where he received the degree of M.E. in 1920. He was then employed for five years in the Engine Design Department of the Engineering Division of the U. S. Army Air Corps. In 1925 he became Chief Engineer of the Fairchild Caminez Engine Company, which company specialized in the development of aircraft engines. He resigned in 1928, and was then engaged in making an investigation of the aircraft-engine industry both in this country and abroad. In 1929 he was employed as Design Engineer by the General Motors Corporation, and later in his present position.

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The requirements of the commercial aircraft engine have often been discussed. However, it is now seen that in addition to the well-recognized necessity of low engine weight per horsepower, together with adequate engine reliability and reduced engine cost, careful consideration must be given to improving present commercial aircraft engines in the following respects: (1) Ability to cool adequately at full throttle under the low airspeed conditions that are obtained in climb with airplanes that have high-speed ranges, together with provisions for the regulation of engine cooling under the more extreme flight conditions that will be obtained with these airplanes; (2) lower head resistance of power plant and cooling system at maximum flying speeds; (3) more efficient and quieter propeller speeds, and therefore the more widespread adoption of propeller reduction gearing; (4) more general use of exhaust silencers as well as quieter running engines; (5) complete balancing of all engine inertia forces, low cyclic variation in engine torque, and elimination of critical shaft speeds and other vibrating tendencies; and (6) better full-throttle engine operation in actual aircraft installations particularly in regard to increased engine life, improved engine reliability, lower maintenance costs, and reduced fuel consumption.

It would be difficult to ascertain all the various experiments to improve present aircraft engines that are going on all over the world, as well as it would be unwise definitely to predict the eventual types of aircraft power plants. However, a discussion of present-day aircraft engines, together with the possibilities and shortcomings of the various types as now revealed in service, would be helpful in establishing some of the trends in engine development.

Air-Cooled Versus Water-Cooled Engines

In this country the majority of the engine manufacturers are building and further developing radial air-cooled engines. A few companies have recently started in the production and development of in-line air-cooled engines. One manufacturer is in regular production on water-cooled aviation engines. In England, where the modern air-cooled radial engine was first developed, there are two large companies regularly producing this type, while two other equally large aircraft-engine manufacturers are still confining their efforts to water-cooled engines. Two more recent English engine builders are now in production on small in-line air-cooled engines. In France and in Germany there appears to be equal effort spent in the development of both water-cooled in-line and air-cooled radial engines, while in Italy the only engines of merit are of the water-cooled type. Practically all engines now in use operate on the conventional four-stroke Otto cycle, but there are significant developments under way of engines operating on the Diesel cycle. In this country air-cooled and water-cooled Diesel aircraft engines are being experimented with, while in Europe several water-cooled Diesel engines are under development. Therefore, to make the discussion of present-day engine trends complete, developments must be considered in: (1) The radial air-cooled engine; (2) the in-line air-cooled engine; (3) water- or fluid-cooled engines; and (4) aircraft Diesel engines.

The radial engine will be considered first because it is the type now most extensively manufactured and used in this country. This type of engine was initially developed for military purposes because: Firstly, air-cooling made it less vulnerable to gunfire; secondly, the radial-engine arrangement gave a short engine length with concentration of mass, which is a desirable characteristic in combat airplanes designed for acrobatic maneuvers; and finally, the radial air-cooled power plant could be built at a lower installed weight per horsepower than the water-cooled power plant that it replaced. The first two advantageous characteristics of the radial engine from a military viewpoint have little if any influence on the commercial use of this type. The principal advantage of this type that must therefore be considered is that its development for military use has produced a power plant of low weight per horsepower. This is a most desirable engine characteristic if it is accompanied by engine life and reliability.

According to reports emanating from the Navy Department, which is a most ardent advocate of the air-cooled radial, long life and reliability are obtained by such engines in its airplane installations. However, commercial operators of these same engines do not apparently have equal satisfaction. The reason for this is at once evident to one experienced in the developments of air-cooled engines. The power output which such an engine will maintain without sacrifice of engine life and reliability depends upon the engine cooling. The cooling effect on an air-cooled engine is a function of the air velocity past the engine, which in turn depends on the speed of the airplane and the slipstream effect of the propeller on the engine. Therefore, every air-cooled engine developing its rated power has a certain minimum airspeed velocity which cannot be lessened without sacrifice of engine life and reliability.

Military Planes Have Good Cooling Conditions

If an air-cooled engine is designed for maximum performance in military use, it must be designed for the airspeed characteristics met in this service. These military planes, with power loadings of less than 10 lb. per hp. and with high speeds in excess of 175 m.p.h., have vastly superior cooling conditions for air-cooled engines than a modern economical commercial type airplane. An air-cooled engine, to be an efficient and reliable power plant, must have different cooling facilities, and must therefore be differently designed for every new type of airplane installation. When a military air-cooled engine designed for an airplane with a high speed of 175 m.p.h. and a power loading of 10 lb. per hp. is used in a commercial airplane with a high speed of 135 m.p.h. and a power loading of 15 lb. per hp., it should be expected that the rated engine horsepower would be greatly reduced for the engine of the commercial plane to obtain the same reliability that the engine has in the military airplane.

Partly to make up for the cooling deficiencies in the commercial airplane the carburetor mixtures can be enriched and the fuel consumption increased, thereby partly cooling the engine with excess fuel. Increasing the oil circulation and the oil consumption also helps in engine cooling. It is also possible to design the propeller section near the hub so that it throws a maximum slipstream velocity on the engine. Such a propeller characteristic is particularly advantageous during airplane climb where the engine operates at full throttle with low forward speed of the plane. Apparently increasing the slipstream on the engine decreases overall propeller efficiency, but it will undoubtedly be necessary to do this with air-cooled engines installed in airplanes that have slow climbing speeds.

Cowling May Effect Engine Cooling

One of the greatest problems encountered in the commercial installation of air-cooled engines is that an airplane builder by the choice of cowling and propeller can greatly improve airplane performance, but by doing so he may seriously affect engine cooling. Increasing airplane performance at a sacrifice of engine cooling and reliability is highly undesirable. Therefore, the only way to be sure of reliable engine operation with sufficient engine cooling in a new air-cooled engine installation is to run extensive cooling tests on the engine under all conditions of flight. This generally entails quite an elaborate test set-up,

because air-cooled engine temperatures vary among different cylinders and on different places on the same cylinder.

Another difficulty is the lack of general authentic data on the desirable maximum temperatures that can be employed. The author's experience has been that for reliable operation cylinder barrels should be kept below 300 deg. fahr. and cylinder heads below 600 deg. fahr. on the type of air-cooled cylinders now generally employed. When this cylinder-barrel temperature is exceeded, piston seizure may occur, and when the head temperature is exceeded, detonation and general engine overheating may ensue. There are times when engines have apparently operated satisfactorily with temperatures 50 deg. to 100 deg. higher than that stated.

Cooling tests on new air-cooled engine installations should be run with all standard cowling, exhaust manifolds, and carburetor settings. Engine temperatures should be determined in full throttle climb and level flight with the weakest carburetor mixtures and poorest fuels that will be used in service. It should also be considered that in extended service poor seating of the valves, bad spark plugs, and tight pistons may develop and that these also increase cylinder heating, so an additional margin of cooling should be allowed for these contingencies in an air-cooled installation in which reliability is aimed at. The importance of such engine-cooling tests cannot be overestimated and it may be desirable for the Department of Commerce to insist upon such tests in its regulations. When giving information on approved air-cooled engines, the cooling-air velocity and temperature, the grade of fuel, and the fuel consumption during the type tests should be published with the engine rating.

In multi-engine airplanes using air-cooled power plants, which are designed to fly safely when one of the engines is not operating, cooling tests are essential under such flying conditions. When one engine is out, it is generally essential to fly with the remaining power plants at full throttle. The airspeed of the plane is reduced under such conditions, and the cooling effect on the operating engines thereby reduced. Cooling tests on an air-cooled multi-engined airplane should show an adequate cooling reserve under such operating conditions if any increased airplane reliability is to be expected from the use of multiple power plants.

Cast-On Fins Being Used

Since engine cooling is a limiting factor in air-cooled engine development, continued progress should be expected along this line. The same type of air-cooled cylinder construction using steel-finned barrels with attached cast-aluminum heads has now been generally employed with but minor modification for the last eight years. It is known that better cylinder-barrel cooling than that obtained with steel fins will allow the development of greater engine-power output without requiring increased air-blast velocities. In France, Germany, and Czechoslovakia, air-cooled engine manufacturers are now using steel cylinder barrels with cast-on aluminum fins. Similar cylinder constructions were previously employed in this country with limited success. One serious difficulty formerly experienced was due to the large difference in coefficient of expansion between the aluminum and the steel which allowed the aluminum fins to expand away from the steel barrel when the cylinder heated up, thereby destroying the intimate contact required for satisfactory cooling. Recent metallurgical developments have shown the way to obtain special iron alloys suitable for cylinder-liner requirements that have expansion coefficients about equal to that of aluminum. It is therefore probable that satisfactory cast-aluminum cylinders with special iron or steel liners may be developed soon which will take full advantage of the higher heat conductivity, higher specific heat, and ability to get more cooling area per pound of metal than is possible with steel cooling fins.

Other methods of increasing cylinder cooling under critical cooling conditions, such as are obtained during climb and take-off in a commercial airplane with a heavy power loading, may also be developed. Placing the carburetor float chamber in front of the main discharge nozzles so that the carburetor mixture will automatically be enriched when the engine nose is pointing up would help cylinder cooling during climb without affecting fuel consumption in straight-away flight. Another method of obtaining added cooling is to arrange an auxiliary oil line for the purpose of spraying oil into the engine upon the inside of the pistons. This auxiliary oil system could be so arranged that it would operate only at full throttle when the engine nose was pointed up. The cooling effect of an increased oil circulation could thereby be employed without increasing oil consumption during level flight.

Improved Fuel Metering Desirable

Lean intake mixtures increase the amount of heat to be dissipated in the cylinder. The cooling characteristics of the engine determine the leanest mixture strength that it is advisable to employ. Where there is any unevenness in distribution, the carburetor must be set rich enough so that the cylinder receiving the leanest mixture will not overheat. Improvements in fuel metering and distributing systems are therefore highly desirable in air-cooled radial engines. It is particularly advantageous in these engines to get proper fuel distribution without heating the air-intake charge. Heating the air charge makes it necessary for the cylinder cooling fins to dissipate more heat per horsepower developed by the engine, both because of the added heat to the charge and also because it decreases the maximum allowable compression ratio. Cold carburetion methods should therefore be particularly attractive for these engines if they can assure perfect fuel distribution. Metering the fuel by means of separate fuel pumps for individual cylinders and injecting directly into the cylinder or intake port is a method now being developed for obtaining exact fuel metering and distribution without applying heat to the air-intake charge.

Means for controlling cylinder-barrel temperatures is probably most important for improving the life and reliability of air-cooled engines. Cold cylinder barrels increase engine friction and promote wear due to increase of oil dilution by gasoline. Overheated cylinder barrels not only increase wear by destroying cylinder lubrication but also are the general cause of piston seizure. To regulate cylinder-barrel temperatures, it is necessary first to determine them. The gaging of cylinder-barrel temperatures by oil temperature is neither exact nor reliable. This has led to the installing of one or more thermocouples on cylinder barrels in many airplane installations. Potentiometers or milliammeters used with these thermocouples are delicate instruments subject to numerous inaccuracies, and these installations show the temperatures of the cylinder at only a relatively few places.

Painting for Cylinder Barrels

As previously pointed out, temperatures vary considerably at different points on the different cylinder barrels. It has therefore been suggested that the cylinder barrels be painted or surfaced with some material which will show by change of color or some other effect when the safe temperature is exceeded. Paints which change color when the surface to which they are applied exceeds a certain temperature, and which regain their original color when the surface cools, have been developed. The general use of such a paint on cylinder barrels would simplify the conducting of cooling tests on air-cooled engines. By taking advantage of the temperature gradient that

exists along the length of the cooling fin, and by employing a paint that changes color at the mean temperature which it is desired to maintain, cylinder-barrel temperatures could be judged by observing the extent of change in the color of the paint.

A number of improvements that may be effected in air-cooled engines, particularly in regards to cylinder cooling, have been outlined. Commercial airplanes that climb at steep angles and low air speeds, that use propeller reduction gearing with large propellers and resultant low slipstream velocity on the engine, that use exhaust silencers with resultant increase of heat to be dissipated by the cylinders, that require engines of small frontal area and low head resistance, that necessitate quiet-running engines so that piston clearances cannot be excessive, and that require reliable power plants of low weight per horsepower, impose more strenuous engine-cooling requirements than the present engines are designed for. Whether air-cooled engines can be made fully to meet these requirements depends upon the development of better cylinder-cooling characteristics. It is evident that possibilities exist for considerable improvement over the present air-cooling arrangements. That this improvement will meet the more exacting requirements imposed by airplane builders and users cannot be conceded.

Air-Cooled-Engine Progress

The in-line air-cooled engine is now receiving considerable attention in this country. Its development is due to the desire to have air-cooling, and to overcome some of the objections to the radial engine. The lesser frontal area of the in-line engine is contrasted with the starfish arrangement of the radial with its large head resistance and its interference to visibility. It is claimed that the general users are more familiar with the in-line cylinder arrangement, and will therefore have more confidence and more ability to service this type in contrast with the radial engines. The in-line construction also overcomes other objections to the radial type such as the inability to obtain perfect inertia balance in the radial engine due to the distorted piston motion caused by the link connecting-rod arrangement. This articulated connecting-rod arrangement also increases the maximum piston side thrust in the radial engine about 50 per cent over that which would normally be obtained in an in-line engine with the same connecting-rod to crank-throw ratio, so that it should be possible to operate the in-line engine with higher cylinder-barrel temperatures without danger of piston seizure. The in-line engine also allows the use of overhead cam shafts so that the push-rod valve mechanisms used in radial engines with their higher inertia of moving parts and their variable tappet clearances due to cylinder expansion can be avoided. However, the in-line air-cooled construction is inherently heavier than the radial air-cooled arrangement because wide cylinder spacing must be allowed for the cooling fins in the in-line engine. There is also considerable controversy as to whether the in-line engine arrangement will allow as good cylinder air-cooling conditions as the radial type, particularly during take-off and climb when the propeller slipstream is most potent in cooling.

As in the radial air-cooled engine, the main problem in the development of the in-line engine rests upon further development in cylinder cooling. Improved cylinder construction and better mixture distribution will help. Considerable improvement in the cooling of the in-line air-cooled engine can also be effected by improved engine cowls and scoops. However, the problem of obtaining low weight per horsepower with the in-line air-cooled engine appears to be greater than with the radial type. The commercial in-line air-cooled engine is competing at present with the radial engine mainly in the smaller sizes. Due to their lower weight per horsepower, better airplane performance should be expected with the radial engines, but the in-line engine will have its adherents due to the fact that it provides a cleaner airplane installation, it allows a simpler exhaust-disposal system, and because it is probably better understood by the general public.

Comparatively little work has been done in this country during the past few years on the development of commercial water-cooled aircraft engines. Although considerable numbers of war-time water-cooled engines are in commercial use, practically all new commercial aircraft engines are of the air-cooled type. In comparing the two engine types, it is usual to compare the modern air-cooled engine with the war-time water-cooled engine, much to the disparagement of the latter. However, in Europe where the modern air-cooled engines were initially developed, it is found that equal effort is being spent on the development of the water-cooled types. Review of aircraft-flight records shows that most of the important world records in regard to speed, duration, and distance are now again held by water-cooled engines. These performances have been established abroad, and are causing American engine designers to reconsider the water-cooled engine types.

The popularity of the air-cooled engine was initially due to the fact that this engine could be built with the same weight per horsepower as the dry weight of the water-cooled engine. The use of air-cooling eliminated the weight of the water-cooling system and also the plumbing troubles that were experienced with it. The extended use of air-cooled engines has shown that this type also has its deficiencies, namely, the difficulty of determining and controlling engine temperatures. Recent developments in water-cooled engines have now brought the installed weight per horsepower of this type complete with cooling system down to that of the air-cooled engines. This decrease in weight per horsepower has been due mainly to an increase in engine speed and in brake mean effective pressure in the water-cooled engines. Equal effort has undoubtedly been spent to increase the power output of air-cooled engines, but the designers of water-cooled engines have met with more success because their problem was less difficult. Power output in an aircraft engine is now generally limited by thermal conditions, and with fluid cooling it appears to be easier to obtain the necessary increased cooling effect.

High-Temperature Coolants Developed

Aside from the influence due to the success of the water-cooled engines abroad, particularly in the last Schneider cup races, and in the establishment of numerous distance and duration records, the greatest factor in bringing attention again to liquid cooling in this country has been the development of high-temperature coolants for engine-cooling purposes by the U. S. Army Air Corps. Water-cooling had previously limited engine temperatures to around 180 deg. fahr. in order to prevent the loss of coolant by evaporation. By substituting a high boiling-point liquid, such as Prestone, it is possible to run coolant temperatures considerably higher. The development of the air-cooled engine has shown that satisfactory engine operation can be obtained with cylinder barrels at 300 deg. fahr. By raising the coolant temperature to this, a considerable reduction is possible in the size of the engine radiator over that which would be necessary for water. This reduction in radiator size means not only a reduction in weight but also in head resistance. Despite the more efficient streamline air flow that can be obtained through a radiator as compared with that through the fins of an air-cooled engine, the head resistance of the water-cooled engine and radiator was often equal to or greater than that of the air-cooled engine. However, with high-temperature liquid cooling,

it appears possible to bring the head resistance of engine and cooling system down to a minimum.

Since high-temperature liquid cooling improves airplane performance, it is reasonable to expect that liquid-cooled engines will be developed to use the new coolants. Engines developed initially for water-cooling probably will not prove satisfactory at the higher coolant temperatures, and the troubles that will at first be experienced with the new cooling fluid may discourage many from its use. With high-temperature cooling, new engine-design problems are introduced, the most vexing being due to the greater thermal expansion caused by the higher temperature range. In cylinder constructions using steel cylinder liners and aluminum water jackets, the difference in expansion of these two materials requires special provision for expansion in the original design when high cooling temperatures are employed. Rubber connections and soft-soldered joints do not stand up well under the higher temperatures, and other practices found satisfactory with water-cooling will need revision.

The trend in liquid-cooled engines is to construct in-line engines of maximum compactness, and to increase the horsepower developed per cubic inch of piston displacement by increasing both the brake mean effective pressure and the normal engine r.p.m. Due to the higher crankshaft speed, most of these engines are now fitted with propeller reduction gearing. Satisfactory propeller reduction gearing for liquid-cooled engines has been developed, and the use of such gearing presents no engine thermal problems with the liquid-cooled engine as it does with the air-cooled types.

Since the engine must be charged with the weight of the cooling system, and since the dependability of the power plant necessitates reliable cooling systems, it is likely that the manufacturers of liquid-cooled engines will undertake to supply engines complete with cooling systems to their customers. This will result in the centralized responsibility for all engine failures and should encourage more development in cooling-system reliability and efficiency. With high-temperature cooling systems, the radiators will be relatively small compared with their water-cooled predecessors. The high-temperature cooling liquids also hold possibilities for novel radiator designs of increased efficiency and reliability that will differ considerably in construction from present water radiators.

New Bearing Materials Allow Greater Bearing Loads

The horsepower outputs of the wartime water-cooled engines were generally restricted by limitations of bearing capacity, crankshaft critical speeds, and valve-cooling difficulties. Since the development of the modern air-cooled engines means of overcoming these limitations have been determined. The new bearing materials, particularly the high-lead bronzes, allow higher bearing loads and surface velocities, so that large-diameter and narrow-width main bearings can be employed. This has materially raised the engine speed at which bearing troubles and crankshaft critical vibrations occur. Improvements in cylinder and valve design together with the development of vastly superior valve materials have minimized the difficulties experienced with valve cooling. Improvements in manifolding and the use of supercharging have greatly increased the breathing capacities of the cylinders at high speed. All this has served to increase the specific output per cubic inch of piston development. With increased experimentation and development of engine details it appears that further improvement in this respect is still possible with the water-cooled engines, while in air-cooled engines the specific power output per unit of displacement appears to be limited by cylinder cooling. A large European water-cooled engine has already been constructed that develops a horsepower per 1.2 cu. in. of piston displacement and weighs about 0.80 lb. per hp. Similar results should be obtained in this country, which will require engine operating speeds of above 3000 r.p.m. with brake mean effective pressures exceeding 175 lb. per sq. in.

In the discussion of engine trends, the relative cost of the various engine types must be considered. From a superficial study of conditions it would appear that the air-cooled engine with a direct propeller drive is considerably simpler in construction and therefore necessarily cheaper in cost than a competitive liquid-cooled engine with its additional cooling system and propeller reduction gearing. However, a careful study of present aircraft-engine costs will show that the development, engineering, and servicing costs on airplane engines represent a large percentage of their total cost, so that an economical aircraft-engine design is one which a manufacturer can tool up on with assurance of little trouble in service and relatively few future design changes. The quantity of engines produced and the freedom of service troubles are of major importance in engine cost. When aircraft and engines of better reliability and performance are built, there will be a larger market for airplanes, and the increased quantity will reflect in lower costs. Therefore, engine reliability and performance will have more weight in ultimate price reductions than mere simplifications or cheap production methods that do not improve the product.

Use of Aircraft Engines in Other Fields

Since quantity of production has a most important influence on cost, it may be pointed out that it is of considerable advantage to build a type of engine for aircraft that can be used in other automotive fields. Because of their direct cooling systems the air-cooled engines can apparently only be employed for aircraft, since no other market has yet been found for the air-cooled aircraft engines now developed. However, liquid-cooled aircraft engines have been found to be excellent power plants for marine work, and all of the water-cooled engines have been employed in such service. Therefore, by designing a liquid-cooled power plant which can also be adapted to marine use, the manufacturer obtains a larger market for his product, with the resulting manufacturing economies. The similarity in construction of liquid-cooled aircraft engines to the usual automobile power plant allows the manufacturer to take more direct advantage of the experience and facilities that have been developed for the economical production of fine automobile engines.

It is now probably universally conceded that the large airplane engines of more than 600 hp. will be of the liquid-cooled type. Few aircraft engines of such power output have yet been developed in this country, although in Europe there are a number of such engines now in regular production. There appears to be no doubt that it will be necessary to equip future large transport airplanes with such power plants, and it should therefore be expected at this time that a more intense development of large liquid-cooled engines will take place in this country. These large engines will probably be of the V or W type of 12 or more cylinders with horsepower ratings of 600 to 2000. With such large power plants, it is now relatively easy to get weight-per-horsepower ratios of 1.5 to 2 lb. per hp. Lower weight than this is not as important for commercial aircraft use as improvements in fuel consumption, maintenance, and engine life. High-powered engines developed mainly for military purposes may not be entirely suitable for commercial service, with the result that there may be developments of two distinct types of large-sized aircraft engines. The military type will be of maximum compactness and minimum weight, designed to operate supercharged at highest speeds. The commercial type will be of more generous proportions designed for a service life of at least

1000 hr. between overhauls, and to operate at fuel consumptions of about 0.45 lb. per hp-hr.

Effect of the Diesel Cycle

The development of the Diesel cycle cannot be overlooked in predicting the engine of the future. The reduced fire hazard resulting from the use of a heavier fuel, and the improved economy, particularly at part throttle, which are obtained with the Diesel cycle, are important items in its favor. The problems of the high-speed Diesel engine are difficult of solution, so that it would be unwise to state when or if ever the Diesel engine will replace the conventional Otto-cycle engine for general aviation use. The Diesel cycle in its present state of development appears to be a relatively slow-speed cycle when compared with the Otto cycle. To replace the Otto cycle for aircraft use it will be necessary to find means of obtaining high b.m.e.p. at higher r.p.m. with the Diesel cycle. Direct injection of the fuel into the cylinder as provided in the Diesel cycle makes two-cycle engine operation entirely feasible in a liquid-cooled engine. This will allow such engines to operate at relatively low crankshaft speeds with high power outputs.

It is not unreasonable to expect that the present developments on Diesel engines will lead to the development of new engine cycles for aircraft that will combine the advantageous features of both the Diesel and the Otto cycles. Fundamental researches on engine cycles and improvements in engine fuels will undoubtedly show their effects in future engine designs. The new fuels that are being developed will allow the employment of higher compression ratios in the Otto cycle with the resultant increase in power output and fuel economy. The use of fuel-injection systems with the Otto cycle together with the perfection of heavy fuels that do not readily detonate will reduce the fire hazard caused by the light fuels now necessary with carburetor fuel-metering devices in the Otto-cycle engines. Two-cycle engine operation with increased power output, but without excessive fuel consumption, are also made possible with Otto-cycle engines by the use of fuel-injection systems. The development of fuel-injection mechanisms that have resulted from Diesel-engine development may therefore be of value to our future Otto-cycle engines.

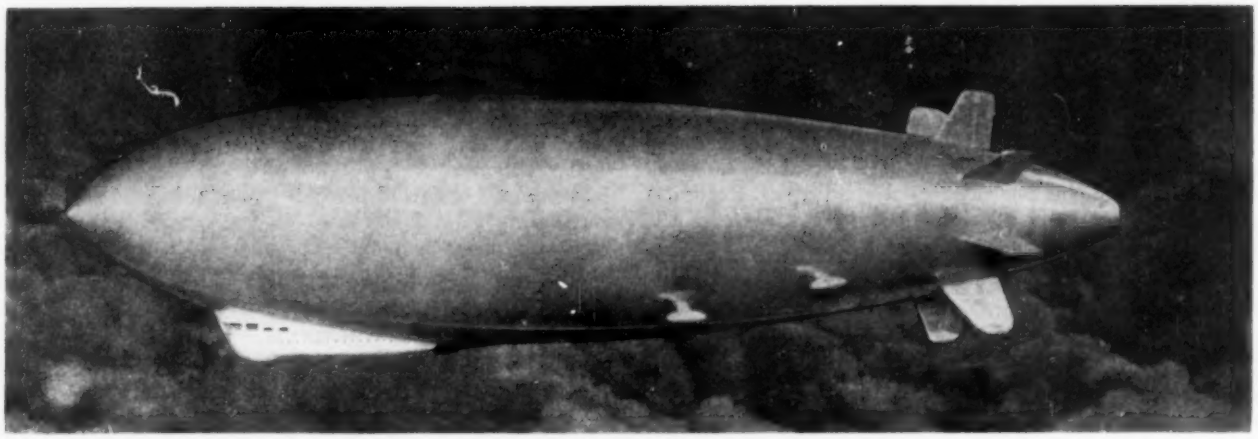

FIG. 1 PROPOSED COMMERCIAL TYPE OF METALCLAD AIRSHIP
(Gross lift 100 tons, maximum speed 100 m.p.h., volume 3,800,000 cu. ft., eight engines totaling 5000 hp., commercial range 2000 miles, pay load 50 passengers plus miscellaneous cargo of 12,500 lb. maximum.)

Some Economic Aspects of the Rigid Airship

BY CARL B. FRITSCHE,[1] DETROIT, MICH.

In this paper the author tells of the uses to which rigid airships may be put, the cost of constructing, operating, and maintaining, and the probable return on investment that can be expected. Two hypothetical airships are chosen for comparison, one of 100 tons gross lift and the other of 300 tons lift. These are compared with ocean craft and with naval vessels. In naval application it is shown that one airship will release three cruisers for other duty, that the cruisers consume more power, and are more vulnerable than the airship.

Military applications of the airship include army transport, reconnaissance, coast patrol, and many other important uses. Theoretical conditions are assumed and many problems are worked out with use of airships. Civil and commercial applications of the airship are discussed, and a comparison is made with the steamship Leviathan. Operating schedules are laid out for airships in service between New York, Philadelphia, Washington, Havana, and Panama, and performance data are given. Commercially the airship is shown supplementing present facilities, transporting passengers, mail, and express at high speed, doing more work per unit of energy, saving much time, and earning considerable profits.

DURING the first year of its demonstration commercial flights the *Graf Zeppelin* flew a total of 75,000 miles and carried 1575 pay passengers, plus a substantial load of mail and express. In addition, it has conquered the Pacific as well as the Atlantic and has flown entirely across every continent in the Northern Hemisphere.[2]

Undoubtedly such a record of performance justifies the conclusion that the utility of the airship has emerged from doubt and uncertainty to a condition of fact which challenges the attention of everyone.

ENERGY REQUIRED IS INDEX TO COST

As is always true when any new mode of transportation is born, three questions inevitably arise: (1) What is its application? (2) What will it cost? and (3) Will it pay?

With respect to the first question, in actual service three classifications naturally present themselves; they are (1) naval, (2) military, and (3) commercial.

The answer to the second question is, of course, problematical due to limited experience and to the absence of any record of a regularly operated commercial dirigible line. Therefore, in answering this question one must rely to a large extent on circumstantial evidence. By far the major operating expense in any form of transportation is the cost of the man-power plus the mechanical power required to negotiate a given journey or to accomplish a given purpose. Therefore, in this discussion an attempt will be made to compare the man-hours and horsepower-

---

[1] Vice-President, Detroit Aircraft Corp. and President of its subsidiary, Aircraft Development Corporation. Mem. A.S.M.E. Mr. Fritsche practiced civil and mining engineering until the outbreak of the World War, when he became interested in aeronautics although not actively engaged in the Air Service. In 1921 he initiated a preliminary investigation of the possibilities of all-metal construction of rigid metal airships. The next year he organized, with others, the Aircraft Development Corporation, and since that time has been engaged in lighter-than-air development exclusively, resulting in the construction and successful demonstration of the "ZMC-2" metalclad airship for the U. S. Navy. In 1925 he organized with others the National Air Transport, Inc., the first commercial air-mail transport line in the United States, and served as secretary of this company from 1925 to 1928.

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] The recent flight to South America increased the commercial mileage to 93,000, pay passengers to 1730, and has added the conquest of the South Atlantic Ocean.

hours required for a given purpose with the energy required for existing modes of transport.

The answer to the third question, "Will it pay?" it is believed will follow as a natural deduction from the facts surrounding the answers to the first two questions.

For the sake of brevity, it is assumed that the airship does have a reasonable application for naval, military, and commercial purposes. Its graphic comparison with existing modes of transport which follows, it is believed, will justify this assumption as well as disclose a reliable index to probable costs.

Metalclad Compared With Ocean Craft

This comparison includes the estimated performance of two sizes of hypothetical airships. That both are of metalclad construction is because of the author's greater familiarity with this type and should not be interpreted as indicating any lack of interest or confidence in rigid airships covered with fabric. The

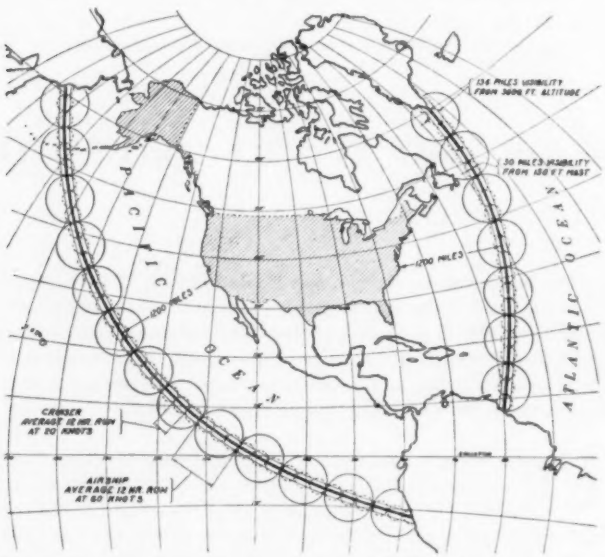

Fig. 2 Hypothetical Comparison of 300-Ton Airship Versus 10,000-Ton Cruiser on Scouting Duty

art is too young to permit of intolerance and unalterable opinions.

These two hypothetical airships, chosen for comparison with existing modes of transport, are as follows:

A 100-ton,[3] 100-m.p.h. metalclad, which it is proposed to build as the next succeeding unit following the successful construction of the ZMC-2, completed and delivered to the U. S. Navy in 1929.

A 300-ton,[3] 100-m.p.h. metalclad, which is of economic transatlantic size and should follow as a natural development within the next seven years.

It is proposed to equip each airship with sufficient engine power to provide a top speed of 100 m.p.h. This speed is considered of prime importance inasmuch as it assures ability of the airship to circumnavigate any severe storm area it may encounter. In this connection, it should be emphasized that while winds within a storm area may blow at a terrific speed, the storm area itself, whether it be a hurricane, typhoon, or cyclone, as a general rule, travels at a speed not in excess of 35 m.p.h. Therefore, properly warned by radio of the location and direction of any storm area, the airship can easily avoid it. Should the airship encounter the fringe of a storm area unexpectedly and without warning, it will possess sufficient speed to master the adverse wind currents, deflect its direction, and avoid the storm center.

[3] Long tons (2240 lb.). Air displacement, approximately 3,800,000 and 11,500,000 cu. ft., respectively.

The designation of the gross lift of these airships is expressed in long tons to facilitate comparison with ocean craft, with which it is proposed to enter them in competition from a performance standpoint. Pay load is expressed in pounds and in short tons in order to facilitate comparison, if any one is so disposed, with the performance of heavier-than-air craft attempting to engage on similar missions.

The general characteristics of a 100-ton metalclad airship are contained in Table 1, and those of a 300-ton airship in Table 2. Figs. 1 and 3 are the artist's conception of the commercial and military types of a ship of this size.

TABLE 1 100-TON METALCLAD AIRSHIP

General characteristics[a]

Gross lift		100 (long) tons
Hull volume		3,800,000 cu. ft.
Length		550 ft.
Maximum diameter		120 ft.
Engines (8) total		5,000 hp.
Maximum speed		100 m.p.h.
Cruising speed		70–80 m.p.h.
Commercial range		2,000 miles
Crew		35
Average fuel load		30,000 lb.
Pay load:		
50 passengers	12,500 lb.	
Express	2,500 lb.	
Mail	10,000 lb.	
Total pay load		25,000 lb.

[a] Based on 95 per cent inflation with 94 per cent pure helium at 60 deg. fahr. and 29.92 in. Hg lifting 62 lb. per 1000 cu. ft.

TABLE 2 300-TON METALCLAD AIRSHIP

General characteristics[a]

Gross lift		300 (long) tons
Hull volume		11,500,000 cu. ft.
Length		780 ft.
Maximum diameter		173 ft.
Engines		10,700 hp.
Maximum speed		100 m.p.h.
Crusing speed		70–80 m.p.h.
Commercial range (N. Y.–London)		3,470 miles
Crew		60
Fuel load		143,000 lb.
Pay load:		
Passengers[b]	50,000 lb.	
Express	60,000 lb.	
Mail	30,000 lb.	
Total pay load		140,000 lb.

[b] Includes additional weight of superior accommodations.

The 300-ton airship is presumed to be equipped with superior accommodations which first-class passengers are accustomed to find on palatial ocean liners. Hence the passenger capacity is limited to 100, although 200 could be carried, but with less comfort. The general-performance characteristics of these two airships applied to naval and military uses would, of course, vary to some degree due to the elimination of accommodations for passengers and commercial loads.

In the comparisons which follow, the performance data on naval and military craft are not guaranteed as accurate, but have been derived from Jane's handbook on the "Navies of the World," and from publicity releases growing out of the Washington conference in 1922, when the general specifications of a 10,000-ton cruiser were internationally defined. Such a cruiser is reported as being equipped with 107,000 hp.; has a maximum speed of 32.5 knots; consumes 0.75 lb. of fuel oil per hp-hr.; and carries a crew of 570 men.

Hence any citation of the performance of naval and military craft reveals no state secrets and for purposes of comparison should be treated in the nature of a supposition based on information which is already of public knowledge.

The performance characteristics of the Leviathan likewise are approximate, but are reasonably reliable, inasmuch as they represent an average of the several announcements and descriptions of this ship and its performance, which have been made public from time to time by the U. S. Shipping Board or have appeared ...

congressional hearings. Apparently they agree with the present capacity of the ship since it has been reconditioned for de luxe transatlantic service. It is realized that the indicated fuel consumption of the Leviathan is considerably higher than that now obtainable with more modern power-plant equipment. However, this fuel consumption is better than the average obtained with the general run of ocean liners now in service, and therefore affords a fair indication as to the relative cost of fuel per ton mile of pay load, as compared with the theoretical performance of airships.

In all of the comparisons which follow, it is assumed that the airships are traveling in still air and the ocean vessels, both military and commercial, are navigating in calm weather. Inasmuch as each type of craft carries 50 per cent fuel reserve to provide for adverse weather conditions, it is believed this assumption of ideal weather conditions for theoretical comparison is justified for the simple reason that extreme adverse weather will affect the speed and cruising radius of the ocean vessels approximately as much as it will affect the airship.

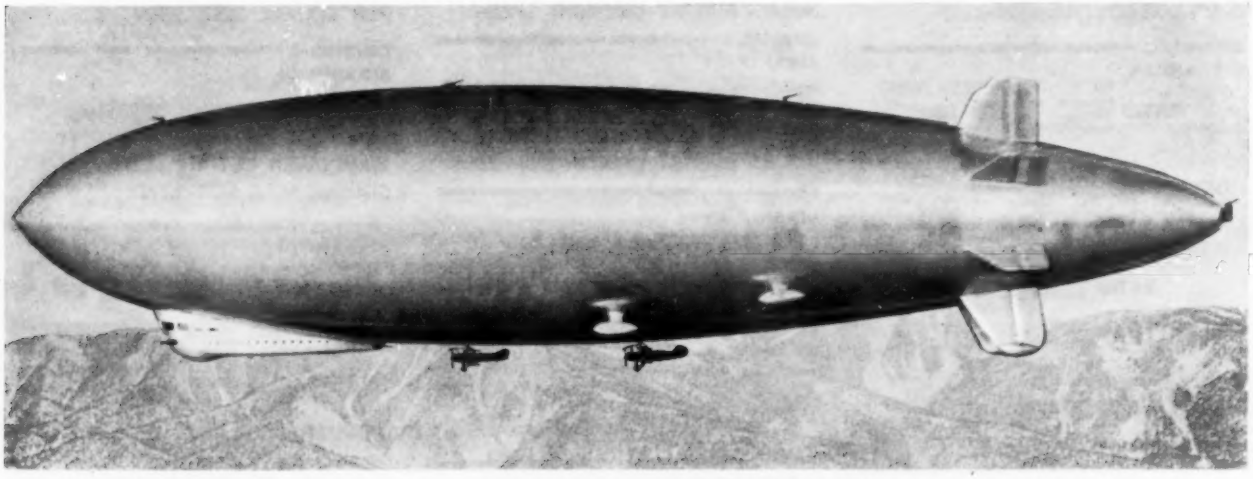

FIG. 3 PROPOSED MILITARY OR NAVAL TYPE OF METALCLAD AIRSHIP
(Gross lift 100 tons, speed 100 m.p.h., maximum range 4400 miles at 70 m.p.h.)

NAVAL APPLICATION

The following is a comparison of a 300-ton airship with a 10,000-ton cruiser engaged in scouting on the high seas. It is admitted the cruiser possesses certain valuable functions which the airship cannot perform. Therefore, the superiority of the airship on scout duty does not justify any conclusion that the cruiser is obsolete. On the contrary, it is assumed the cruiser is thus released for important duty elsewhere, which the airship is incapable of performing.

Fig. 2 is a map disclosing a theoretical defense of the east and west coasts of the United States, Alaska, and the Panama Canal against surprise attack by the enemy fleet. The succession of circles delineates the theoretical scout line located at an average distance of 1200 miles from the coast. This distance is chosen for the reason that in modern warfare it is recognized that the enemy fleet must, if possible, be intercepted and destroyed before its aircraft carriers get within bombing range of the thickly populated industrial centers along the seaboard. It is generally recognized that the best defense against an aerial attack on the Panama Canal or any large city is to destroy the enemy at its own base, namely, its aircraft carrier, before the air attack is launched, else any aircraft bombing squadron may take advantage of poor visibility and cloud formations to conceal its advance on its objective, and thus succeed with a disastrous surprise attack.

In the patrol path indicated on Fig. 2 the airships and the cruisers each are engaged solely in scouting duty. Their function is not to destroy but to discover the enemy and immediately radio to the high command of the main fleet, which is several hundred miles to the rear, full information with respect to the location, strength, and disposition of the enemy fleet. After supplying the main fleet with this vital information, the airships or cruisers have served their function well and ably, and their destruction by the enemy fleet will have little influence on the outcome of the approaching engagement.

With this vital information at its disposal, it is then the function of the main fleet to intercept the enemy fleet, if possible, before it gets within aircraft bombing range of any vulnerable point on the seaboard. Likewise, in the meantime, the probable objective of the enemy fleet will have been ascertained and the aerial defense (composed of army airplanes and airships)[4] along the seacoast, in close proximity to its objective, will be on the alert for any enemy bombing aircraft which may have escaped destruction by the main fleet. The above theory of aircraft defense is offered by the author, with apologies, as being modestly original and, so far as his knowledge is concerned, it does not disclose any military secrets of any nation.

ONE AIRSHIP RELEASES THREE CRUISERS

It will be observed from Fig. 2 that the effective cruising speed of the 10,000-ton cruiser engaged in scout duty is 20 knots (23 m.p.h.), whereas that of the airship is 60 knots (69 m.p.h.). Thus it is disclosed, when applied purely to scout duty, that one 300-ton airship is equivalent to three 10,000-ton cruisers in any range of action covering any definite time interval.

Fig. 4 graphically compares the complement and the estimated cost of these two types of craft. Fig. 5 discloses the superiority of the airship over the cruiser from the standpoint of visibility. From the top of a 150-ft. mast the visibility of the cruiser is limited to a radius of 15 miles. From an altitude of 3000 ft. the visibility of the airship increases to a radius of 67 miles. Engaged in a 12-hour run at 20 knots (23 m.p.h.) the cruiser can survey 8300 square miles, whereas the airship at 60 knots (69 m.p.h.) can survey 111,000 square miles, or over 13 times as much territory.

Referring again to Fig. 4 it is revealed that one cruiser has a

complement of 570 men, whereas the airship has a complement of 60 men. Likewise the estimated cost of one cruiser is $17,000,000 and of one 300-ton airship, $10,000,000. Consequently in the event of the destruction of either type of craft by the enemy the loss in men for the cruiser is almost 10 times greater than that for the airship, and the loss in original cost of the cruiser 1.7 times that of the airship. Such economy in both men and money cannot be ignored in the planning of a naval defense and naval strategy adequate for the future.

Inasmuch as it is revealed that on scouting duty one 300-ton airship is equivalent to three 10,000-ton cruisers, it is of interest to indulge in a collective comparison of these two types of craft. Fig. 6 shows that to accomplish the same mission a capital investment of $51,000,000 is required to build three cruisers as against $10,000,000 for one airship, or over five times as much; also, that the complement of three cruisers is 1710 men as against 60 men for the airship, or 28½ times as much.

Fig. 7 reveals that the total displacement of three cruisers is 30,000 tons, as against 300 tons for the airship, or 100 times as much. Also that the total hp. required for the three cruisers is 321,000, as against 10,700 for the airship, or 30 times as much.

Fig. 8 shows that the fuel consumed on a 12-hour run at cruising speed by the three cruisers is 338 tons, as against 11 tons for the airship, or 31 times as much; also, that the cost of the fuel for the three cruisers is $2366, as against $275 for the airship, or more than 8 times as much.

Cruiser Requires 95 Times More Energy

Fig. 9 is perhaps the most important comparison of all. It discloses the amount of energy required to accomplish a given mission, this energy being measured in terms of both mechanical power and man power. The mechanical power output required per square mile surveyed by the cruiser is 36 hp-hr. as against 0.38 hp-hr. for the airship, or 95 times as much.

The man-power output required per square mile surveyed by the cruiser is 0.83 man-hours, as against 0.0065 man-hours for the airship, or 128 times as much.

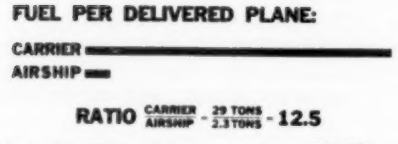
Such startling disclosure of the superiority of the airship over the cruiser when engaged in scouting, it is maintained, presents circumstantial evidence of great preponderance which establishes the naval application of the airship, its economy in cost, and its efficiency in service.

At a first glance some will maintain, however, that the cruiser can engage in scout duty at sea for a longer interval of time than the airship. An examination of Fig. 10 reveals such is not the case. Based on the supposed fuel capacity of the cruiser and its theoretical consumption of fuel, it is estimated that the maximum range of the cruiser at 30 knots (34.5 m.p.h.) is 4000 sea miles, as against 16,000 sea miles (18,500 statute miles) for the airship, the superiority of the airship being four to one. With respect to endurance, the airship can cruise at a speed of 30 knots (34.5 m.p.h.) for 22 days, as against 5½ days for the cruiser, or 4 times as much.

It is realized that a low speed of 30 knots is uneconomical for the airship due to its propeller design being based on a high cruising speed, and that a 30-knot speed is too high to be economical for the cruiser. This speed is chosen in order to furnish a convenient yardstick to establish a comparison that is phenomenally interesting and which should convince those who doubt the superiority in range of action of the airship over that of the cruiser.

Airship Less Vulnerable

It will be maintained by some critics of the airship that it is too



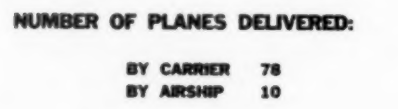


Fig. 16 Fuel Comparison for 300-Ton Airship Versus Aircraft Carrier From Pensacola to Panama

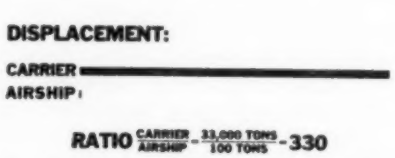

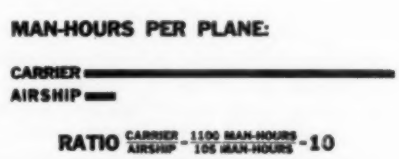

Fig. 18 Cost and Displacement of 100-Ton Airship Compared With Aircraft Carrier

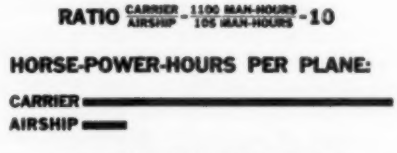

Fig. 21 Man-Hours and Horsepower-Hours per Plane Delivered With 100-Ton Airship Versus Aircraft Carrier From Miami to Panama

vulnerable and in close proximity to the range of anti-aircraft guns or when subjected to direct attack by airplane it will soon be destroyed. Granting this to be true, is it not also equally true that a 10,000-ton cruiser deployed several hundred miles in advance of the main fleet, when sighted by the enemy, will also in the majority of instances be destroyed because of the overwhelming superiority of the enemy fleet.

Comparing the two types of craft in this regard, however, the airship can sight the enemy fleet at longer range, determine its position and strength, reverse its direction and return to its main fleet with a speed at least three times that of the cruiser. Furthermore, it will be thoroughly practicable for a 300-ton airship to carry its own defense airplanes to aid in warding off enemy aerial attack. The airship it appears is vulnerable to attack principally from one source, namely, from the air, whereas the cruiser is subject to attack and destruction from a number of sources, including direct fire from the enemy fleet, attack by enemy bombing planes, attack by submarines, and destruction through contact with enemy mines. Certainly, it appears that the odds are in favor of the airship in so far as vulnerability is concerned.

Let it be recalled in conclusion that the experience of men and the function of equipment engaged in war is not to save themselves, but to spend themselves for the cause they serve. The airship, after discovering the enemy, its location, strength, and disposition, and having radioed this vital information to its own high command, has nobly served its function and what happens after will have no effect upon the outcome of the impending engagement between the two fleets. "Forewarned is forearmed" is the determining factor in a modern naval engagement.

MILITARY APPLICATION

The military application of the airship for army transport, reconnaissance, coast patrol, and other purposes is equally as important as is naval use. Perhaps the most vital problem concerning any army at any time is its service of supply. One phase of this problem takes first rank, namely, the quick transport of replacement airplanes to Panama and Hawaii in time of national emergency. It is unthinkable that sufficient airplanes could be maintained in storage to cope with the exigencies of war. The real test of effectiveness will be the quick construction and delivery of not only replacement planes, but the immediate concentration, at these strategic points, of aircraft units which normally have their base in the United States.

Obviously military planes cannot fly non-stop from California to Hawaii with any degree of certainty. Furthermore, present military planes cannot conveniently fly non-stop from Florida to Panama and still carry a full military load.

The delivery of replacement planes to Hawaii apparently must be made on board ocean vessels or aircraft carriers. The delivery of replacement and other military planes to Panama can be accomplished either by means of ocean vessels or aircraft carriers, or by two or three intermediate refuelings in Central America. However, without questioning the friendship of any of the countries to the south of the Rio Grande, it is obvious that military considerations demand that an alternative method of delivering airplanes to Panama be provided for in time of war other than by making use of refueling stations in Central America. The question of the violation of neutrality also arises. Obviously the most interesting alternative method is the use of aircraft carriers, both for Panama and for Hawaii. Therefore, it is proposed to compare the performance characteristics and respective efficiency of a 33,000-ton aircraft carrier with a 300-ton airship and with a 100-ton airship, each engaged in similar missions.

Table 3 gives certain performance characteristics necessary for this comparison.

TABLE 3 AIRCRAFT-CARRIER DATA

Displacement loaded	33,000 tons (long)
Horsepower	180,000
Cruising speed	30 knots (34½ m.p.h.)
Horsepower required (cruising)	140,000
Fuel oil ...ed per hp-hr	0.75 lb.
Crew (in ...uding airplane personnel)	1,900
Planes accommodated, assembled ready for combat	78

Figs. 11, 12, 13, and 14 give a graphic comparison of a 300-ton airship with an aircraft carrier, each engaged in delivering military airplanes from San Diego, California, to Hawaii. This comparison reveals an estimated cost of the carrier at $45,000,000 and of the airship, $10,000,000, or 4½ times greater for the carrier.

Convoy Duty, San Diego to Hawaii

The displacement of the carrier is 33,000 tons and of the airship 300 tons, or 110 times greater for the carrier. The carrier, it is presumed, will have a capacity for 78 airplanes ready for action, whereas the airship, by transporting 10 planes internally disposed and convoying 10 additional planes which are refueled periodically en route, can deliver 20 airplanes to Hawaii. The time required to reach Hawaii from San Diego, a distance of 2400 statute miles, at 70 knots (80 m.p.h.) is 30 hr., and for the carrier at 30 knots (34.5 m.p.h.) is 69.5 hr., or over 2 times greater.

The fuel required for the airship in still air is 104 tons and for the carrier, 3650 tons, or 35 times more. The fuel required per airplane delivered via airship is 5.2 tons and for the carrier, 46.8 tons, or nine times greater.

Again, the energy required for a given mission, which after all is perhaps the truest measure of efficiency, comes in for consideration. On the San Diego-Hawaii route, the man-hours required per airplane delivered by airship is 150 and via the carrier 1690, or over 11 times greater.

The horsepower-hours required per airplane delivered by airship are 15,720; via the carrier, 125,000, or 8 times greater. Four airships costing a total of less than the cost of one carrier can deliver the same number of planes from San Diego to Hawaii in less than half the elapsed time and at an expenditure of about ⅛ the energy.

Pensacola to Panama

Similarly the transportation of replacement military airplanes from Pensacola, Fla., to Panama via 300-ton airship and via carrier is graphically illustrated in Figs. 15, 16, and 17. Summarizing, two airships at a cost less than half that of one carrier can transport 12 more airplanes from Pensacola to Panama, a distance of 1530 statute miles, in half the time required for the carrier, and at an expenditure of only 1/14 the energy measured in man-hours and ⅛ the energy measured in horsepower-hours.

Miami to Panama

It is realized that the 300-ton airship still awaits future development and therefore it is important to compare the performance on a similar mission of a 100-ton airship (a size now practicable) engaged in convoying replacement airplanes to Panama from Miami, a distance of 1170 statute miles. This is a perfectly feasible tactical mission in so far as the 100-ton airship is concerned. Properly equipped with hook-on devices and cruising at a speed in excess of airplane stalling speed, it is capable of convoying 10 military airplanes, non-stop, by refueling en route in an elapsed time of 14½ hours.

A comparison of the performance of this 100-ton airship with a 33,000-ton airplane carrier is graphically described in Figs. 18, 19, 20, and 21. Summarizing, the energy required to transport one airplane from Miami to Panama by airship, measured in man power, is 105 man-hours and for the carrier 1100 man-hours, or over 10 times greater. Measured in mechanical power output

required, the airship expends energy equivalent to 11,000 hp-hr. per airplane delivered and the cruiser 74,500 hp-hr., or almost 7 times as much.

Long Distance Reconnaissance

While it is true in the above comparison the standard naval airplane carrier has been used, this is done solely for convenience, inasmuch as it is the fastest and most convenient ocean vessel available for such purposes. The designation of the naval carrier in this comparison, however, does not in any manner subtract from the army's responsibility to provide for alternative means for the quick transport of replacement airplanes from the United States to Panama in times of national emergency. It is believed that the use of the airship by the army for this purpose ranks equally in importance with any other military or naval use for which this type of craft might be employed.

Having convoyed airplanes to Panama, the airship is still available, because of its long endurance, to engage in scout duty and reconnaissance at considerable distance from the canal as a base. This is a service for which the airship is particularly well adapted in the rainy season, when, it is reported, military airplanes at Panama are often grounded a considerable part of the time on account of poor visibility and adverse weather conditions, which are very serious for the airplane, but do not interfere with the safe continuation of the airship on scout duty.

Some authorities maintain that it is impossible to defend the

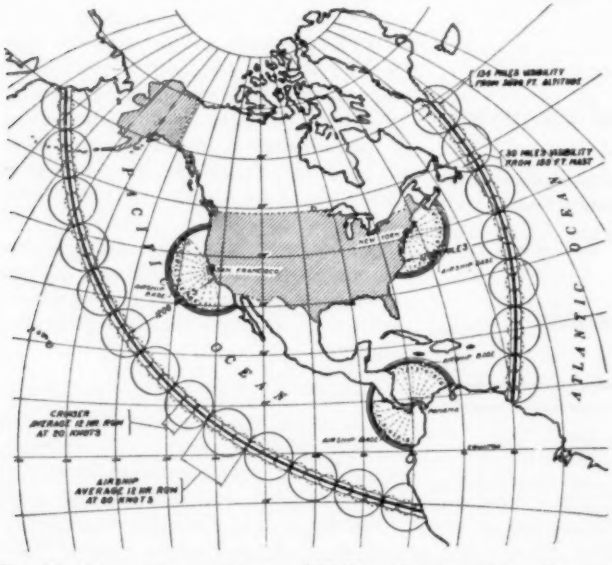

Fig. 22 Joint Coast Patrol 100-Ton Airship Plus Planes Versus Planes Alone

Panama Canal without having available an adequate number of airships for long-distance reconnaissance. In this respect, as an adjunct to the heavier-than-air force, they provide a most valuable auxiliary.

Airship Patrol Ideal for Panama

This is well illustrated in Figs. 22, 23, and 24, which describe the effectiveness of a 100-ton metalclad airship engaged in coast patrol in conjunction with observation airplanes.

Fig. 22 is a map on which are delineated four zones of activity, namely: Panama Canal, Atlantic side; Panama Canal, Pacific side; the eastern seaboard, with New York as the center of operations; and the western seaboard, with San Francisco as the center of operations.

Choosing the patrol problem of Panama on the Atlantic side for examination (see detail in Fig. 23), it will be observed that the airship is stationed 500 miles northeast of the canal. Its function is to cruise at low speed, serving as a mother ship and for refueling purposes for the eight observation military planes which are engaged constantly in patrol duty along an arc having a radius of 500 miles with Panama as its center, and extending from the shore of Nicaragua to the shore of Colombia.

Possessing an effective cruising speed of 125 m.p.h., it is feasible for a modern observation plane to negotiate the round trip from the airship to either Nicaragua or Colombia, and return in an elapsed time of 6 hr. At the conclusion of each round trip the plane hooks onto the airship for refueling and a 2-hr. rest, while simultaneously one of the reserve planes takes off to replace the returning plane. In this manner it is entire practicable, except when weather conditions are seriously adverse, to keep under constant observation every avenue of approach over water leading to the Panama Canal. A 100-ton airship is capable of an endurance of 48 hr. on this mission without the necessity of obtaining additional fuel for its own use and for the use of its observation airplanes. In this manner one airship plus eight observation planes should be able to establish and maintain an

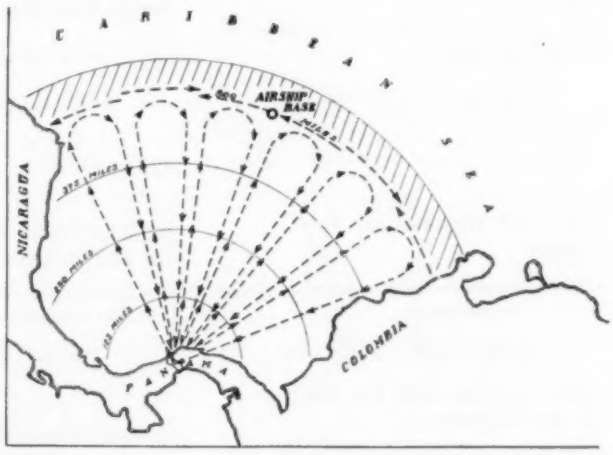

Fig. 23 Coast Patrol Summary

Zone	Observation planes required: Airship base	Land base
Panama (Atlantic side)	8	72
Panama (Pacific side)	8	72
New York	10	96
San Francisco	12	120
Total	38	360

almost air-tight defense against surprise attack over sea on the Panama Canal.

Radio Directs Attack

In actual practice when one of the observation planes has discovered the enemy, this information is relayed by a short-range radio to the airship and immediately transmitted over the powerful radio carried on the airship to the main aircraft base at the Panama Canal. Attack and bombardment squadrons then take off from Panama to intercept and destroy the enemy. Close watch of the enemy's maneuvers is maintained by the dirigible and its eight planes, and, by means of constant communication via radio with the airship, the attack and bombardment squadron commanders can direct their course to the enemy with precision.

The question will be raised, "Why establish a patrol at a distance of 500 miles from the canal?" The obvious answer is that the defense of the canal is thus made much more certain inasmuch as it is possible in this manner to discover the approach of the

enemy before its heavily laden bombing planes on board enemy aircraft carriers get within flight bombing range of the canal.

If an airship were not available for this purpose, naturally the observation planes would necessarily operate direct from a land base at the Panama Canal. To establish a patrol as frequent and as effective as with the airship as a base would require 72 instead of 8 observation planes. These planes would be divided into 6 squadrons of 12 units each, 10 planes being on active duty and 2 held in reserve. The units of each squadron would fly successively at one-hour intervals over the six loops, as indicated on Fig. 23. Having a 10-hour fuel capacity and flying at a speed of 125 m.p.h. each plane would require four hours to reach the patrol zone; would travel along the arc of the zone for one hour and require four hours to return to Panama for refueling. That this method would be exorbitantly expensive compared with the combination of one airship with eight observation planes is graphically described in Fig. 24.

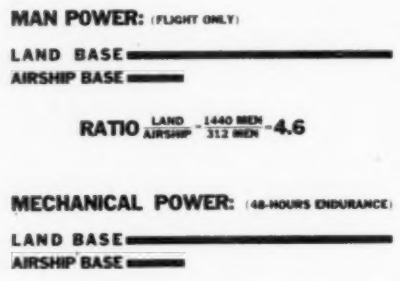

Fig. 24 Energy Required for 48-Hour Patrol With Land and Airship Bases

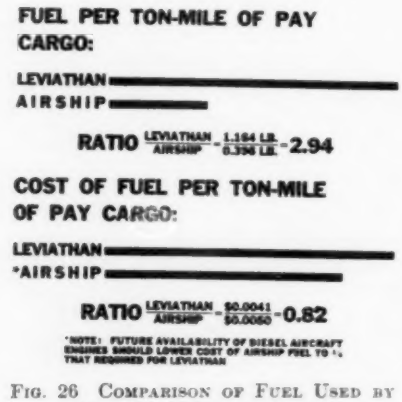

Fig. 26 Comparison of Fuel Used by Airship Versus Leviathan

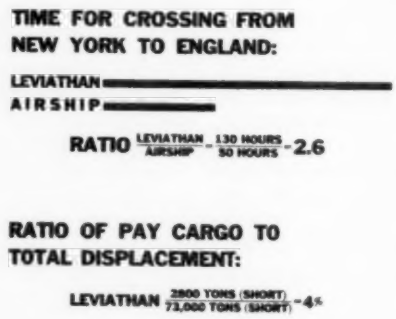

Fig. 25 Comparison of Time of Voyage and Pay Load for Airship Versus Leviathan

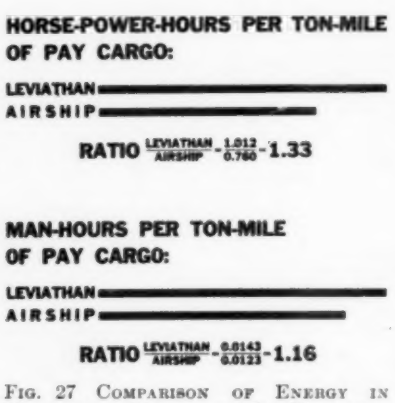

Fig. 27 Comparison of Energy in Horsepower-Hours and Man-Hours for Airship Versus Leviathan

ARMY OR NAVY

Obviously another question arises, "Is not this long-range patrol duty a function of the Navy rather than of the Army?" Apparently a reasonable answer to this question is that in times of national emergency no twilight zone or fine line of distinction will be drawn in determining whose duty it is to discover and destroy the enemy. In actual practice this is the obligation of every fighting arm of the government. The peril of air attack on vital centers such as the Panama Canal and elsewhere is such that both the Army and Navy must be in a position from the standpoint of equipment and experience to defeat the objective of the enemy, and for this purpose all forces immediately available and in close proximity to the point of attack must be and will be utilized.

Furthermore, some authorities maintain that the advent of the use of aircraft in modern warfare has automatically removed the zone of operations of the fleet from close proximity to the coast to a position located several hundred miles at sea. This is described in Fig. 22, where the outposts of the fleet on both the Atlantic and Pacific are located at a point 1200 miles from the coast. The main fleet cruises at a strategic distance behind the patrol zone ready to dash forward to intercept the enemy when warned of its approach. Immediately adjacent to the coast are the four theoretical zones of actual coast patrol radiating from New York, San Francisco, and the Panama Canal.

Airship Patrol More Efficient

Assuming, for purposes of comparison, that all four of these zones are patrolled simultaneously, it is shown in Fig. 23 that four airships, operating in conjunction with 38 observation planes, are able to accomplish as much work as 360 planes operating from land bases.

The energy required for a 48-hr. patrol mission is graphically described in Fig. 24. Using the airship as a base, 312 men (flight duty only) are required, as compared with 1440 men operating direct from land, or a ratio of 4.6 to 1 in favor of the airship. The mechanical power output required for the four airships and the 38 observation planes attached is 434,400 hp-hr. for a 48-hr. mission, while for the 360 planes operating from land bases is 1,944,000 hp-hr. or 4.5 times greater.

In the face of such an array of facts, no one can successfully dispute the military application of the airship, its economy in service, and its superiority for certain vital missions.

Other Military and Naval Uses

Other military and naval uses for the airship suggest themselves. For example, the 100-ton airship would be capable of transporting a 40,000-lb. military load from either Scott Field, Illinois, or Washington, D. C., to Panama in about 30 hr. It would also be valuable for the following purposes:

Protection of merchant marine
Destruction of enemy shipping
Convoy of troop ships
Direct reconnaissance
Training of personnel
Transportation of personnel and equipment
Observation of artillery practice
Patrol of Nicaragua Canal route
Quick transport of staff headquarters
Submarine search
Destruction of mines by direct gun fire
Courier service in the Caribbean
Patrol and direction of revenue cutter movement

Of these additional military uses, perhaps the most important are submarine search and destruction of mines by direct gun fire. The handicap of the airplane on such missions is due to its inability to cruise at low speed. On the other hand, the ability of

the airship to hover or fly at low speed enables it to search diligently the ocean depths for submarines, attack them independently or direct surface craft to their location, and thus accomplish their destruction with depth bombs or else destroy their will to come forth and do battle.

Airship Convoy War Record

It is a matter of official record of the last war that not one single American troop ship was successfully attacked by submarine while convoyed by airships. The record discloses that during the last year of the war American and British airships, engaged in convoy duty, flew a total of 2,000,000 miles, were in the air a sum total of 80,000 hr. and accounted for the destruction of 27 submarines. Certainly the superior visibility and adaptability of the airship in combating submarines, as compared to surface craft, is self-evident. Also, because of longer endurance the airship is superior from a tactical standpoint to the airplane. The necessity for precision in direct gun fire in destroying mines also gives the airship a distinct advantage over either surface craft or the airplane. This is true from the standpoint of both visibility and stability of the gun platform.

CIVIL APPLICATION

Peaceful missions of the airship, the accomplishment of which the Army and Navy are often charged with, are as follows:

River, harbor, and levee survey
Hydrographic survey
Topographic survey
Photography
Reclamation survey
Forest patrol and fire fighting
Medical relief in isolated sections
Bombing ice jams
Exploration

From an economic and humanitarian standpoint perhaps the most important of these have to do with Mississippi flood relief and control. For example, operating from Scott Field hangar at Belleville, Ill., a 100-ton airship engaged in flood relief in the Mississippi Valley can transport food and medical supplies to provide for 10,000 people each day. Possessing the ability to fly at low speed, of which the airplane is incapable, the airship can diligently search out refugees in isolated sections; cast supplies overboard via parachute and even lower Red Cross units to the ground by means of a practicable winch arrangement.

Aerial Survey More Economical

Such a ship would conveniently and economically expedite a detailed survey of the Mississippi Valley necessary for the planning of a comprehensive flood-control system. The enormous territory directly and indirectly affected by the Mississippi and its tributaries during flood periods comprises over 200,000 square miles (almost the size of the state of Texas) and lies in seventeen states, the respective adjacent areas of which are as follows:

State	Square miles
Alabama	1,000
Arkansas	36,000
Illinois	20,000
Indiana	7,000
Iowa	6,000
Kansas	3,000
Kentucky	10,000
Louisiana	37,000
Minnesota	2,000
Mississippi	23,000
Missouri	20,000
Nebraska	3,000
Ohio	3,000
Oklahoma	10,000
Tennessee	15,000
Texas	11,000
Wisconsin	3,000
Total	210,000

It is true that topographical maps and river surveys have been made of most of the Mississippi valley, but many of these maps, except the mosaics recently made via airplane, are a generation old and do not provide the detail essential for the planning of a successful flood-control system.

If it were undertaken to make a complete detailed survey on the ground of these 210,000 square miles, the map would never be completed up-to-date because it would take a generation to finish the survey. On the other hand, by undertaking such work to which a large airship having a complete photographic laboratory on board is adaptable, it could be completed within less than two years at approximately only one-tenth the cost. It would provide a map precise and superior in detail, giving a complete bird's-eye view of the whole situation for careful study by Army engineers charged with this responsibility.

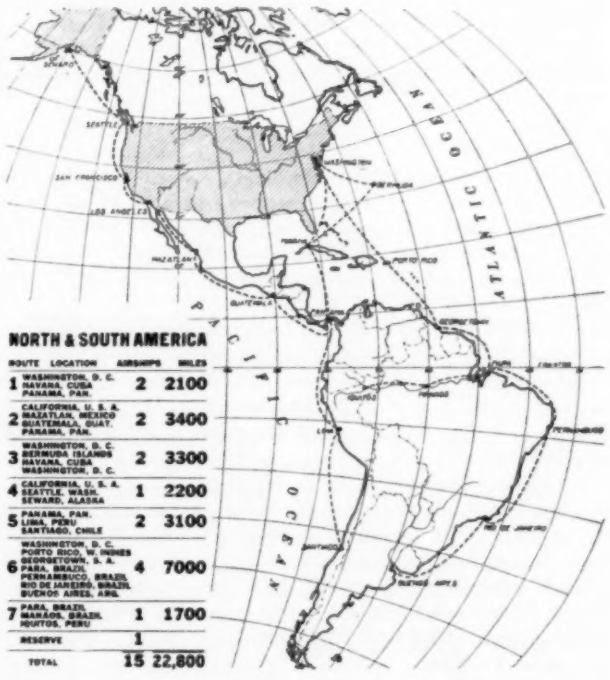

Fig. 28 Suggested Routes for Merchant Airships

Who can question that the foregoing uses of the airship engaged in either military or peaceful missions are worth while? Surely anything that will assist in diminishing the annual recurrence of devastating floods, costing thousands of human lives and the loss of millions in property, is of tremendous economic value.

COMMERCIAL APPLICATION

Most aeronautical engineers seem to be agreed that the airship rather than the airplane will prove to be more economical and satisfactory in long-distance heavy-cargo air transport. It is predicted that in the present generation airships will encircle the globe in regular operation, supplementing present land and water transport facilities, and, by shortening the line of communications, their use will expedite trade and thus increase the volume of commerce.

If this be true, the development of the airship is of vital economic importance to our foreign trade, which now annually represents a volume of 100,000,000 tons and a value of almost $10,000,000,000. Our annual shipping bill for commerce on the high seas for freight is $750,000,000, and for passengers $250,000,000, making a total of $1,000,000,000. To carry this enor-

mous volume of traffic requires 6000 vessels having a total displacement of 23,000,000 tons, and flying the flags of 28 countries. Of this volume of commerce, ships flying the American flag carry only 40 per cent in tonnage and only 34 per cent in value.

In foreign trade ready access to the source of supply has a profound influence upon a prospective customer. Therein lies the value of quick communication via airship. Consider the value of merchant airships flying between our eastern seaboard and Central and South America that would shorten the line of communications to Havana, Cuba, to only one day; from Washington, D. C., or from California to Panama, 2 days; to Lima, Peru 3 days; Santiago, Chile, 4 days; to Para (mouth of the Amazon), 3 days; Rio de Janeiro, 4 days; and to Buenos Aires, 5 days.

Certainly if this can be accomplished it will have an everlasting influence upon the prosperity of our trade with those countries, and upon the promotion of a friendly relationship between North and South America. Applied in a world-wide sense, the adaptation of American-built and American-owned merchant airships means American supremacy in the great international trade routes.

Airship vs. "Leviathan"

Any consideration of the employment of the airship engaged in international trade requires comparison with existing modes of transport. For this purpose a direct comparison of the performance of a 300-ton airship with the *Leviathan* engaged in trade between New York and England is graphically described in Figs. 25, 26, and 27.

Individual data for both the *Leviathan* and the airship are contained in Table 4. The airship traveling direct to London, England, would negotiate a journey of 3470 statute miles and the *Leviathan* from New York to Southampton, the nearest convenient port to London, would negotiate a journey of 3580 statute miles.

Engaged in this service, the airship is capable of transporting 70 tons of pay load, whereas the *Leviathan* carries only 2800 tons of pay load. This is graphically compared in Fig. 25, which discloses that the airship is capable of carrying 21 per cent of its gross lift in pay load, whereas the *Leviathan* can carry only 4 per cent of its gross displacement in pay load. This circumstantial evidence alone should establish the economic future of the airship as a merchant vessel.

TABLE 4 AIRSHIP DATA—METALCLAD CONSTRUCTION

Displacement (loaded)	300 tons (long)
Horsepower	10,700
Gasoline used per hp-hr	0.52 lb.
Cost of gasoline per ton[a]	$25
Crew	60
Effective crusing speed	61 knots (70 m.p.h.)
Hp. required	3,700
Passengers	100
Total pay load	70 tons (short)

"LEVIATHAN" DATA

Displacement (loaded)	65,000 tons (long)
Horsepower	90,000
Fuel oil used per hp-hr	1.15 lb.
Cost of fuel oil per ton[a]	$7
Crew	1,100
Effective cruising speed	24 knots (28 m.p.h.)
Hp. required	78,000
Passengers	2,700
Total pay load	2,800 tons (short)

[a] F.O.B. tank car.

In still air the airship would require 50 hr. for the crossing and the *Leviathan* about 130 hr., a difference of 80 hr., or over 3 days, the airship cruising at 61 knots (70 m.p.h.) and the *Leviathan* cruising at 24 knots (28 m.p.h.).

Fig. 26 shows that the airship requires 0.396 lb. of fuel per ton mile of pay cargo, whereas the *Leviathan* requires 1.164 lb. of fuel per ton mile of pay cargo, or 2.94 times greater.

Airship Requires Less Energy Per Ton Mile

Fig. 26 indicates also that even though the airship is burning gasoline, whereas the *Leviathan* is using cheap fuel oil, there is little difference in the actual cost of fuel per ton mile of pay cargo. The future availability of Diesel aircraft engines should lower the cost of airship fuel to considerably less than that required for the *Leviathan*.

It is startling to observe from Fig. 27 that the energy required to transport one ton of pay cargo from New York to London is less for the airship than for the *Leviathan*. This energy measured in horsepower-hours per ton mile of pay cargo for the airship is 0.76, and for the *Leviathan* 1.012, or 1.33 times greater. The man-hours per ton mile of pay cargo for the airship are 0.0123, and for the *Leviathan* 0.0143, or 1.16 times greater. This comparison of energy required is of vital consideration when its cost in dollars and cents is examined in Table 5, which is based on figures made public by the U. S. Shipping Board.

TABLE 5 "LEVIATHAN" OPERATING EXPENSES

(Fiscal year ending June 30, 1928)

Wages	$ 943,930
Fuel	2,004,652
Food and stores	1,409,594
Stevedoring	17,917
Other cargo expense	33,671
Port charges	497,483
Brokerage fees	1,251,767
Adjustments	75,025
Insurance	181,021
Maintenance	266,763
Betterments	76,382
Advertising	161,004
Administrative	136,484
Miscellaneous	470,223
Total expenses	$7,525,916

The preceding figures, based on Government operation, do not include depreciation and taxes. The total cost of energy measured in man-power and mechanical power for one year is as follows:

Wages	$ 943,930
Fuel	2,004,652
Maintenance of power plants (est.)	200,000
Total	$3,148,582

This cost of energy represents 42 per cent of all reported expenses. If depreciation of power plants were included, doubtless this cost of energy would represent approximately 50 per cent of all expenses. This justifies beyond all question the relative accuracy of the use of energy as a yardstick to determine the future economic value of airships, as compared to existing modes of transport.

In view of the foregoing circumstantial evidence, it is not too optimistic to predict that the large merchant airship of the future, irrespective of its saving in time, will be able to compete successfully with palatial ocean liners on a dollar-and-cents basis in the transport of first-class passengers, mail, and express.

The 100-Ton Airship

But the 300-ton airship must await future development. Hence, for immediate application, we must return again to the 100-ton airship which, comparatively speaking, can now be seriously considered in connection with the establishment of commercial airship lines. A ship of this size is too small for regular transatlantic service. However, it will carry an ample commercial load, including 50 passengers, to be profitable in developing the natural trade routes which lead from the centers of population on the east and west coasts to the Panama Canal and to South America. It is admirable for service to such important islands as Bermuda and Cuba.

Fig. 28 is a map on which are delineated seven routes to which

this size ship is adaptable and which represent a reasonable 10-year building program.

Washington-Havana-Panama Route

A detailed study of the proposed Washington-Havana-Panama route shows that the vicinity of Washington is chosen as the northern terminal instead of New York. This is considered desirable because meteorological conditions near Washington favor continuous operation with freedom from interruption by violent weather. Existing transport facilities, rail, and airplane, can be used to connect New York, Boston, Detroit, Philadelphia, Chicago, and other industrial centers with the Washington airship terminal. Furthermore, Washington is easily accessible to 80 per cent of the industrial population of the United States.

In addition, when, by using the airship, from two days to as much as two weeks' time is saved, it is not important that the northern terminal be located immediately adjacent to the largest city in the United States. A reasonable time table for this route is contained in Table 6.

TABLE 6 PANAMA OPERATING SCHEDULE

New York, Philadelphia, Washington, Havana, Panama

Southbound—Read down			Northbound—Read up	
Monday, Wednesday, Saturday	12:05 a.m. Lv.	Ar. 7:00 a.m. New York	Wednesday, Friday, Sunday
Monday, Wednesday, Saturday	2:10 a.m. Lv.	Ar. 7:00 a.m. Philadelphia	Wednesday, Friday, Sunday
Monday, Wednesday, Saturday	7:30 a.m. Lv.	Ar. 10:30 p.m. Washington	Tuesday, Thursday, Saturday
Monday, Wednesday, Saturday	10:00 p.m. Ar.	Lv. 8:00 a.m. Havana	Tuesday, Thursday, Saturday
Tuesday, Thursday, Sunday	7:00 a.m. Lv.	Ar. 8:30 p.m. Havana	Monday, Wednesday, Friday
Tuesday, Thursday, Sunday	8:30 p.m. Ar.	Lv. 7:00 a.m. Panama	Monday, Wednesday, Friday

Note: New York and Philadelphia via Pennsylvania Railroad to Washington Airship Terminal.

ELAPSED TIME SCHEDULE

	Havana hours	Panama hours
New York to	22	44½
Philadelphia to	20	42½
Washington to	14½	37
Havana to	..	13½

Stop over at Havana: Southbound, 9 hours; Northbound, 11½ hours.
Stop over at Panama: 10½ hours.

Performance Data

A general estimate of the performance of a 100-ton commercial airship is found in Figs. 29, 30, 31, 32, 33, and 34. In preparing these graphic charts, particularly with reference to operating costs, an attempt has been made to be conservative in order that the figures herein indicated may be accepted as reasonably reliable. These estimated costs are not guaranteed as perfect. There is no definite experience at this time on which to base an exact estimate. However, access has been had to the related experience to be found in the actual operation of the larger and more important air-mail transport lines in the United States. Therefore, no important essential items have been omitted, and while future experience may disclose that individual figures are in error, it is believed that the totals are reasonably certain for purposes of estimate.

Fig. 29 and Table 7, based on a cruising speed of 80 m.p.h., show the fuel load required with a 50 per cent reserve and the pounds of pay load carried over any given range.

Fig. 30 and Table 9, based on a full pay load and a cruising speed of 80 m.p.h., show the actual cost per passenger over any given range. Fig. 31 and Table 9, based on a full pay load and a cruising speed of 80 m.p.h., show the actual cost per pound of mail and express over any given range. Fig. 32 and Table 8, based on a cruising speed of 70 m.p.h., show the fuel load required with a 50 per cent reserve and the pounds of pay load carried over any given range.

TABLE 7 100-TON METALCLAD, 80 M.P.H. CRUISING SPEED

Range miles	Lb. fuel plus 50 per cent reserve	Pay load capacity lb. 50 passengers plus luggage	Mail and express
700	17,500	15,000	24,500
800	20,000	15,000	22,000
900	22,500	15,000	19,500

2100	40,740	12,000 (40 Pass.)	4,260
2200	42,680	9,000 (30 Pass.)	5,320
2300	44,620	9,000 (30 Pass.)	3,380
2400	46,560	6,000 (20 Pass.)	4,440
2500	48,500	6,000 (20 Pass.)	2,500

Fig. 33 and Table 9, based on a full pay load and a cruising speed of 70 m.p.h., show the actual cost per passenger over any given range. Fig. 34 and Table 9, based on a full pay load and a cruising speed of 70 m.p.h., show the actual cost per pound of mail and express over any given range.

These graphic charts and tables are based on full load in order to simplify their application to the study of any particular route. They also contemplate an operating minimum of 250,000 miles per annum. No profit has been included. Sleeping accommodations are provided for 50 passengers, and the free luggage allowance is 50 lb. per passenger.

TABLE 9 UNIT OPERATING COSTS—100-TON METALCLAD—BASED ON FULL PAY LOAD AND 250,000 MILES OPERATION ANNUALLY

Range, miles	Cruising 80 m.p.h. Per pass., inc. 100 lb. luggage	Cruising 80 m.p.h. Mail and express, per lb.	Cruising 70 m.p.h. Per pass., inc. 100 lb. luggage	Cruising 70 m.p.h. Mail and express, per lb.
700	$ 54.00	$0.18	$ 48.00	$0.16
800	66.00	0.22	57.00	0.19
900	78.00	0.26	66.00	0.22
1000	93.00	0.31	78.00	0.26
1100	111.00	0.37	90.00	0.30
1200	135.00	0.45	105.00	0.35
1300	159.00	0.53	120.00	0.40
1400	192.00	0.64	138.00	0.46
1500	231.00	0.77	159.00	0.53
1600	282.00	0.94	183.00	0.61
1700	351.00	1.17	210.00	0.70
1800	450.00	1.50	240.00	0.80
1900	.....	...	279.00	0.93
2000	.....	...	324.00	1.08
2100	.....	...	381.00	1.27
2200	.....	...	453.00	1.51
2300	.....	...	549.00	1.83
2400	.....	...	678.00	2.26
2500	.....	...	867.00	2.89

Of course it is realized that no commercial shipping line carries 100 per cent pay load on every trip, and, furthermore, in the operation of airships there will be certain short seasons when, because of adverse weather, certain scheduled trips will necessarily be cancelled. Some time will also be lost because of the necessity for overhauling and repairs.

Commercial Rate

Therefore, in using these tables the following formula applies:

$$\frac{\text{Unit cost per passenger or per pound}}{\text{Load factor} \times \text{Service factor}} + \text{Profit} = \text{Commercial rate}$$

To illustrate: Consulting Table 9 it is found that the cost per passenger on an 800-mile range is $66. Assuming that in actual operation this ship will carry on an average 75 per cent of its pay load capacity and will complete 80 per cent of its scheduled trips per annum, this will give a load factor of 0.75 and a service factor

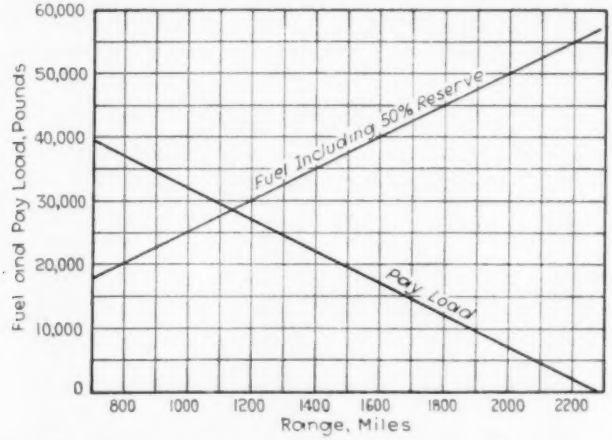

Fig. 29 Pounds of Pay Load and Fuel Required for 100-Ton Commercial Airship at 80 M.p.h. Cruising Speed

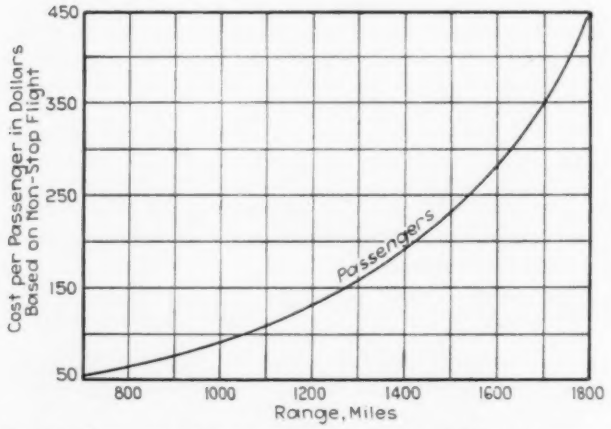

Fig. 30 Operating Cost per Passenger at 80 M.p.h. Cruising Speed, Based on 100 Per Cent Pay-Load Capacity

of 0.80. On this basis the actual cost per passenger is determined as follows:

$$\frac{\$66}{0.75 \times 0.80} = \$110$$

To this must be added a profit, which in turn will vary with the different routes and will be determined by the amount of capital required, including flying equipment and terminal facilities. It is believed that the pioneering hazard justifies the assumption of an annual profit of 20 per cent on the capital invested.

Table 10 sets forth in detail the estimated operating costs per mile based on a cruising speed of 80 m.p.h., a fuel reserve of 50 per cent, and the annual operation of 250,000 miles. In estimating the fuel cost it is assumed that 25 per cent of the reserve will be used in overcoming head winds. This table reveals in round numbers an operating cost of $10 per mile. Should the cruising speed be reduced to 70 m.p.h., the cost would be reduced to $9.83 per mile, because of the saving in fuel. Should two airships be operated over the same route, utilizing the same terminal facilities and each absorbing its share of overhead, the cost per mile would be reduced to $8.51. Additional units utilizing the same terminal facilities, repair shops, etc., would further reduce the cost.

It is interesting to observe that the much-heralded high cost of mooring airships has been grossly exaggerated. According to Table 10 this item represents only 10 per cent of the entire cost per mile. It is believed this terminal charge will be found to compare most favorably with present terminal expense involved in the operation of commercial airplanes.

In estimating the operating cost over any route, it is recommended that where the distance between the terminals does not exceed 1300 miles, the cost curves in Figs. 30 and 31, based on 80 m.p.h. cruising speed, should be used. Where the distance exceeds 1300 miles, the cost curves in Figs. 33 and 34, based on 70

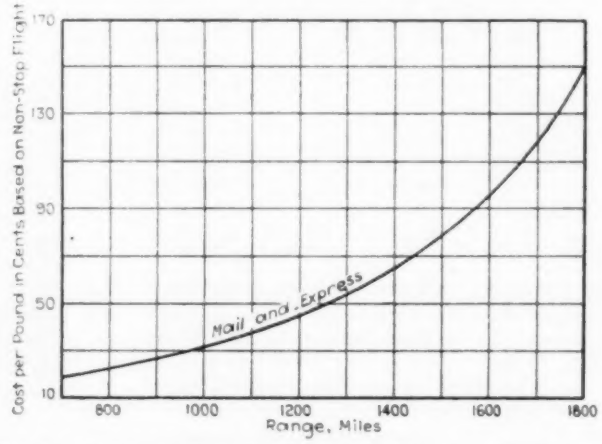

Fig. 31 Operating Cost Per Pound of Mail and Express at 80 M.p.h. Cruising Speed, Based on 100 Per Cent Pay-Load Capacity

m.p.h. cruising speed, should be used. In other words, on the longer ranges it is more economical to reduce the speed, thus reducing the fuel requirements and increasing the pay load accordingly.

Transportation Charges

On the basis of the preceding analyses of costs and assumed operation of two airships on the Washington-Havana-Panama

TABLE 10 OPERATING COST PER MILE

100-ton Metalclad—Sleeping accommodations for 50 passengers—Cruising speed, 80 m.p.h., Fuel reserve, 50 per cent—Cost based on operating 250,000 miles per annum

	Item		Cost per mile
1	Executive		$ 0.20
2	Administration		0.30
3	Traffic		0.30
4	Transportation:		
	(a) Fuel	$0.83	
	(b) Crew	0.58	
	(c) Helium	0.74	
	(d) Miscellaneous	0.20	
			2.35
5	Terminals		1.00
6	Maintenance		0.99
7	Communications		0.30
8	Insurance		1.00
9	Depreciation:		
	(a) Engines	$0.58	
	(b) Airships	2.00	
	(c) Buildings	0.59	
			3.17
10	Unforeseen items		0.40
	Total cost per mile		$10.01

line, it is believed that the transportation charges, as indicated in Table 11, are satisfactory for the purpose of preliminary estimate.

TABLE 11 WASHINGTON-HAVANA-PANAMA LINE—SCHEDULE OF AIRSHIP PASSENGER FARES

(Including railroad or bus transportation to airship terminal)

	New York	Philadelphia	Washington	Havana	Panama
New York	....	....	....	$215	$370
Philadelphia	....	....	....	$212	$367
Washington	....	....	....	$200	$355
Havana	$215	$212	$200	....	$155
Panama	$370	$367	$355	$155	....

Baggage arrangements: 50 lb. baggage per passenger carried free. Excess baggage charge 75 cents per lb. between Washington and Havana, and between Havana and Panama. Excess baggage $1.50 per lb. Washington to Panama.

Express rates: Express, exclusive of jewelry, bullion, and securities, transported at the following rates, including insurance:

Washington to Havana	$1 per lb.
Havana to Panama	$1 per lb.
Washington to Panama	$2 per lb.

Minimum mail rates: $0.0008 per lb. mile. Washington to Panama $1.64 per lb.

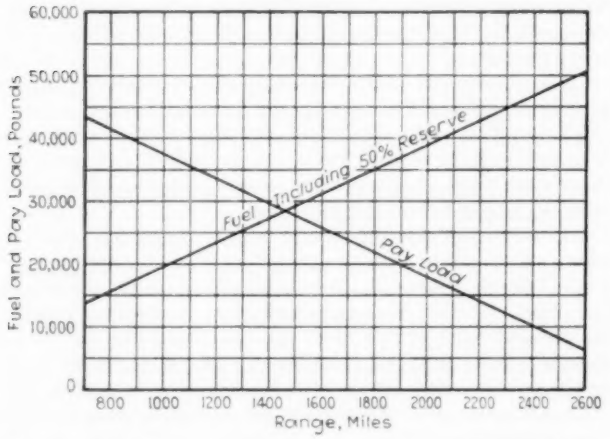

FIG. 32 POUNDS OF PAY LOAD AND FUEL REQUIRED AT 70 M.P.H. CRUISING SPEED

The estimated capital required for the establishment of service adequate for three round trips per week between Washington and Panama is given in Table 12.

TABLE 12 ESTIMATED CAPITAL REQUIRED

Two metalclad airships (100 tons gross lift each)	$ 8,000,000
10,000,000 cu. ft. helium at $40 per M. inc. freight	400,000
Spare parts, reserve engines, etc	200,000
One airship hangar 325 ft. wide by 700 ft. long 200,000 sq. ft. at $10	2,000,000
Four mooring towers, including fuel tanks and utilities	800,000
Helium purification plant and gasometers	400,000
Repair shops	150,000
Crews' quarters and miscellaneous buildings	100,000
Terminal buildings and equipment	300,000
Land	200,000
Electrical equipment, radio stations, etc	200,000
Unforeseen items	750,000
Working capital	1,500,000
Total capital investment required	$15,000,000

The annual mileage of two 100-ton airships operating on the Washington-Havana-Panama line would be as follows:

Air line distance, Washington to Havana	1,160 miles
Air line distance, Havana to Panama	930 miles
Total distance, one-way trip	2,090 miles

On the basis of a 100 per cent operating schedule each ship will make 1½ round trips per week. Two ships will make a total of 312 one-way trips per annum. 312 trips at 2090 miles equals 652,080 gross mileage per annum for both ships. Allowing for cancelled trips on account of weather, overhauling, etc., it is conservatively estimated that 80 per cent of the scheduled trips will be completed, thus giving a total gross mileage for both ships of 521,664 miles.

The revenue necessary per trip in order to earn a profit of 20 per cent on the investment of $15,000,000 is shown in Table 13.

TABLE 13 REVENUE NECESSARY PER TRIP

(Scheduled trips completed estimated at 80 per cent)

On the basis of operating two ships, the operating cost per mile is	$8.51
The total distance from Washington via Havana to Panama, is	2,090 miles
2,090 miles at $8.51 gives a total operating cost per trip of	$17,785
Add—Profit based on 20 per cent of total capital invested ($15,000,000) 2,090 miles at $5.75	12,018
Total revenue necessary per trip	$29,803

Revenue necessary per mile $\frac{\$29,803}{2,090} = \$14.26$

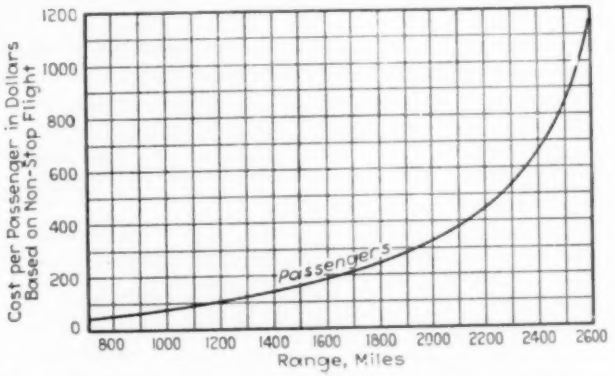

FIG. 33 OPERATING COST PER PASSENGER AT 70 M.P.H. CRUISING SPEED, BASED ON 100 PER CENT PAY-LOAD CAPACITY

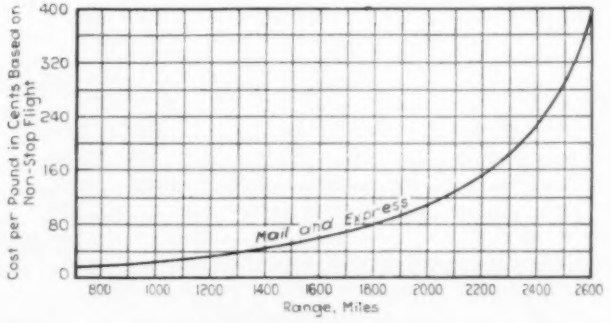

FIG. 34 OPERATING COST PER POUND OF MAIL AND EXPRESS AT 70 M.P.H. CRUISING SPEED, BASED ON 100 PER CENT PAY-LOAD CAPACITY

The anticipated revenue on the Washington-Havana-Panama line, assuming a 75 per cent pay load and a completion of 80 per cent of all scheduled trips, is given in Table 14.

TABLE 14 WASHINGTON-HAVANA-PANAMA LINE—ANTICIPATED GROSS REVENUE PER ANNUM

(Assuming 75 per cent payload and 80 per cent schedule)

75 per cent of 50 = 37½ passengers at $355	$ 13312	
75 per cent × 2500 lb. = 1875 lb. express at $2.00	3750	
10,000 lb. mail at $1.64	16400	
Total revenue per trip	$ 33,462	
80 per cent of 312 trips = 250 trips per annum × $33,462.00 equals gross revenue per annum of		$8,365,500
$17,785 × 312 (total possible number of trips per annum) reveals annual maximum operating cost of	$5,548,920	
Less saving in fuel, crews' pay, helium and depreciation per 62 trips cancelled	268,240	
Total operating cost per annum		5,280,680
Conservative anticipated annual profit		$3,084,820

This represents about 20 per cent profit on the total capital invested ($15,000,000).

TEN-YEAR PROGRAM OF DEVELOPMENT

The suggested program for future development which follows

may sound ambitious, yet it is thoroughly practicable from the standpoint of the development and commercial application of merchant airships. Certainly it will be a tremendous stimulus to international trade to shorten the distance between Washington and eastern industrial centers and Havana to only one day; Porto Rico, one day; from Washington and California to Panama, two days; the mouth of the Amazon, three days; Rio de Janeiro, four days; Santiago, four days; Buenos Aires, five days; the headwaters of the Amazon River, five to six days.

South and Central America during the coming century are destined to duplicate the marvellous development which during the past century has made the United States the most prosperous nation in the world.

All that is needed is improvement in transportation facilities and the shortening of the line of communications.

TEN-YEAR PROGRAM WITH SUGGESTED ROUTES

ROUTE NO. 1 WASHINGTON TO HAVANA-PANAMA

Distance	2,100 miles
Capital required	$15,000,000
Round trips	3 per week
Equipment required	2 airships
Beginning of operations	1934
Maximum annual mileage	655,200 miles

ROUTE NO. 2 CALIFORNIA TO MAZATLAN, MEX., GUATEMALA, PANAMA

Distance	3,400 miles
Capital required	$15,000,000
Round trips	2 per week
Equipment required	2 airships
Beginning of operations	1935
Maximum annual mileage	707,200 miles

ROUTE NO. 3 WASHINGTON TO BERMUDA-HAVANA-WASHINGTON

Distance	3,300 miles
Capital required	$13,000,000
Round trips	2 per week
Equipment required	2 airships
Beginning of operations	1936
Maximum annual mileage	686,400 miles

ROUTE NO. 4 CALIFORNIA TO SEATTLE-SEWARD, ALASKA

Distance	2,200 miles
Capital required	$ 5,000,000
Round trips	1 per week
Equipment required	1 airship
Beginning of operations	1937
Maximum annual mileage	228,800 miles

ROUTE NO. 5 PANAMA TO LIMA, PERU, SANTIAGO, CHILE

Distance	3,100 miles
Capital required	$15,000,000
Round trips	2 per week
Equipment required	2 airships
Beginning of operations	1938
Maximum annual mileage	644,800

ROUTE NO. 6 WASHINGTON TO PORTO RICO-GEORGETOWN, PARA, PERNAMBUCO, RIO DE JANEIRO, BUENOS AIRES

Distance	7,000 miles
Capital required	$27,000,000
Round trips	2 per week
Equipment required	4 airships
Beginning of operations	1939
Maximum annual mileage	1,428,000 miles

ROUTE NO. 7 AMAZON RIVER VALLEY-PARA, MANAOS, IQUITOS, PERU

Distance	1,700 miles
Capital required	$ 6,000,000
Round trips	1 per week
Equipment required	1 airship
Beginning of operations	1940
Maximum annual mileage	176,800 miles

RESERVE EQUIPMENT

One airship:	
Capital required	$ 4,000,000

RECAPITULATION, TEN-YEAR PROGRAM

Total number of routes		7
Total route mileage—one way		22,800 miles
Maximum annual mileage		4,527,200 miles
Equipment required		15 airships
Capital required:		
(*a*) 15 Airships	$60,000,000	
(*b*) Terminals	30,000,000	
(*c*) Working capital	10,000,000	
Total		$100,000,000

CONCLUSION

The author recognizes the legitimate right of any one to interpret differently the facts presented herein and to question any conclusions that may be reached. Circumstantial evidence is not infallible. Experience should confirm the qualitative analysis, but quantitatively the results no doubt will vary.

The theoretical application of the airship for naval, military, civilian, and commercial uses appears so promising that the expenditure of both public and private funds for actual demonstration is well justified. The cost for certain missions for which the airship is peculiarly adapted should unquestionably be less than for existing forms of transport. The question as to whether it will pay can be answered only with reference to specific application of the airship.

With respect to naval and military uses, neither the value of adequate preparation for the national defense, nor the tragedy of a poisonous gas attack on a metropolitan center can be measured in dollars and cents. Long distance reconnaissance, coast patrol, and transportation of personnel and supplies appear to be the most useful application of the rigid airship in this regard. In any well-balanced program of national defense, the function of the airship is not to replace, but rather to release, certain existing facilities and equipment for other important duties for which they are peculiarly fitted, thus aiding in the efficient disposition of the armed forces.

Commercially the airship will supplement present facilities, not replace them. The airship will transport first-class passengers, mail and express at higher speed, do more work per unit of energy, save more time, earn more profits. It has power in abundance, long range, safety, comfort, dependability, and economy in operation and maintenance.

It is destined to play an important role in the general advancement and prosperity of our country. Its future is as brilliant as that of the first steamship. As a means of promoting the peaceful pursuits of commerce, as an instrument for bridging quickly the physical barriers that often are obstacles to better understanding among nations, it is an international asset. Because of its speed the airship will expedite trade and thus increase the volume of commerce. Therefore its general application to world trade routes is inevitable.

In 1900 Thomas A. Edison was asked if the automobile would ever pay. His reply is historic as to the automobile and prophetic as to the airship. "A great invention which facilitates commerce enriches a country just as much as the discovery of vast hordes of gold."

Discussion

GEORGE V. WHITTLE.[5] While the significance of the comparisons given in the paper between surface ships and airships may be questioned, as may also some of the suggested uses of the airships, these are details which do not affect the author's general conclusions regarding the utility of the airship, which are endorsed.

Airships have limitations which should be recognized, and claims for them restricted accordingly. Those who have studied the possibilities of the airship will, in the main, agree that its economic field is over the sea, where it has both naval and commercial uses. For long-distance operation over water the airship offers great carrying capacity, with comfort and safety, at a speed not attainable by water transportation. For short-distance travel over water, the flying boat seems best; and over land, the airplane appears economically supreme for high-speed transportation. It is generally understood that air transport does not compete directly with the older means of transportation, but rather supplements the latter and scores where time is of great importance. As indicated the airship and airplane will not be direct competitors, as each has a sphere of usefulness peculiarly

[5] Lieutenant (CC) U. S. N.

its own. In the highly developed air-transportation systems of the future, it seems that airships will be used on the long ocean routes, and will be served at the terminals by airplane and flying-boat lines serving as feeders to the main stem.

The spectacular flights of the *Graf Zeppelin*, and to a lesser extent, the numerous but not so much advertised flights of the *Los Angeles*, have focused public attention on the rigid airship as a means of transportation. The technical skill and manufacturing ability necessary to produce airships far superior to either of these exist in this country today. The new Navy airships, each of which will be roughly $2^1/_2$ times the volume of the *Los Angeles*, will be much superior in performance to either the *Los Angeles* or the *Graf Zeppelin*, due to the technical progress of the art and the gain which comes from increased size. The first of these airships should be ready for trials in 1931. Invention and refinement can be expected to contribute in a large way to the advancement of the art for many years to come. In this connection, attention is invited to the pioneering work being done at the Naval Air Station, Lakehurst, N. J., in the mooring and ground handling of airships in which mechanical equipment is being substituted for manual handling, which will ultimately effect considerable economies in operation.

Every means of transportation has requirements which must be met, if it is to function properly. In the case of the airship, one of the most important requirements is good meteorological information, which the government should provide commercial-airship operators in a manner analogous to the aids to navigation now provided for surface vessels.

Airships are here to stay. The technical, constructional, and operational talent is available for commercial-airship enterprise and awaits the call of the airship transport operator.

T. G. W. Settle.[6] Estimated performance and other data of two hypothetical metalclad airships of 100 and 300 tons displacement respectively are used in the study because, as the author states, he is more familiar with that type of vessel than with the Zeppelin type of ship. He very generously and properly indicates that this is not to be taken in any sense as a disparagement of the Zeppelin in favor of the metalclad. And the paper is to be construed as a presentation of the case of "The Airship" rather than that of a particular kind of airship, despite the fact that the data presented are labeled "metalclad." It is probable that the airship of the future will be neither strictly "Zeppelin" nor "metalclad" in the present rather narrow interpretations of these terms; and it is to be hoped and expected that present-day performance forecasts of future airships will be exceeded. The paper does not discuss nor compare the estimated technical characteristics of the large metalclad with Zeppelin-type vessels.

The author at the beginning briefly reviews the recent convincing "full-scale" demonstrations by the *Graf Zeppelin* of the commercial utility and practicability of the airship, and very justifiably takes the position that the airship has passed through the stage of "doubt and uncertainty" and has focused upon itself the attention of the world as a practical and useful vehicle for transport.

The point is well taken that engine power sufficient for higher speeds is most desirable, particularly with a view to enabling the airship to take best advantage of good weather conditions, or least disadvantage from adverse ones. Dr. Eckener, referring to the portion of his world cruise in the vicinity of Japan, said that he "played with the typhoon instead of allowing it to play with him." However, to make this possible in the bigger and better airships of the future, we must have airship engines (compression-ignition type, sooner or later), and in much larger power units than any available today. Probably the most "lagging" major feature of airship development at the present time is the engine. There is only one fully developed and proved airship engine in the world today, and that a gasoline (or gaseous fuel) 560-hp. engine. It is feared that airship-engine progress is doomed to lag behind structural, operational, and handling development for some time to come, and to react unfavorably, of course, on operational technique.

In the more detailed discussions of the several functions of the airship and analyses of costs in money and energy, in the pages of the paper, quite a mass of figures, statistics, and ratios are presented. In reading this over, it comes to one's mind that figures and statistics, like a good lawyer, can be made to "prove anything." Many of the assumptions and data on the airship side are hypothetical, or otherwise open to argument, while the corresponding data for the surface carrier are more largely based on actual experience. However, it seems to the writer that the bulk of the comparative "figures" are valid qualitatively if not always quantitatively, and that the airship side of the comparison is, in general, presented in the proper sense and conservatively.

Naval Application

The author compares the airship scout cruiser (300 tons) with a surface scout cruiser (10,000 tons) and very properly indicates that the former does not replace the latter in naval strategy, but does form a most valuable addition on the "scouting line" and can perform certain functions much more efficiently than the surface cruiser. However, the author displays a serious misconception of naval strategy in a major campaign. The scouting line is disposed not with reference to any coast line, but with reference to our "main body," that is, our "battle fleet," which in turn is governed in its movements by the disposition of the enemy and considerations of the "grand strategy" of the war, rather than by simple geography; a fleet is a mobile force which must not be "coast bound," unless forced to be so by enemy action and force. However, the above does not affect the main point sought to be made by the author in this section, that is, that the airship is a most valuable and essential type of fleet-scouting vessel, and one that for certain purposes is the equivalent of several surface cruisers.

Fig. 5 does not present altogether a true picture, since both the airship and surface cruisers will carry planes, which will often extend the effective visibility of each considerably; of course, the airship is a much better plane "carrier" than is the surface cruiser, in point of "getting the planes back;" the surface ship has to heave to, to hoist the plane aboard.

The simple and unqualified statement that an airship is equivalent to a certain number of surface cruisers is unfortunate, since no such simple equivalency can exist where there are such a large number of more or less indeterminate factors entering into the case. It would be as erroneous to state simply that a certain number of planes were equivalent to a certain amount of railroad rolling stock in the field of land transport.

The author has done well to emphasize the enormous cruising range and "sea-keeping" ability of the airship. It is believed that the airship has a very high degree of defense against and invulnerability to enemy action as is indicated by the author although, again, any numerical "odds" in regard to vulnerability of the two types of craft is without justification in so complex a problem.

The author could well have mentioned several legitimate secondary functions of the airship cruiser, that is, convoy escort, bombardment of enemy territory, enemy commerce destruction, dispatch, and maintenance of "our" line of communications.

Military Application

While the writer agrees very largely with the paper in the

[6] Lieutenant, U. S. N.

naval application of the airship, he cannot do so in the case of military application. It is believed that the Army's proper relation to and utilization of the airship will very closely parallel its relation to and utilization of other ocean-going vessels (surface).

Possibly in peace-time and probably in certain wars, the Army will need to utilize airships, in addition to surface ships, for overseas transport of men and munitions, but these airships, just as such surface vessels now and in the past so utilized, will be merchant ships, bought, chartered, or commandeered by the Army (or the Navy) and manned by merchant (or Navy) crews. In time of war, the available merchant airship tonnage will be largely divided between the Navy, for auxiliary cruisers (and transports), and the Army for transports, the allocation ratios depending upon the exigencies of the particular war, but probably always leaning heavily toward the Navy.

The comparison of an airship with a surface ship plane-carrier for transport of planes seems rather futile, since it is inconceivable that a surface carrier would be so used in a major war. However, for overseas transport of planes and other munitions, the merchant airship would probably compare very favorably with the surface cargo ship under many sets of circumstances.

It cannot be seen that the Army has any proper use whatever for the airship (large, rigid) for reconnaissance or coastal patrol. For reconnaissance the blimp (non-rigid or small pressure airship) may have some very infrequent application, but in general it seems that the airplane and cavalry are the Army's proper and usual arms for this function. For coastal patrol, that is, such coastal patrol functions as properly come under the cognizance of the Army (coast artillery), the blimp, without doubt, has a legitimate role, along with planes and Army mine craft in certain harbors.

The items in the list of "other military uses" for the airship have either already been discussed or should properly be handled by blimps, planes, or Navy agencies.

The last paragraph in this section deals with the wartime use of blimps by the Allies (Navy forces) for convoy escort duty, and the reason cannot be guessed for its inclusion at this point, in this paper on the "airship" (which throughout the paper is taken to mean the large rigid airship). A proper secondary function of a naval airship cruiser is as a convoy "ocean escort," as pointed out above.

Peaceful Application (Army)

The items listed under this heading, except "exploration," it would seem should properly be handled by blimps or planes, some under the cognizance of civilian departments of the government; at any event, the Army use of large rigid airships for these missions is not believed to be justifiable. Just what is meant by "exploration" is not clear, but it would seem that any exploration mission of a character such as to dictate the use of a rigid airship, should be carried on by a civilian department of the government or by private enterprise, and utilizing a commercial airship fitted up for the specific purpose.

Commercial Application

In this section the writer can again heartily agree with the author in his optimistic view of the future of airships in the commercial field. The point might well have been more clearly and definitely made that there is no competition between the airship and the airplane; that they rather have a complementary relationship to each other, much as the steamship and railroad feed into and serve each other.

As before, the writer does not put too much faith in the actual figures quoted, but believes that a good general comparative picture is presented which argues the case of the airship conservatively. The airship lines, of course, must have adequate financial backing and administrative organization, and necessary port works, just as steamship lines must have the same things; airship lines must have proper meteorological service just as surface ocean systems must have "hydrographic office" service and advices.

Rather than competing with the steamship, the airship will take the "cream" of passenger, mail, and cargo traffic from transoceanic surface carriers, in an analogous fashion to the airplane taking the cream of overland and coasting traffic from the railroad and coastwise steamers.

Conclusion

Paralleling the author's conclusion, it is believed that the practical application of the airship for naval and commercial uses has been fully demonstrated in full scale by the long list of successful airships which have been built and operating during the past score of years; the theoretical economic proofs, at least qualitatively, are very well handled in this paper.

However, it cannot be agreed that the airship has either a theoretical or a demonstrated "military" application; the airship's only logical relationship with an army is exactly that of the ocean-going surface craft. In this connection, the experience of the Germans during the war in connection with attempted military utilizations of airships is very enlightening, and is believed to fully uphold the views of the writer on this phase of the question.

In regard to questions "What will it cost?" and "Will it pay?" it is believed that the author has handled these very excellently in his paper; he has taken performance and estimated data at hand, and has made many instructive and interesting analyses of the economics of the airship versus surface carrier. While he admits the fallibility of this "circumstantial" evidence, and while the figures, curves, and numerical ratios given are not to be taken too literally, nevertheless, these all constitute what seems to be a good and conservative qualitative picture. This paper, and its analyses, will serve to crystallize thought in channels investigated; it will encourage healthy argument among "professionals," and will be very illuminating to laymen. While not agreeing at all points with the author, it is nevertheless believed that he has handled a difficult and involved subject excellently; his paper is a valuable addition to current airship literature, and he well deserves the appreciation of the airship "profession" for his painstaking and effective work.

AER-53-4

Rubber in Airplane Construction

By C. SAURER,[1] AKRON, OHIO

There are a large number of uses to which rubber can be put in airplane construction. Its ability to dissipate shocks and vibrations makes it useful for engine mountings, shock absorbers, and propeller insulators. It can also be used to produce a leakproof tank lining, for seat cushions, and as a lining for airplane cabins to insulate the passengers from outside noise and changes in temperature. The paper describes several types of construction in which rubber is used to advantage.

RUBBER at the present time, regardless of its form, shape, or size, is generally thought of in terms of devices for absorbing shocks and energy. This mental association is made because it has become well known from experience that the major physical characteristic of rubber is its ability to receive shocks and vibrations of varying intensities without passing them on to contacting objects, or in other words, its ability to dissipate energy. It is not claimed that rubber insulation, even when used to its best advantage, will dampen out all vibratory and shock movements, but rather that it is a most ideal substance for the absolute cushioning of these movements.

Rubber in its various compounded forms has other remarkable and interesting characteristics such as its ability, when acted upon by force, to change its form, either in the direction of compression or elongation, returning practically to its original form when the force is removed. Also its peculiar characteristic of almost equally resisting movement in all directions makes it fit in ideally in shock-insulation work. Tensile strength as high as 5000 lb. per sq. in., permanent set in the direction of compression as low as 7 per cent, hysteresis control, and variations in hardness ranging from soft, putty-like consistency to horny, hard rubber are all commercial possibilities available to present-day designers. However, regardless of what may be the other characteristics of rubber, it is its ability to dampen out shocks and vibrations that should most interest the airplane designer.

Vibrations are necessarily attendant to motor action, and it is the designer's and builder's job to reduce these vibrations to a minimum before being passed on to the fuselage and occupants of the plane. This is necessary not only to preserve the plane itself, but also to add to the comfort and safety of air transportation. For proof that rubber is and has been doing a wonderfully successful job in this capacity, one has only to refer to what has been accomplished in the automotive industry. The comparatively recent development wherein an effective bond can be secured between soft rubber and steel has put into the hands of the automobile designer one of the most potent tools for construction and performance improvements in recent years. Torque insulators smoothing out shocks in the transmission shafts, clutch rubber assemblies toning out jerks caused by sudden action of clutch engagement, rubber spring shackles, and engine-motor mountings eliminating 4/5 of motor vibrations, are all materially adding to the remarkable smoothness of automobile operation. One normally thinks of an automobile as a steel-fabricated vehicle, and yet a well-known manufacturer recently announced that its car contained over 400 separate rubber parts. This in itself is conclusive proof that rubber is doing an excellent job in the automotive field.

The particular underlying principles promoting these remarkable improvements in the automotive field are in the same way even more applicable to the airplane industry. In fact, it is largely due to the entirely satisfactory performance of rubber in automobiles that has prompted rubber manufacturers to lay out development programs for the extensive use of rubber in airplanes.

Rubber in Airplane-Engine Mountings

Of the 400 or more rubber parts used on an automobile, the most important, aside from tires, are the rubber motor supports. They have done more for the absorption of vibration and the elimination of noise than any other device.

In the airplane they are of even greater importance, as they retard and prevent crystallization of otherwise affected metal structure, thus prolonging its life. Much thought has been given to the design of airplane-motor supports, the requirements being very different from those of an automobile. In an automobile motor, the reciprocating action of the pistons sets up vibrations which are primarily vertical.

Of the many forms of rubber insulators the most successful ones have applied the principle of vertical vibration elimination, depending upon an efficient bond of rubber between steel parts. Figs. 1 and 2 show two such installations. Any desired degree of cushion in the vertical plane is obtainable without the ill effects of a substantial engine movement.

These motor supports are directly applicable to airplane motors of the "in-line" type. It is recommended that the support shown in Fig. 2 be used, because of its greater factor of safety. With the radial-type motor the problem becomes quite different as three major sets of vibrations are encountered. First, there are radially disposed vibrations in a vertical plane set up by the motor. Second, there are propellor vibrations, mostly running in opposite rotation to the motor vibration, but in the same vertical plane. Third, there are vibrations from the propeller thrust; these are at right angles to the vertical-plane vibrations and are radially disposed. Besides these three majo vibrations, many other factors, such as gravity, torque reaction, gyroscopic action, etc., have to be considered.

The best solution for these varied problems of vibration elimination on radial-type motors is to have radially installed motor supports, as shown in Fig. 3. These motor supports are not intended to absorb all vibration, but to absorb and reduce periodic vibration and to check a large part of the greater shocks. Safety, light weight, suitability for torque, torque reaction, and gyroscopic action were deciding factors in the adoption of this design. It is hardly possible to insulate the motor from the rest of the airplane in such a way that no vibrations are transmitted. To absorb all the vibrations completely an amount of material would be necessary which would so increase the weight of the plane as to make it impractical from a weight and cost standpoint.

Rubber in Airplane Shock Absorbers

The shock to be absorbed by an airplane shock absorber should be not less than four times the static weight of the plane. To dissipate the shock of the landing impact, the travel of the shock

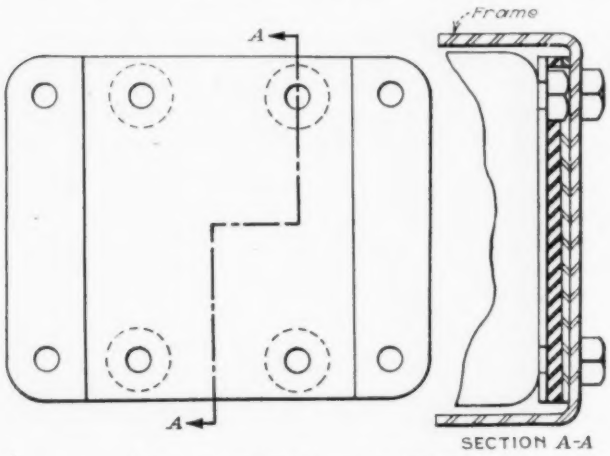

Fig. 1 Adhesion Type of Support

absorber should range over a long enough period of time to bring this weight slowly to rest. This has been accomplished by air, hydraulic, steel-spring, or rubber devices, or combinations of these. The light weight and strength of rubber have made the compression-disk and tension-cord shock absorbers popular with the airplane designer. The comparatively low cost and easy maintenance of such an installation have been an added reason for their use. The tension-cord shock absorber is undoubtedly the cheapest and lightest device to bring the falling weight of the plane to rest. A steel spring designed to absorb the same energy and weight in the same length of travel would be approximately 75 times heavier than the shock cords. According to the designer's views, the shock cords are used in various ways; they are laced between spokes and cross each other; they may be used straight and wound parallel. The differences in spacings and windings are many. The shock cords have a maximum elongation of 10 to 11 times the original length; in use they seldom exceed $^1/_2$ the total elongation possible. A cable of $^1/_2$ in. diameter carries approximately 220 lb. for every inch of elongation. Tests made with tension-cord shock absorbers show that approximately 14 per cent of the energy is absorbed by them, the variety in designs or spacings having very little effect on this.

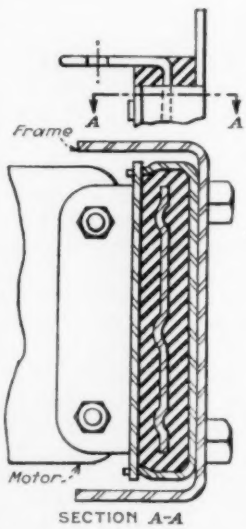

Fig. 2 Support for Airplane Motors of the In-Line Type

The compression-disk shock absorbers vary somewhat from the tension-cord shock absorber, in so far as total travel is concerned, the travel being considerably less under impact than on the tension cords. As the load increases on the rubber disks, the travel reduces rapidly. Therefore, special care has to be taken in the design to prevent the shock of the impact from being transmitted to the fuselage. The energy absorbed in the compression-disk device is approximately 17 per cent. The performance of rubber shock absorbers can be improved by rebound checks, preventing the plane frame from bouncing.

Other uses of rubber in airplane construction are leakproof tanks. These are especially valuable in military airplanes. The construction of this tank lining is very similar to puncture-proof inner tubes. Several layers of rubber are put together in such a fashion that they are in compression and will seal holes of small size automatically. These leakproof tanks are also some insurance against crashes.

The time for general adoption in airplane designs of air-filled rubber-seat cushions should not be very distant. The light

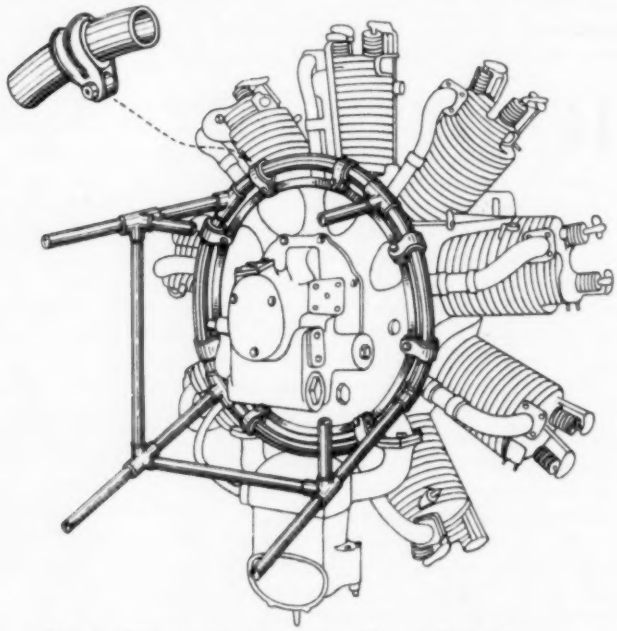

Fig. 3 Support Insulator for Radial-Type Engines

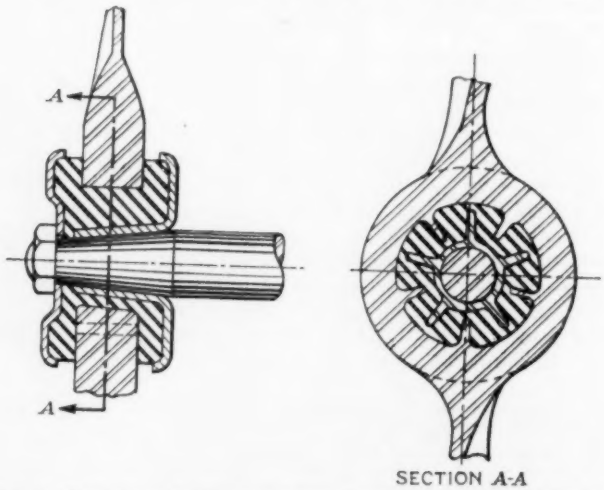

Fig. 4 Propeller Insulator Interposed Between the Motor Drive Shaft and the Propeller Hub

weight and wonderful comfort derived from such a seating arrangement, coupled with the life-saver qualities for seaplanes, will certainly open a field both for the airplane designer and the rubber manufacturer.

Another article which is now being developed in cabin planes is a rubber lining which will insulate the passengers from outside

noises and changes in temperature. Experiments and developments are conducted to reduce the weight and cost of such linings to make them practical for installation on planes.

A propeller insulator would also greatly help in the reduction of vibration. This would be a device similar to an automobile's torque joint, and would be interposed between the motor drive shaft and the propeller hub, as shown in Fig. 4. The long-desired rubber fender for automobiles might become a reality on airplanes as a streamline housing for wheels.

Aside from insulation of gasoline lines, cables, grommets, handle bars, and so on, where rubber is used on airplanes, there are many other points where it might be used, be it in solid or movable joints, in insulation of vibration, or for any other problems such as where steel is subject to crystallization from changeable stresses.

Airplane Tires and Wheels

By H. F. SCHIPPEL,[1] AKRON, OHIO

This paper tells of some of the mounting conditions of airplane tires on wheels, and of the relation between static load, ultimate cushioned load, and energy capacity. Static and dynamic loading curves and corresponding hysteresis loops are also presented, and the forces and power losses are resolved horizontally and vertically. Results of extensive wind-tunnel tests show the effects of tire size, wheel size, safety-tread design, streamlining, and tire misalignment.

TIRE EQUIPMENT and performance cannot be discussed without including the wheel, and even the shock absorber, for these three principal parts of the airplane landing gear are closely interrelated. This paper discusses some of the accepted practices in connection with the application of pneumatic tires to airplanes and the performance of airplane tires.

Tire Mounting Conditions

The straight-side tire has now without question been accepted as the standard for the industry, although the changeover from clincher to straight-side tires has not yet been completely accomplished. The rim equipment is of the drop-center type, which has been selected on account of its strength and lightness having eliminated the necessity of a felloe band. A typical tire mounting is shown in cross-section in Fig. 1. The bead of the tire registers on the rim ledge, which has a 5-deg. slope and makes a close fit so that the inner tube can come in direct contact without danger of injury. The necessity of a flap is therefore eliminated. However, particular attention is paid to the design of the tire bead so that it does not overhang the side of the well, as shown in the center illustration, Fig. 1. This condition may possibly arise when oversize tires or extra-ply tires are used, due to the greater bead width, but usually there is no overhang. Whenever such overhanging exists, tube chafing is likely to occur, and this may eventually lead to a leaky tube and a flat tire. In cases where bead overhang is unavoidable, the tire may be furnished with bead flaps, as shown at the bottom of Fig. 1. These flaps are not entirely desirable, however, because they interfere with mounting of the tire.

Airplane wheels are of the wire-spoke and disk types. In the former the spokes are laced into the drop-center rim, the heads passing through the rim either on the bead ledge or in the well, or both, and sometimes on the side of the well. The ends of the spokes and nipples may be ragged, and it is important that the tube be kept from contact with them. For this purpose a rim band is provided, as shown in Fig. 1, which successfully covers the spokes on the bottom of the well, but not on the side of the well unless the rim band is made unusually wide, in which case it cannot with certainty be maintained in correct position due to possible disturbance when mounting the tire. An alternative solution lies in the use of bead flaps, but this practice, as mentioned before, is not wholly desirable.

Rim bands are not required on disk wheels, there being no danger in allowing the tube to make complete contact with the rim. It has been the practice of airplane-tire manufacturers to furnish rim bands with each tire, whether sold for original equipment or replacement, but by a new agreement among the tire and wheel manufacturers, these rim bands are furnished by the wheel manufacturers when necessary. A further advan-

tage of this change in practice occurs in the case of oversizing, the rim band according to old practice being too large for the undersize rim.

Tire Load Ratings

The method of rating airplane tires for static load capacity is very similar to that used for passenger-car tires. The rating is made on a basis of radial deflection, calculated by the method

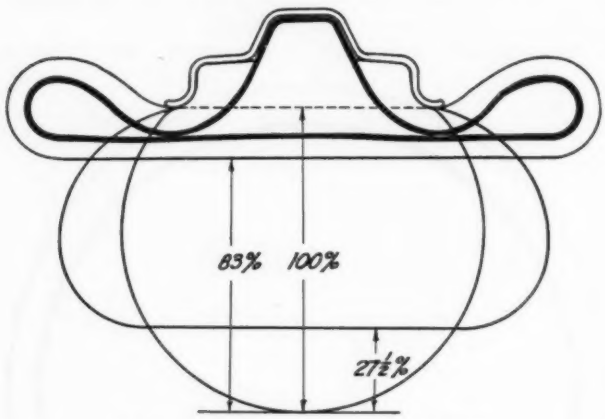

Fig. 2 Deflection of 30- by 5-In. Tire

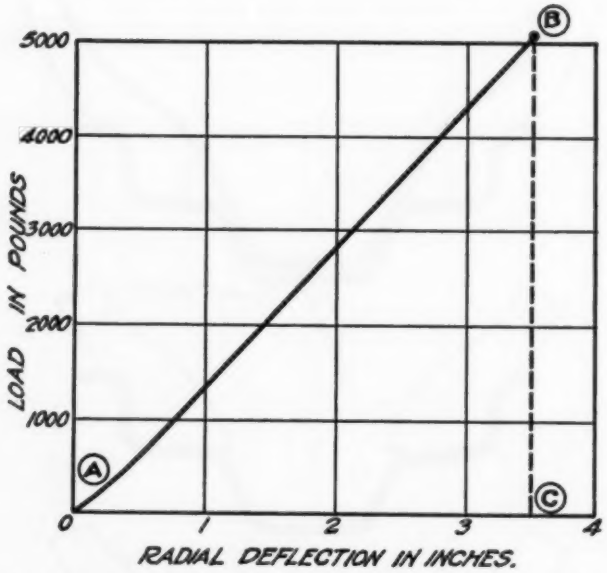

Fig. 3 Graph of Deflection of 30- by 5-In. Tire on 30- by 5-In. Rim at 50 Lb. Inflation

shown in the army specifications. This method rates tires according to a definite radial deflection taken as a percentage of the cross-sectional height of the tire measured from the point of extreme overall diameter to the top of the rim flange. The present line of tires is rated on the basis of a radial deflection equal to 27½ per cent of this distance. On this basis the tire cannot deflect 100 per cent, because twice the thickness of tire and tube intervenes between the rim flange and the ground at complete collapse of the tire. Fig. 2 shows this clearly. In the case of the 30- by 5-in. tire the maximum possible deflection is about 83 per cent. Fig. 3 shows a typical loading curve for an airplane tire, loaded up to the extreme deflection noted above, or collapse point. It will be noted that this tire, which is rated at 1600 lb. static load, has a maximum cushioned load capacity of 5100 lb. This indicates that the ratio of maximum to static load rating is 5100 ÷ 1600 = 3.2. But the maximum design load for the plane which takes the 30- by 5-in. tire is about 6 times 1600 lb. or 9600 lb. It is therefore quite obvious that under the conditions of maximum allowed impact of the plane upon the ground, the tire is not only completely flattened, but is pinched between the rim and the ground. This is not a highly desirable condition, and is only tolerated because apparently the tire has the ability to withstand this punishment, or because such a severe landing occurs but infrequently. The ideal condition for the tire would be to have its collapsing load equal to the static load multiplied by the load factor, but this would reduce the static rating of the 30- by 5-in. tire, for example, from 1600 lb. to 5100 ÷ 6 = 850 lb., or approximately one-half its present rating. An alternative and equally undesirable method of equalizing this condition would be to increase the

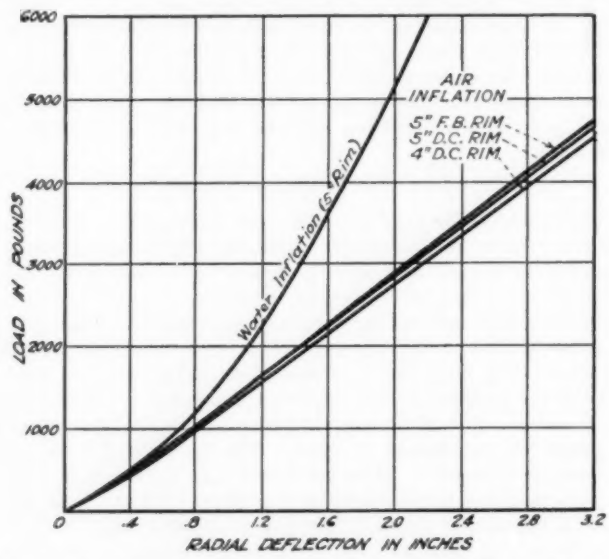

Fig. 4 Variation of Radial Deflection With Load—30- by 5-In. Tire on 30- by 5-In. Rim at 50 Lb. Initial Inflation—Air vs. Water

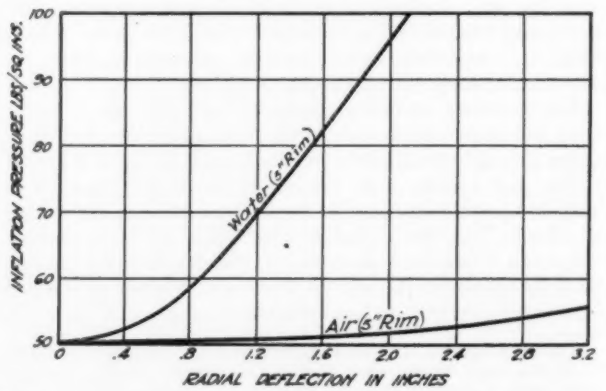

Fig. 5 Variation of Radial Deflection With Inflation—30- by 5-In. Tire on 30- by 5-In. Rim

collapsing load to the required value by increasing the inflation pressure to about 100 lb.

There seems to be an impression that the drop-center rim increases the cushioning properties of a tire because of the extra amount of air volume in the drop-center portion of the rim. This impression probably arises from the fact that the capacity of a

tire is often spoken of as proportional to its air volume. Although this is true in an approximate way, yet it is the active air space only that is of consequence in relation to tire cushioning, because it is only that air space that substantially affects the loading characteristics of the tire. Figs. 4 and 5 show in a diagrammatic way the significance of this statement. Fig. 4 shows the relation between load and radial deflection for a 30- by 5-in. airplane tire mounted on the regular drop-center rim and on a hypothetical flat-base rim having the same dimensions as the drop-center rim, except for the absence of the well portion. The latter curve was obtained by calculation on the following basis: When a tire is loaded, the portion of the tire in contact with the ground suffers a decrease in internal volume, and this produces an increase in inflation pressure. For example, a 30- by 5-in. tire, mounted on a 5-in. drop-center rim, and inflated to 50 lb., shows a pressure rise of 5 lb. when loaded to 5100 lb. The curve of pressure rise is shown in Fig. 5. The drop-center portion of the rim represents only 5 per cent of the total volume of air in the inner tube, and hence the pressure rise in the 30- by 5-in. tire when mounted on a hypothetical flat-base rim would be $5^1/_4$ lb., which would increase the ultimate load-carrying capacity of the tire by approximately 25 lb., which is almost

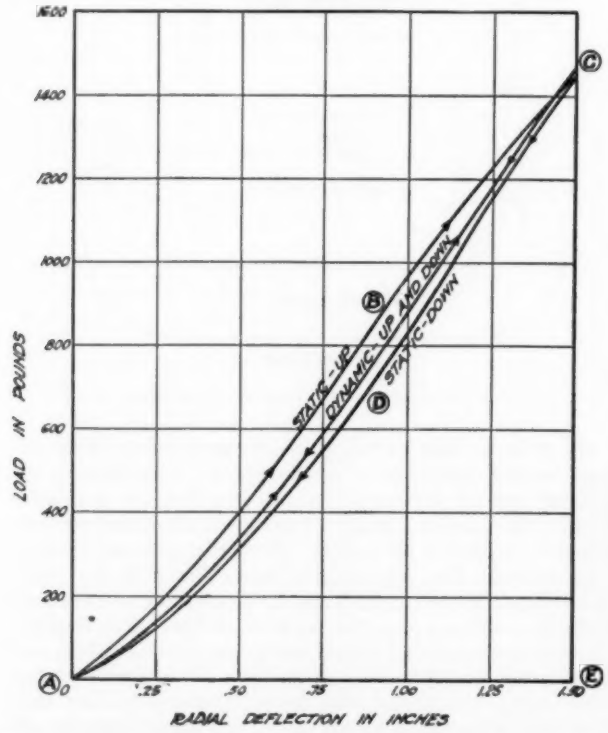

FIG. 6 STATIONARY AND ROLLING LOADING CURVES FOR 30- BY 5-IN. AIRPLANE TIRE ON 29- BY $4^1/_2$-IN. PASSENGER-CAR RIM—ROLLING TEST AT 50 M.P.H.—TIRE LOADED AGAINST DRUM 67 IN. DIAMETER

insignificant. However, the results serve to indicate that the increased air volume of the tire on the drop-center rim decreases rather than increases the load-carrying capacity, through the effect that air volume has upon the pressure rise under load. In order to show the full extent to which one can increase load-carrying capacity by decrease in air volume, a test was made with the air entirely replaced by water. The water being incompressible, the cushioning property of the tire was entirely dependent upon the elasticity of the cords in the tire carcass. The pressure rose from 50 lb. at no load to 96 lb. at 5100 lb. load, but at full radial deflection the tire was capable of supporting 10,000 lb., at which load the inflation pressure would have been 150 lb. The load capacity of a tire is also affected to a small extent by the width of the rim on which the tire is mounted. Fig. 4 shows the loading curves for the 30- by 5-in. tire on the 4-in. and 5-in. airplane rims.

ENERGY CAPACITY AND ABSORPTION

The simple and approximate method of measuring the energy capacity of a tire under radial deflection will be considered first. This method is the static test, in which the stationary

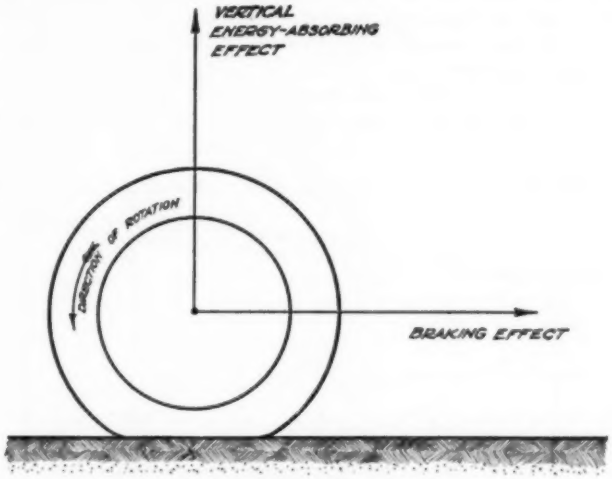

FIG. 7 ENERGY LOSS IN TIRE WHEN ROLLING ALONG THE GROUND

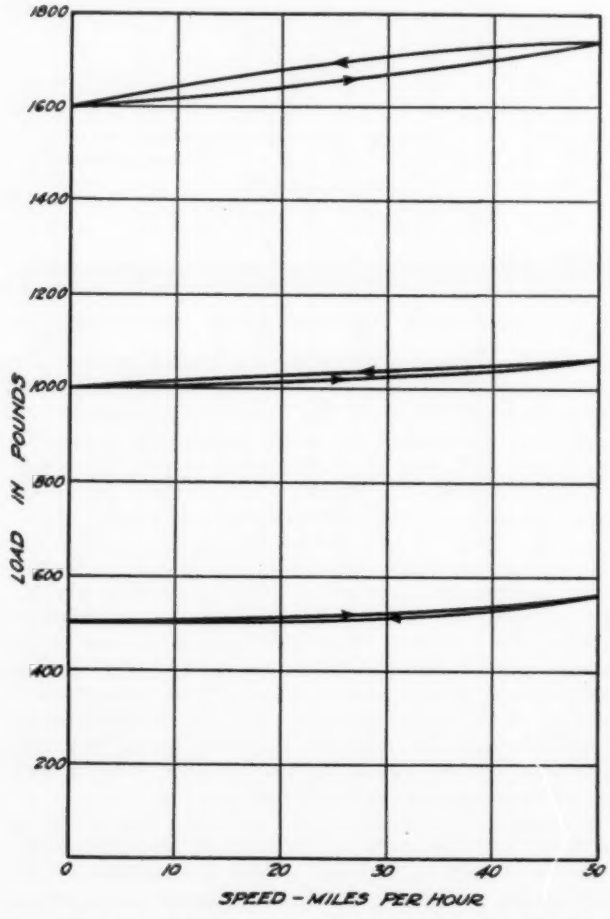
tire is loaded against a flat plate in a loading machine, and deflected until the tire is compressed between the rim and the contact plate. The curve in Fig. 3, for a 30- by 5-in. tire, was obtained by this method, the energy stored being represented by the area *ABC* lying under the loading curve. This energy is 8950 inch-pounds, and represents the ability of the tire to absorb energy in a vertical direction when the airplane makes a landing. It should more correctly be stated, however, that this only approximately represents the vertical energy capacity, because the curve was obtained by a loading test that was comparatively slow compared to the rate of deflection under service conditions. It is quite possible that the energy capacity may be greater under the condition of rapid loading. Unfortunately, the necessary equipment was not available to make the rapid loading test. However, a careful study of the conditions under which a tire is deflected against the ground in actual service will disclose the fact that even this rapid loading test would not give the true figures.

In actual service, the tire is not stationary, but rolls along the ground at a rapid rate, and the length of tire carcass loaded is not represented by the small section in instantaneous contact with the ground, but by the length equal to the distance traversed by the plane over the ground during the interval of contact. This condition was simulated in the laboratory by loading the tire against a large wheel revolving at a speed representative of the initial landing speed of an airplane, viz., 50 m.p.h. On account of the curvature of the drum it was necessary to obtain a new static loading curve for comparison with the dynamic curve. Fig. 6 shows the results obtained. The curve *ABC* represents the static test results for increasing load and *CDA* the curve for decreasing load, and the area *ABCDA* represents the static hysteresis loss for the complete loading cycle. It will be noted that the tire was not loaded to complete collapse, because at a speed of 50 m.p.h. the temperature rise due to internal friction in the tire during the length of time

required to make the test would have affected the inflation pressure and also the results. The static curves show that the amount of energy stored in the tire upon increasing load was 1047 in-lb., and the amount returned during decreasing load was 919 in-lb. The area of the hysteresis loop is therefore 125 in-lb., and so it may be said that the efficiency of the tire statically as an energy dissipator is 12.2 per cent. However, static loading tests on a Riehle machine have shown this efficiency to be only 6 per cent; so it is feared that the above static loading test may be in error on account of friction of the carriage on which the tire was mounted. However, the results are at least of qualitative interest. Fig. 6 also shows the results of the dynamic loading test at 50 m.p.h. The curve falls inside the static hysteresis loop, and it shows no hysteresis loop, since the curves of increasing and decreasing loads coincide. It may therefore be concluded that the efficiency of the rolling tire as an energy dissipator in a vertical direction is zero.



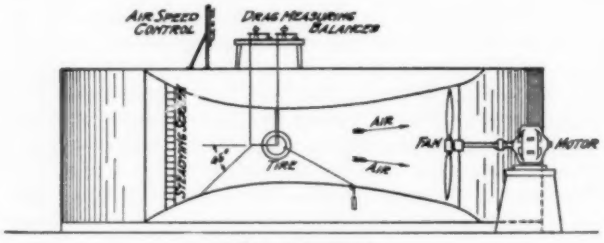


FIG. 8 DYNAMIC LOADING—30- BY 5-IN. AIRPLANE TIRE AT 50-LB. INITIAL AIR PRESSURE AND CONSTANT VERTICAL DEFLECTION

But since, during the interval of the single high-speed impact of the plane on the ground, the tire may have traveled over 100 ft. along its outside periphery, there must necessarily have been a considerable amount of energy absorbed due to the hysteresis of the tire carcass. If, then, there is all this absorption of energy why does the tire show no hysteresis loop on the dynamic loading curve? The answer is, that it is necessary to distinguish between effective braking action and "shock-absorbing" action in a tire, or horizontal and vertical components of energy absorption. (See Fig. 7.) In other words, the energy loss in a tire when rolling along the ground appears as a net horizontal, or braking action, and not vertical or "shock-absorbing" action. It is unfortunate that the search for the good qualities in airplane tires should have exposed such gross incompetence of the tire in the vertical direction. But so long as this creates a demand for rubber shock absorbers, the tire cannot be condemned for failure to support the rubber industry.

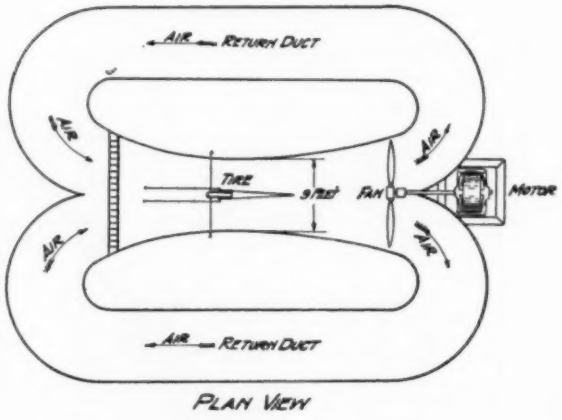

FIG. 9 DIAGRAMMATIC VIEWS OF WIND TUNNEL

Fig. 8 throws light on this particular performance of the tire from another angle. Here are presented curves showing the apparent increase in vertical reaction of a tire due to rotative speed. The increase is really a centrifugal effect, and could be expressed in terms of equivalent inflation-pressure increase, if so desired. The upper curve shows that if at the beginning the load is 1600 lb. with the tire at rest, this load increases to 1740 lb. at 50 m.p.h., or 8.6 per cent increase. This centrifugal effect increases the vertical energy capacity of a tire, and this increase would be very apparent if the dynamic loading curve in Fig. 6 is plotted with the point of zero load set back of the zero for radial deflection by $^3/_{32}$ in., which is the increase in the tire height at 50 m.p.h.

AIR DRAG

On account of the increasing use of anti-skid tires on airplane landing wheels, it is important that their comparative air-drag values become definitely known. It is also important that information be made available on other factors in connection with tire and wheel design, such as the efficiency of streamlining of the wheels and tires, and the effect of toe-in or out-of-alignment of the plane of the tire and wheel with respect to the line of flight.

With these objectives in view, The B. F. Goodrich Company, under the personal direction of Prof. Alexander Klemin, conducted tests in the 9-ft. wind-tunnel at the Daniel Guggenheim

School of Aeronautics of New York University, on various combinations of tires and wheels, as follows:

1. 14- by 3-in. smooth airplane tire on 14- by 3-in. wheel
2. 20- by 4-in. smooth on 18- by 3-in. wheel
3. 20- by 4-in. safety tread on 18- by 3-in. wheel

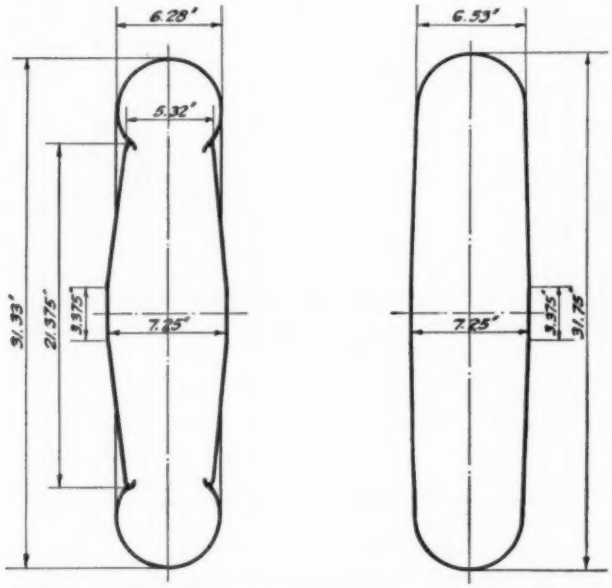

FIG. 10 AT LEFT SMOOTH AIRPLANE TIRE AND AT RIGHT SMOOTH STREAMLINE AIRPLANE TIRE 32- BY 6-IN. ON 32- BY 6-IN. WIRE WHEEL WITH METAL SHIELDS

4. 30- by 5-in. smooth streamline tire on 28- by 4-in. wheel
5. Same as 4 but toe-in 2 deg. 2 min. (0.35 in.)
6. Same as 4 but toe-in 4 deg. 4 min. (0.70 in.)
7. Same as 4 but toe-in 6 deg. 6 min. (1.05 in.)
8. 30-by 5 in. smooth tire on 28- by 4-in. wheel
9. Same as 8 but toe-in 2 deg. 2 min. (0.35 in.)
10. Same as 8 but toe-in 4 deg. 4 min. (0.70 in.)
11. Same as 8 but toe-in 6 deg. 6 min. (1.05 in.)
12. 30- by 5-in. safety tread on 28- by 4-in. wheel
13. 32- by 6-in. safety tread on 28- by 4-in. wheel
14. 32- by 6-in. smooth streamline tire on 32- by 6-in. wheel
15. 32- by 6-in. smooth on 32- by 6-in. wheel
16. 32- by 6-in. safety tread on 32- by 6-in. wheel
17. 6.00–20 (32 × 6.00) Silvertown passenger-car balloon tire on 32- by 6-in. wheel
18. 32- by 6-in. smooth airplane tire on 32-by 6-in. wheel without streamline disks on wheel
19. 36- by 8-in. smooth on 36- by 8-in. wheel
20. 40- by 10-in. safety tread on 36- by 8-in. wheel

Each combination was tested at 40, 50, 60, 70, 80, and 90 m.p.h., and the drag in pounds calculated for each air speed, as well as the drag coefficients based on actual cross-sectional area through the center of the axle, and on the projected area which is slightly greater. Fig. 9 shows diagrammatic plan and elevation views of the wind tunnel.

The wheels used were of the wire-spoke type, and sheet-metal fairings were used except where noted above. Detailed results are shown in the curve sheets, Figs. 11 to 16, inclusive, in which the numbers shown refer to the tests listed. The drag given is the net drag on tire and wheel, correction being made for the drag on the axle and connecting wires.

In order to calculate drag coefficients, the projected areas for each tire must be computed similar to the method shown on the attached sample drawing Fig. 10 for the 32- by 6-in. tire. The actual areas, as viewed in an aerodynamic sense, comprise the complete projection of each unit, and these areas are slightly larger than the cross-sectional areas. The method of calculating the drag coefficient is as follows:

$$\text{Drag coefficient} = \frac{\text{Drag in pounds}}{\text{Projected area in sq. ft.} \times \text{m.p.h.}^2}$$

The drag coefficient therefore numerically equals the drag per square foot of projected area for an air speed of 1 m.p.h. In the case of streamlined wheels the projected area was computed disregarding the increase in area due to the shields, as this makes the comparison of these wheels with ordinary ones clearer. No allowance for increase in area was made in the cases of toe-in.

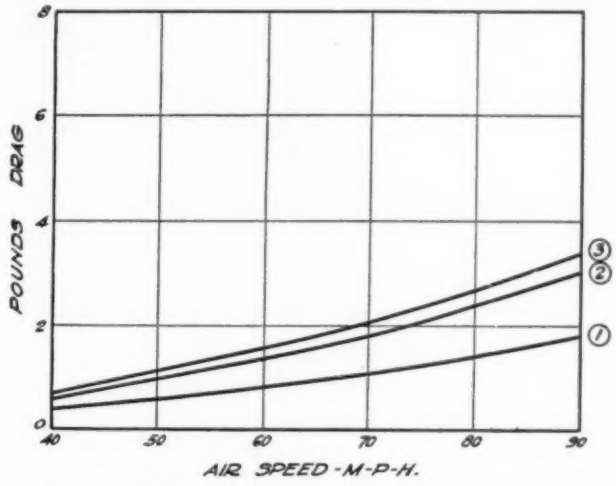

FIG. 11 AIR DRAG OF AIRPLANE TIRES NOS. 1, 2, AND 3

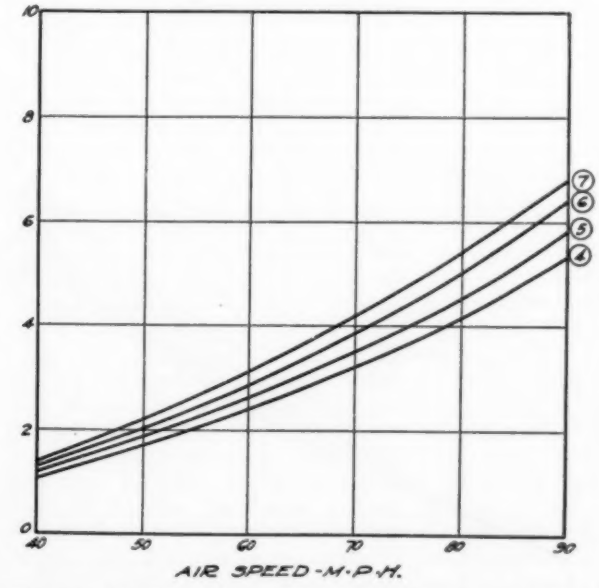

FIG. 12 AIR DRAG OF AIRPLANE TIRES NOS. 4, 5, 6, AND 7

DISCUSSION OF RESULTS

The drag coefficients have minimum values for 30- by 5-in. tires mounted on 28- by 4-in. wheels and slightly increase both

for smaller and larger wheels. The scale effect is the most pronounced in the case of smooth tires mounted on streamline wheels; there is a decrease of about 8 per cent in the value of drag coefficient from 40 m.p.h. to 90 m.p.h.

A comparison of drag on tires of different tread shows that the safety-tread tires have 5 per cent to 10 per cent greater drag than smooth ones. There is a saving in resistance of about the same magnitude by adoption of streamline tires. Streamline tires are still more advantageous in case they are set with toe-in, as the increase in drag due to the toe-in of 6.1 deg. is 45 per cent in the case of non-streamline tires, and only about 25 per cent in the case of streamline tires. This fact is of importance when it is considered that perfect alignment of the plane of the wheel with the path of flight may not always be easy to maintain in manufacture or service.

The test on the Silvertown 6.00–20 passenger-car tire shows that substitution of this kind of tire for an airplane safety-tread tire does not make a great difference from a drag standpoint, but the weight penalty is considerable. The resistance

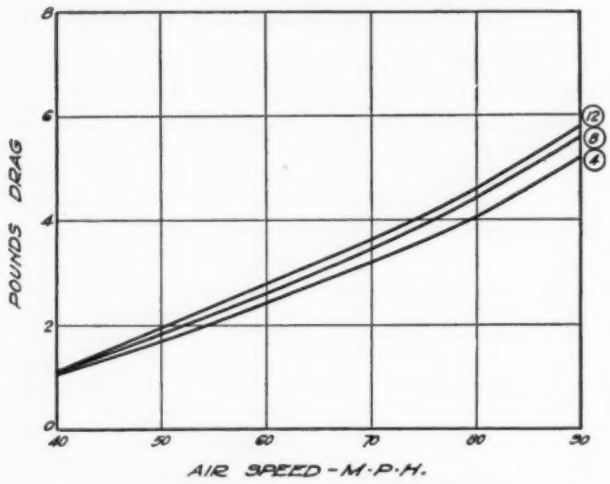

FIG. 13 AIR DRAG OF AIRPLANE TIRES NOS. 4, 8, AND 12

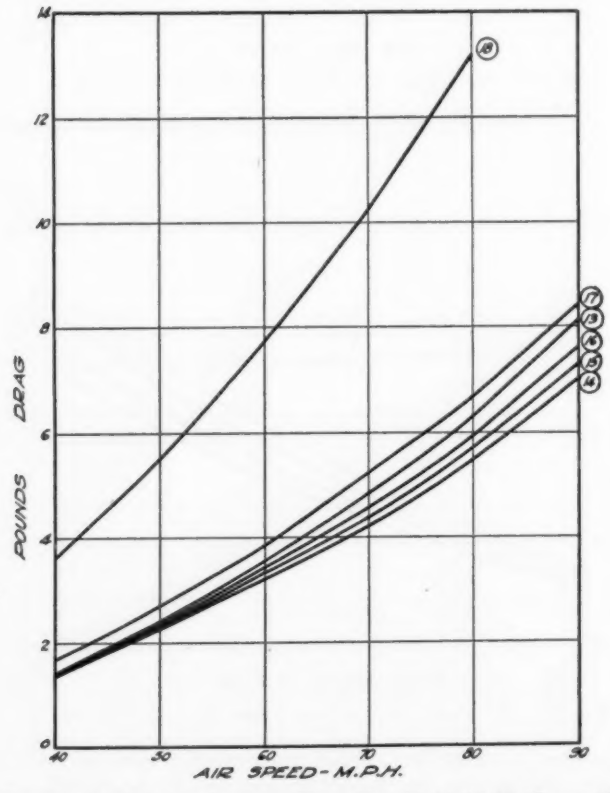

FIG. 15 AIR DRAG OF AIRPLANE TIRES NOS. 13, 14, 15, 16, 17, AND 18

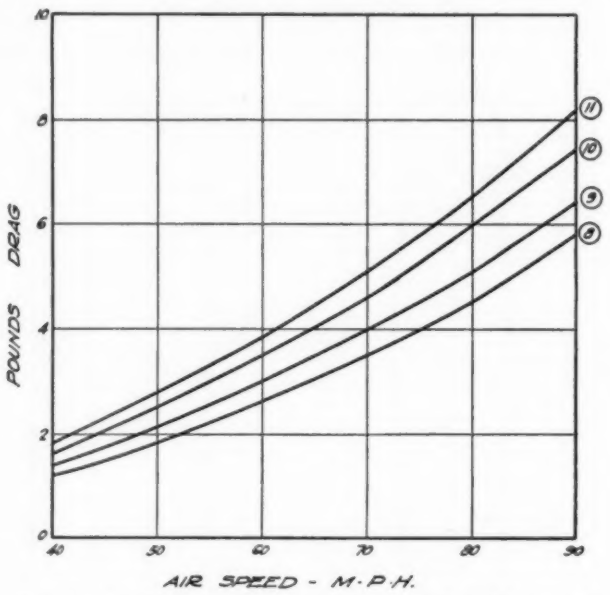

FIG. 14 AIR DRAG OF AIRPLANE TIRES NOS. 8, 9, 10, AND 11

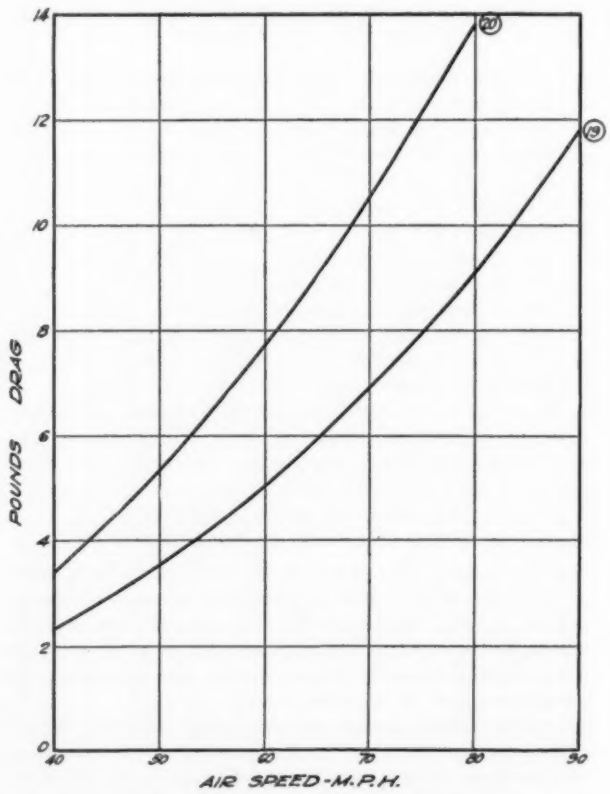

FIG. 16 AIR DRAG OF AIRPLANE TIRES NOS. 19 AND 20

of tire and wheel with the disks removed is about twice as great as the resistance with the disks on.

It is interesting to note the effect of oversizing upon the drag. For example, at 90 m.p.h. the 30- by 5-in. safety-tread tire on a 28- by 4-in. wheel shows a drag of 5.81 lb., while the 32- by 6-in. safety-tread tire on the same wheel shows a drag of 8.17 lb., an increase of 41 per cent. It is also interesting that the 32- by 6-in. safety tire has less drag when mounted on a 32- by 6-in. wheel than when on a 28- by 4-in. wheel.

Discussion

A. L. KIMBALL.[2] The writer does not agree with the author's conclusion that the hysteresis action is zero for a tire rolling on a surface for up-and-down vibratory motion. Although his dynamometer tests give a zero hysteresis loop, for the tire rolling against a revolving drum, it is to be noted that measurements are made when the up-and-down motion is zero. If measurements could be made while the tire was in motion during its up-and-down path a hysteresis loop would be obtained.

Referring to Fig. 17, when the tire is rolling against a moving surface as shown, the rubber in contact with the ground along AC, to the right of the vertical OA, is in the act of being compressed, while that along AB is in the act of expanding. This means that the frictional force which resists deformation produces an increased reaction on the ground from A to C, but a decreased reaction from A to B. This results in the couple shown by the pair of small arrows, which has to be overcome during rolling motion and accounts for the power absorbed in the tire as it rolls.

Assume, however, that a downward component of motion is superimposed on the horizontal. The median line OA then swings to the left slightly to a position OA'. The point of maximum compression is no longer directly under the hub at A, but swings over to A' due to the superimposed downward component of motion. This means that the zone of increasing compression is $A'C$ instead of AC, and that of expansion is $A'B$ instead of AB. Since more rubber is being compressed upward than is expanding downward, the right-hand member of the couple is greater than the left-hand, so that work must be done during the downward motion because of a resultant upward force to be overcome.

The following is an approximate calculation of the energy dissipation due to up-and-down vibration during rolling.

Assume, as an approximation, that when the tire is not rolling, but only moves up and down, the total hysteresis force is F. The work dW_v during an up or down motion through a distance dy is Fdy.

When the tire is rolling, a motion through this same element dy results in the work

$$dW_r = Fdy\left(\frac{2AA'}{BC}\right)$$

where as an approximation the force F is supposed to be uniformly distributed.

But $\frac{A'A}{AO} = \frac{V_y}{V_x}$ approximately, where V_x is the constant forward motion and V_y the instantaneous motion along dy.

Let the tire vibrate up and down according to the law $y = y_o \sin \omega$ where y_o is the half amplitude.

Then $V_y = \frac{dy}{dt} = y_o\omega \cos \omega t$

Also $dy = y_o \cos \omega t \, d(\omega t)$

[2] Research Engineer, General Electric Co., Schenectady, N. Y.

Substituting in equation for dW_r

$$dW_r = \frac{2Fry_o^2\omega \cos^2 \omega t \, d(\omega t)}{lV_x}$$

where $r = AO$ and $l = BC$.
Integrating over one cycle

$$\Delta W_r = \frac{2Fr}{lV_x} y_o^2\omega \oint \cos^2 \omega t \, d(\omega t) = \frac{2\pi Fry_o^2\omega}{lV_x}$$

which is approximately the energy dissipated during one up-and-down vibration. The energy dissipated during one cycle for the static test with no wheel rotation $= \oint F dy = 4Fy_o$ approximately, since the amplitude is assumed relatively small so F is approximately constant, but reverses in sign at the top and bottom of the cycle. The symbol y_o represents the half amplitude as before.

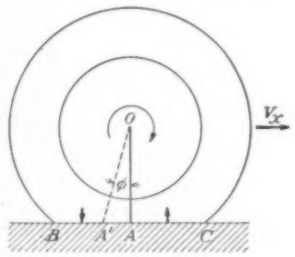

FIG. 17

The ratio of the energy dissipated during up-and-down motion in the static case to that in the case of the rolling wheel is:

$$\frac{\Delta W_v}{\Delta W_r} = \frac{lV_x}{\pi^2 r y_o f}$$

where $2\pi f$ is substituted in place of ω, f being the frequency of the up-and-down vibration.

If $l = 5$ in., $V_x = 500$ in. per sec., $v = 15$ in., $f = 10$ cycles per sec. and $y_o = 1/7$ in.

$\frac{\Delta W_v}{\Delta W_r} = \frac{20}{3}$, that is, the energy dissipated due to up-and-down motion during rotation is only about $1/7$ that without rotation.

The formula shows that ΔW_r increases with the frequency so the above ratio becomes smaller as the frequency of up-and-down vibration increases. ΔW_r decreases, however, with V_x, giving a correspondingly larger value of the ratio.

A remarkable feature of this result is the increase of W_r with frequency. The law of hysteresis assumed is that the dissipation per cycle per unit volume of the rubber is independent of frequency, that is, that a viscosity which would cause a viscous reaction which increases with velocity of strain, is not present. The hysteresis cycle is like that of magnetic hysteresis in iron, where frequency does not enter. It is for this reason that the force F is taken as a constant. A consideration of the fundamentals employed above will show that an equivalent rectangular loop is employed. Since we are interested in loop area, the shape is immaterial for the purpose of analysis given.

This law of independence of loop area of frequency has been studied by the writer and has been found to hold for a variety of solids, including various metals, wood, celluloid, and rubber.[3] It is possible, however, that in the case of rubber, with strain velocities as high as they are in a rapidly rolling wheel, a strain velocity effect may enter, which increases the loop area. Experiment shows that loop area depends upon the strain amplitude squared. In the above case, where during the up-and-down vibration the strain is relatively small compared with the entire range, the force F is assumed constant and independent of amplitude, which gives a loop area proportional to the first power of the amplitude.

Although this discussion is rather inadequate, it at least gives an idea of what happens, and brings out the important

[3] A. L. Kimball and D. E. Lovell, "Internal Friction in Solids," *Physical Review*, Dec., 1927.

fact that the higher the frequency of bouncing the greater the dissipation and the higher the speed V_x the less the dissipation for a given amplitude. A complete analysis would be very complicated. It is thus seen that with very high rolling speeds indeed, the hysteresis dissipation due to up-and-down vibration may be relatively small, although it can never be actually zero.

Aviation Natural Gasoline

By R. C. ALDEN,[1] BARTLESVILLE, OKLA.

The usual natural gasoline of commerce is an extremely volatile product and quite unsuitable for direct use as a motor fuel in the conventional fuel systems of today. By careful fractionation, however, it has been found possible to produce "aviation natural gasoline," a fuel that has made a splendid record commercially during the last three years. A considerable amount of research work has been done with regard to this product, and the author discusses it under the following heads: (1) Initial flight tests to determine specification bases for commercial purposes; (2) effects of changes in specifications for aviation natural gasoline; (3) survey of commercial aviation gasolines; (4) flight tests to determine actual temperature in airplane fuel systems; and (5) other investigations. An extensive table of test results of commercial aviation gasolines is included, as well as a bibliography of articles having a bearing on aviation natural gasoline.

NATURAL gasoline is the name applied to the gasoline recovered from natural gas. Formerly, the product was called "casing-head" gasoline from the fact that the first natural gasolines were recovered entirely from the gas withdrawn through the casing heads of oil wells.

The present daily production of natural gasoline amounts to more than six million gallons, which represents approximately twelve per cent of the total gasoline supply. The natural gas from which natural gasoline is obtained may contain before treatment as little as one-tenth to as much as twenty gallons of commercial natural gasoline per thousand cubic feet. The average richness of gas treated for natural gasoline is about one and one-quarter gallons per thousand cubic feet.

Natural gasoline has been used almost exclusively as a blending agent, which, when added to the refinery product in suitable proportions, greatly improved the ease of starting and accelerating characteristics of the finished motor fuel. For this purpose high volatility of the natural gasoline was required, inasmuch as the product had to be shipped from its points of manufacture to the refinery or other point of use, thus increasing its costs.

During the past five years developments in the refining industry have made it possible for the refiners to obtain increased volatility without the use of natural gasoline. The use of vapor-recovery systems and the oil-cracking process has been responsible for this condition. Fortunately, for the natural-gasoline industry, competition in the marketing end has been so keen that this progress has been passed on to the public in the form of better motor fuels. It is safe to say that if the motor-fuel standards of 1923 were in effect today there would be very little market for natural gasoline.

An interesting sidelight on this development of gasoline quality is shown in Table 1, which shows the "front end" volatility of the composite gasolines reported in the Semi-annual Motor Gasoline Surveys of the U. S. Bureau of Mines.

Although Table 1 is a study of motor gasolines, it has a very definite bearing on the subject of aviation gasolines. The trend toward more volatile fuels is quite evident, and a knowledge of the economic conditions surrounding the petroleum industry leads to the conclusion that these volatile fuels have come to stay for a considerable length of time. It therefore follows that fuel systems for automotive and airplane engines should be designed with this trend in mind.

Because refineries are making such rapid progress in imparting volatility to their finished gasolines in their own processing, the more progressive manufacturers of natural gasoline have undertaken extensive research programs in order to assure markets for their product. One of the most interesting of the developments resulting therefrom has been aviation natural gasoline.

The usual natural gasoline of commerce is an extremely volatile product, quite unsuitable for direct use as a motor fuel in the conventional fuel systems of today. A typical Grade AA natural gasoline has a vapor pressure at 100 deg. fahr. of 28 lb. per sq. in. abs. It contains about 1 per cent by volume of propane and 30 per cent of butanes. The vapor pressures at 100 deg. fahr. of propane, isobutane, and normal butane are 186, 74, and 53 lb. per sq. in., respectively. When these volatile constituents are removed, the residual product has a vapor pressure at 100 deg. fahr. of approximately 11 lb. per sq. in. Further fractionation of the "butane-free" product, at the expense of the pentanes content, can be employed to reduce the vapor pressure further. This residual kettle product, resulting from the careful fractionation of natural gasoline, composes the product known as aviation natural gasoline.

TABLE 1 "FRONT END" VOLATILITY OF COMPOSITE GASOLINES REPORTED IN THE SEMI-ANNUAL MOTOR-GASOLINE SURVEYS OF THE U. S. BUREAU OF MINES

	Winter					Summer

1930	96.6	93	139	129	10.25					

[1] A constant distillation residue of 1.0 per cent was assumed.
[2] Graphically determined by method described in the *Oil & Gas Journal*, May 15, 1930, p. 40.

The equipment used in the manufacture of aviation natural gasoline is the same as that used in the manufacture of commereial propane, butane, pentane, and the refinery grades of natural gasoline. The "wild" condensate extracted from the natural gas is fed into one column, where conditions of temperature, pressure, and rate of reflux are maintained to give the desired kettle product. The overhead vapors are liquefied and subjected to further refractionation.

Aviation natural gasoline thus produced is an exceptionally well-fractionated, or "stabilized," product. With the average raw material it is necessary to eliminate a portion of the pentane content in order to reduce the vapor pressure to the desired limits. For example, Table 2 can be taken as illustrative of the composition changes which take place in the processing of the "wild" condensate extracted from natural gas in the production of aviation natural.

[1] Assistant Director, Phillips Petroleum Co.

Presented at a joint meeting of the Chicago Section and Aeronautic Division of the A.S.M.E., Chicago, Ill., August 25, 1930.

TABLE 2 COMPOSITION OF FEED AND KETTLE PRODUCTS IN THE FRACTIONATION OF AVIATION NATURAL GASOLINE

(Composition in terms of volume per cent)

	Initial condensate	Grade AA natural	"Butane-free" natural	Aviation natural
Propane and lighter	14.0	1.0	..	..
Butanes	32.0	30.0	1.0	0.3
Pentanes	28.0	31.0	46.0	31.7
Hexanes	14.0	15.0	25.0	31.0
Heptanes and heavier	12.0	15.0	28.0	37.0

It is interesting to note in regard to the processing of aviation natural gasoline that the emphasis in fractionation is placed on the light ends. In other words, very careful control is maintained in regard to the vapor pressure of the finished product. This, of course, is due to the fact that the possible contaminants of the finished product are more volatile than the finished product itself. This is in direct contrast with usual refinery practice, where the possible contaminants are less volatile than the finished product, with the result that the emphasis in fractionation is placed on the heavy ends. With the ever-increasing supply of volatile hydrocarbons, it is becoming increasingly necessary to exercise careful control of what might be termed the "front-end" volatility of fuels for internal-combustion engines.

Aviation natural gasoline is a comparatively new product. In its present form it has been on the market a little over three years. In this short time it has made a splendid record commercially. It is estimated that in 1929 between 15 and 20 per cent of the gasoline used in commercial flying was aviation natural. Among the more spectacular achievements to its credit can be cited its use by Col. Arthur Goebel in winning the Dole race from Oakland, Calif., to Hawaii, and the 1929 endurance flight of the *St. Louis Robin*.

A considerable amount of research work has been done in behalf of aviation natural gasoline. This work can be divided into five headings, each of which will be briefly discussed.

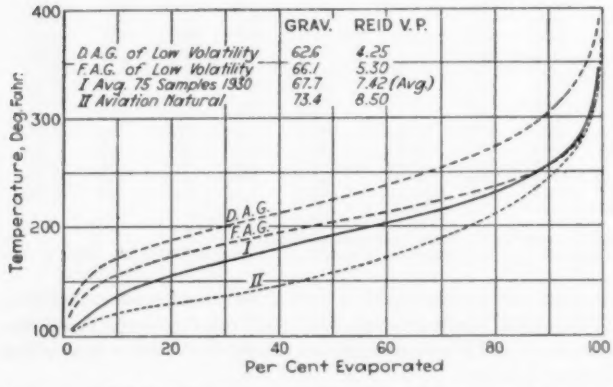

FIG. 1 A.S.T.M. DISTILLATION CHARACTERISTICS OF AVIATION GASOLINES

1 INITIAL FLIGHT TESTS TO DETERMINE SPECIFICATION BASES FOR COMMERCIAL PURPOSES

Fig. 1 shows the A.S.T.M. distillation characteristics of refinery products which meet the requirements of domestic and fighting grades of aviation gasoline as compared with a typical aviation natural. The significant characteristics to note are:

a The remarkably low mid-portion of the distillation curve of aviation natural. This signifies superior distribution to the cylinders of the engine and excellent cold-weather performance.

b The low 10 per cent evaporated temperature, which signifies easy starting, particularly in cold weather.

c The flat "front end" of the curve. This signifies the absence of light hydrocarbons and means that the product has a very low vapor pressure as compared with products not having this characteristic.

Because of these differences, each manufacturer who has launched an aviation natural program has considered it advisable to conduct actual flight tests prior to placing his product on the market. In the flight tests, a wide variety of gasolines has been used, ranging from Grade AA natural in extreme volatility to very deeply cut butane-free naturals. The most rigorous flying

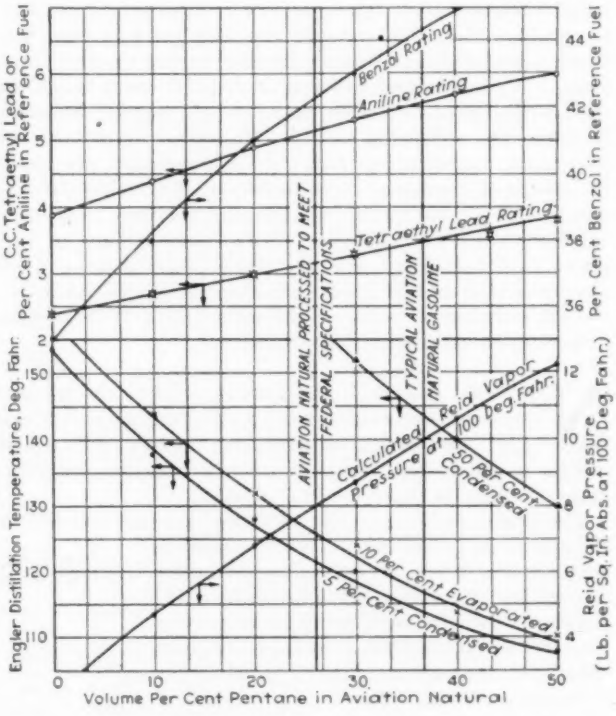

FIG. 2 EFFECT OF PENTANE CONTENT ON SEVERAL SALIENT CHARACTERISTICS OF NATURAL GASOLINE

conditions were imposed, particularly in regard to extreme ground temperatures, rate of climb, and sustained flight.

In this test work it was found that even the more volatile products could be used under many conditions. In order to be on the safe side and to avoid undue handling losses, most manufacturers established a maximum Reid vapor pressure limit of 10.5 lb. per sq. in. at 100 deg. fahr. Inasmuch as this is a shipping specification, the vapor pressure at points of consumption will be somewhat lower than 10.5 lb. per sq. in. In terms of the A.S.T.M. distillation, this means that the 5 per cent condensed temperature will vary through the approximate range of 112 to 119 deg. fahr. and the 50 per cent condensed temperature will vary through the approximate range of 140 to 154 deg. fahr.

It is worth noting at this point that the existing specifications for F.A.G. (Fighting Aviation Grade) and D.A.G. (Domestic Aviation Grade), formulated eight years ago, require a minimum 5 per cent condensed temperature of 122 deg. fahr. Consequently, in this one respect the conventional aviation natural does not meet the federal requirements. On the other hand, the maximum temperatures at 50 per cent condensed for D.A.G. and F.A.G. are 221 and 203 deg. fahr., respectively. Consequently, in this regard, aviation natural is much superior to the fuels which barely meet federal requirements.

Besides the specifications which have resulted from the initial flight tests, several facts were developed of general interest. No noteworthy differences were found as to fuel consumption from

a volumetric viewpoint as compared with other gasolines. The consumption when expressed in terms of weight did, however, show an advantage in favor of the lighter aviation natural, this difference being worthy of consideration.

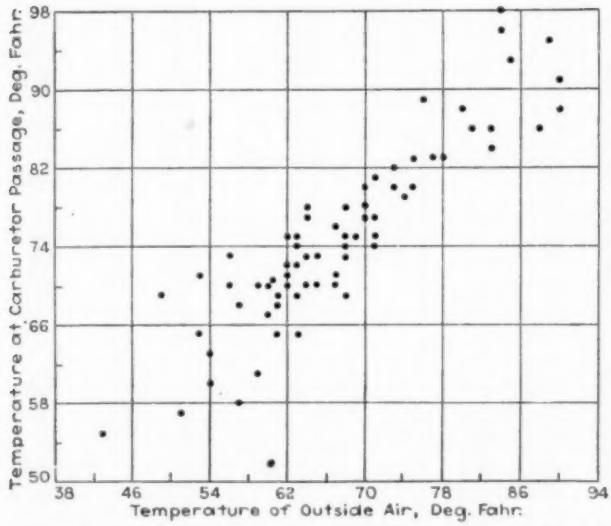

FIG. 3 FUEL-SYSTEM TEMPERATURE IN WASP-ENGINED TRAVELAIR MONOPLANE

2 EFFECTS OF CHANGES IN SPECIFICATIONS FOR AVIATION NATURAL

As has been stated, aviation natural is a natural gasoline product with the butanes and lighter eliminated and some of the pentanes removed. In readjusting the product to consider other specification bases than those ordinarily in practice, the control is effected by varying the pentane content.

In Fig. 2, the pentane content of a typical Mid-Continent base material is the abscissa. The effect of this variable on several salient characteristics is represented by the various curves. The most important fact to be noted from Fig. 2 is the decrease in anti-knock rating with decreased volatility as measured by the several methods depicted.

From Fig. 2 the conclusion is readily reached that any volatility limitation for aviation gasoline that is not founded on the soundest engineering data causes a needless sacrifice of anti-knock value.

For purposes of comparison of anti-knock ratings it can be stated that the reference fuel used in the tests shown on Fig. 2 required 7.3 per cent aniline to equal the "Ethyl Standard" for motor gasoline prior to July 1, 1930.

3 SURVEY OF COMMERCIAL AVIATION GASOLINES

Since November, 1929, the Research Department of the author's company has conducted a monthly survey of aviation gasolines in order to determine the quality of the products in commercial use. The samples for this survey have been collected at widely scattered airports. Extreme care was exercised in sampling and shipping the products. Upon arrival at the central laboratory the following tests were made: A.S.T.M. distillations, composition analyses, Reid vapor pressures, and anti-knock determinations.

For the benefit of those who may desire to study the results of this rather comprehensive survey, a detailed tabulation is presented in Table 3.

Some of the interesting facts developed in the course of the survey are as follows:

a Approximately half the samples examined are considerably more volatile at the A.S.T.M. distillation 50 per cent point than is required by federal specifications.

b From a composition viewpoint, the essential difference between aviation naturals and other aviation gasolines is that the latter usually have considerably more in the butane range and less in the pentane and hexane ranges.

c Several products not aviation naturals are almost identical in test characteristics with aviation naturals.

d A considerable proportion of the fuels examined failed to meet federal specifications in regard to the A.S.T.M. distillation 5 per cent condensed temperature.

e Products having Reid vapor pressures as high as 11 lb. per sq. in. at 100 deg. fahr. are on the market. Smooth curves drawn through a plot of Reid vapor pressure against the 5 per cent condensed temperature show that it is easily possible to procure gasolines of 10.5 lb. vapor pressure, and even as high as 11.0 lb., under existing F.A.G. and D.A.G. specifications.

f The 10 per cent evaporated temperature in the A.S.T.M. distillation is not indicative of the Reid vapor pressure.

g Although there is a lack of uniformity among the several marketers of aviation natural gasoline, as to volatility specifications, one manufacturer has demonstrated a decided ability to maintain his product at a satisfactory high level of uniformity.

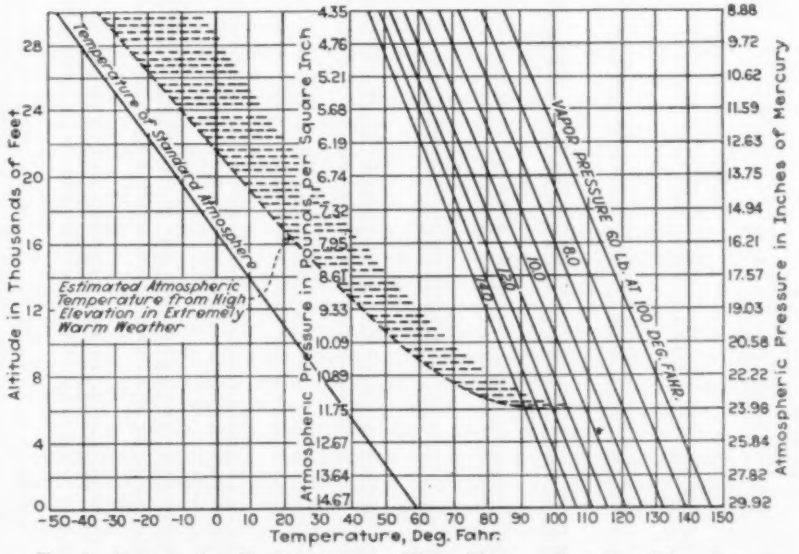

FIG. 4 ALTITUDE AND TEMPERATURE AT WHICH VARIOUS GASOLINES WILL BOIL

In order to demonstrate the rapid increase in the average volatility of aviation gasolines, Curve I was added to Fig. 2. This curve represents the composite gasoline resulting from the survey described. It is to be noted that the average commercial aviation gasoline, as revealed by the survey, has considerably lower boiling points, that is, more volatility than required by D.A.G. or F.A.G. specifications. When it is recalled that a few years ago practically all marketers of commercial aviation gasoline adhered very closely to the maximum boiling points of federal specifications, it will be realized that the period has witnessed a considerable change in the quality of aviation gasolines. Curve II of Fig. 2 permits a comparison of aviation natural gasoline with past and present practice.

This trend toward greater volatility is naturally of importance

TABLE 3 TEST RESULTS OF SURVEY OF COMMERCIAL AVIATION GASOLINES

[7] 38.2 per cent benzene.

to the designer of aviation motors, as it minimizes the problem of securing complete vaporization and equalized distribution of fuel to the various cylinders. In the experience of the company with which the author is associated, using a large variety of motors and of gasolines, it has been found that exhaust-heated manifolds or hot spots in carburetors are entirely unnecessary with these modern fuels, and, under some conditions, decidedly injurious as they reduce the volumetric efficiency of the engine, increase detonation possibilities, and result in a loss in r.p.m. of the motor. On the other hand, the low manifold temperatures resulting from the rapid vaporization of these gasolines increases the tendency of the carburetor to frost up, and become clogged with ice. This condition can be eliminated by a controllable device for moderately heating the air at the carburetor intake. In one instance these low manifold temperatures have been successfully utilized for cooling the hot oil from the motor.

4 Flight Tests to Determine Actual Temperature in Airplane Fuel Systems

Under the direction of Dr. G. G. Brown of the University of Michigan, the Natural Gasoline Association of America has sponsored a research program which has for its primary object the determination of temperatures in the fuel systems of airplanes in actual flight. This investigation is now under way. Thus far two ships, one a Hornet-engined Boeing biplane, the other a Wasp-engined Travelair monoplane, have been equipped with instruments to determine the temperatures in the fuel system.

The investigation is not far enough along to provide a basis for definite conclusions. However, in the work with the wasp-engined Travelair monoplane, several interesting observations have been made.

The maximum temperature in the fuel system, exclusive of the fuel tank, has never exceeded the outside air temperature by more than 20 deg. fahr. At the higher air temperatures (60 to 80 deg. fahr.) the difference has not exceeded 15 deg. fahr. Fig. 3 shows the relation between the temperature of the outside air and of the gasoline in the carburetor passage for this fuel system.

In order to furnish a basis of comparison for the significance of the generalization just stated, Fig. 4 is presented. The diagram shows the effect of altitude on the boiling points of gasolines of several vapor-pressure values. The temperature–vapor-pressure relationships on which the curves in Fig. 4 are based are those of the paraffin hydrocarbons. The straight line at the left represents the temperature of the standard atmosphere as defined in National Advisory Committee for Aeronautics, Report No. 218, "Standard Atmosphere—Tables and Data," by Walter S. Diehl. The dotted line represents the author's estimate of the air temperatures above territory at high elevation on an exceptionally warm day. The shaded section represents the 20-deg. difference observed above. It is to be noted that the shaded portion is closest to the gasoline curves at ground conditions and recedes from the curves with increased altitude.

Where the gasoline curves cross the shaded section represents the conditions where difficulty with vapor lock would occur in the particular fuel system studied. Under the extreme conditions outlined, namely, high altitude and excessively high ground temperatures, fuels having vapor pressures of 10.5 lb. per sq. in. are on the border line of satisfactory operation. Even under these extreme conditions, fuels with vapor pressures of 8.5 to 9.0 lb. per sq. in. would appear to provide a suitable factor of safety.

Fig. 4 indicates that any fuel which will operate an airplane engine for several minutes on the ground will be satisfactory in that fuel system from a vapor-lock viewpoint under all other conditions. It does not follow that a fuel which performed satisfactorily on the ground in a gravity-feed system would necessarily be satisfactory under all conditions of flight from a suction-feed system.

Another interesting observation in the flight tests with the Travelair plane was the fact that the gasoline temperatures in the fuel system were at no time in the course of the experiments as high as the temperature of the gasoline in the fuel tank on the ground before the take-off. With the rapid effect of air temperatures on fuel-system temperatures previously noted, this would indicate that a condition of vapor lock would be practically impossible in this particular installation, inasmuch as the gasoline, if susceptible of vapor locking, would be "weathered" in the fuel tank to such an extent that it could not again reach the "bubble point." The effect would be similar to that observed by Bauer where he noted that vapor lock could not occur in automobiles

equipped with vacuum tanks provided the vacuum tank was the hottest part of the fuel system. It is, of course, possible to conceive conditions of flight and of loading with gasoline which would invalidate this observation.

It has been suggested that the use of natural gasoline results in high cylinder-head temperatures. Some preliminary experiments have been conducted to determine this fact. The indications so far are that for fuels of corresponding anti-knock rating and with the proper adjustment of air-fuel ratios, there is no noticeable difference in cylinder-head temperatures.

The test results just submitted are not presented as conclusive. They are limited to the particular fuel system studied and the flight conditions of the tests so far conducted. The data have been presented as illustrative of the type of work being conducted under the present research program of the Natural Gasoline Association of America.

5 Other Investigations

Prominent in this field has been the U. S. Bureau of Standards, which is doing excellent work in providing a better understanding of the fundamental factors involved in vapor pressure, vapor lock, A.S.T.M. distillation data, and engine performance by means of laboratory investigations. With the continually augmented supply of volatile gasolines, it is absolutely necessary for all interests concerned to consider gasolines from an entirely different viewpoint than formerly. The Bureau of Standards has made some valuable contributions to this end.

Although not directly on the subject of aviation gasoline, the investigations conducted during the past three years at the University of Michigan under the direction of Dr. G. G. Brown and sponsored by the Natural Gasoline Association of America have a very close relation to the subject. The research work referred to is a very comprehensive study of the effect of volatility on motor-fuel performance.

Many industrial laboratories and organizations have contributed to the general knowledge concerning fuel qualities. For the benefit of those interested in the subject, an incomplete bibliography is appended, with special emphasis on those articles which have a bearing on the use of aviation natural gasoline.

Although there are many advantages in the use of more volatile fuels, such as ease of starting, improved warming-up characteristics, superior accelerating ability, and higher anti-knock ratings, the introduction of these fuels is not without its entries on the other side of the ledger. The problem of vapor locking is a very definite liability, and a factor to be seriously considered. Due no doubt to its pronounced commercial success, there has been a marked tendency to attribute this relatively new factor in gasoline performance to the activity of the natural-gasoline industry. But it cannot be too strongly emphasized that aviation natural gasoline is but one of the several manifestations of an economic condition which clearly indicate the gasolines of the future will be decidedly more volatile than those of the past. The surveys of motor and aviation gasolines cited in this paper clearly demonstrate this trend. And as certain as is this trend, it is just as certain that the designers of gasoline-consuming units have not kept abreast of the times. Automobiles continue to appear on the market with fuel systems so located that it appears a deliberate attempt had been made to heat the gasoline to the utmost on its path to the carburetor needle. In the airplane industry, safety is an added inducement to keep the gasoline removed from zones of high temperature. Moreover, the airplane industry is young and without the burden of tradition, so that the application of sound engineering principles is not so difficult. With the trend toward more volatile fuels receiving so much emphasis at this time, the airplane industry can well afford to keep a watchful eye on the design of its fuel systems.

Discussion

H. K. Cummings.[2] The Phillips Petroleum Company has made an important contribution to information regarding the commercial aviation gasolines available today by permitting Mr. Alden to give in Table 3 complete laboratory data on 126 samples representing 27 different brands of gasoline as sold at various airports between November, 1929, and July, 1930. It is hoped that arrangements can soon be made for a semiannual aviation gasoline survey to be undertaken by the Department of Commerce.

The anti-knock ratings reported in Table 3 and those shown graphically in Fig. 2, like all ratings expressed in terms of a particular reference gasoline, are difficult to compare with results obtained in other laboratories, even though the author furnishes the additional information that his reference fuel required 7.3 per cent aniline to equal the 1929 "Ethyl Standard" for motor gasoline. An approximate evaluation of this gasoline-aniline scale in terms of octane numbers, as recently recommended by the Detonation Sub-committee of the Cooperative Fuel Research Steering Committee, would be very helpful. The octane number of a fuel is defined as the percentage by volume of iso-octane (2-2-4 trimethyl pentane) which must be mixed with normal heptane to give a blend having the same tendency to knock as the fuel in question. The octane number of his 7.3 per cent aniline blend would be about 72, while the octane numbers of most straight-run Pennsylvania gasolines are between 40 and 50.

In connection with the author's conclusion 3 (*f*), Dr. Bridgeman's work shows that the Reid vapor pressure can be determined from the A.S.T.M. 10 per cent evaporated temperature, if allowance is made for the slope of the distillation curve at

[2] Bureau of Standards, Washington, D. C.

that point, provided the gasoline is propane-free or contains a known percentage of propane. As a corollary, the propane content can be calculated from the Reid vapor pressure and the distillation data.

It should be noted that the temperature data presented in Fig. 3 apply only to a single airplane. For a given initial gasoline temperature, the spread between air temperature and gasoline temperature at altitude varies widely in different types of airplane. From data already obtained on fuel-line temperatures in seven types of airplane during flight, it appears that the temperature of the gasoline in the main tank when the airplane leaves the ground is the most important single factor as regards vapor lock. The volatility of the gasoline and the design of the fuel system are of course the other factors. In some installations it may be desirable to provide means for cooling the gasoline as it leaves the fuel tank.

As pointed out by the author, weathering of the gasoline in the fuel tank affords some factor of safety. The amount of weathering depends on the rate of climb and the size of vent provided. Tests at the Bureau of Standards indicate that weathering is ordinarily negligible up to the vapor-locking temperature. If vapor lock does not occur when the gasoline first starts to boil, weathering will probably take care of it.

J. H. Doolittle.[3] This is an extremely well-written paper, and the author handles the subject in a masterly fashion. On a few points the writer either does not quite understand Mr. Alden or is not in complete agreement with him. He stated that the Federal specifications took cognizance of vapor pressure. This has been true in the past, but the new Army specifications will, it is believed, limit the Reed vapor pressure to 6½ lb. The military specifications are of course somewhat more strict than those required for commercial use, as military airplanes usually have the gasoline tanks located in the wings and employ a pump to deliver it to the carburetor. This pump sometimes imposes a negative pressure head on the gasoline in the line, especially when the fuel tanks are almost empty. In commercial work the gasoline tanks are generally located in the wings and gravity feed is utilized. Furthermore, in military work, especially with supercharged engines, the airplanes are sometimes obliged to operate at extremely high altitudes, so high that the temperature becomes constant while the pressure continues to decrease. This has the effect of steepening the dotted curve and will tend to bend it over toward the vapor pressure curves shown on the right-hand side of the sheet.

Although a maximum temperature difference between the gas-line temperature and the outside-air temperature was found to be 15 deg. in the Travelair tested, in our Travelair "mystery" plane, with its poor ventilation and N.A.C.A. cowling, this temperature difference was of the order of 30 deg. In this airplane in hot weather we experienced gas locks several times when testing out gasoline of moderately high vapor pressure. Frank Hawks in one of his first test flights in a smaller airplane had the motor stop, and the writer is quite sure that this was due to vapor lock. In both his plane and ours, ventilation systems were arranged to take in cold air at the leading edge of the wings and pass it around the gasoline system. In this way the temperature difference between fuel system and outside air was substantially reduced and no further difficulty with gas lock was experienced. Mr. Alden states that fuels with a vapor pressure of from 8½ to 9 lb. per sq. in. would appear to provide a suitable factor of safety. Considering Fig. 4, suppose it is assumed that Yuma, Ariz., is located approximately at sea level (200 ft. above). The temperature there this summer was 112 deg. Adding to this the 15-deg. difference found in their Travelair, we found the maximum vapor pressure to be 8.8 without any factor of safety, and if the vapor pressure in our own Travelair is considered to be 8.8 with a 30-deg. temperature difference, the maximum vapor pressure is 6.8. Even this does not take into consideration variations in barometric pressure at any given point. Added to this there is sometimes, up to altitudes of 4000 ft., a temperature inversion where the temperature at altitude is actually higher than the temperature at the ground. This phenomena is most common in the winter time, but has been observed even on very hot summer days.

[3] Aviation Department, Shell Petroleum Corporation, St. Louis, Mo.

Robert E. Wilson[4] and Daniel P. Barnard, 4th.[5] The author is to be congratulated for his most thorough survey of the composition-vapor pressure characteristics of aviation gasolines. To the best of information it is the most complete yet published, and should be of considerable assistance to the further development of these fuels.

It has been the writers' experience that fuels of rather high vapor pressures may be used under many conditions with no signs of vapor lock, and to this extent there is complete accord with the author. Unfortunately, however, the fact that such fuels may be used in the majority of instances does not give them a clean bill of health, as there always exists the possibility that some combination of circumstances may cause a fuel system to vapor-lock under the most embarrassing conditions. Most of the commercial transport planes now in use will handle a fuel of, say, 8 or 8.5 lb. Reid vapor pressure with entire success under normal conditions. Let the air temperature rise to 100 or 110 deg. fahr., however, as frequently occurs in summer in the southern half of the country, and vapor lock with such a fuel not only becomes possible, but in many planes it is probable. Furthermore, it appears to have been quite definitely established that current military equipment cannot safely utilize a fuel having more than 6.5 to 7 lb. Reid vapor pressure.

It is unfortunate that the author does not express his knock ratings in terms of iso-octane and normal heptane. Experience indicates, however, that natural gasolines of the highest practicable volatility do not possess knock ratings even near the 74 per cent iso-octane–26 per cent *n*-heptane which is evidently required for the engines built concurrently for transport and military use. It is worthy of note that a fuel such as natural gasoline having 90 per cent evaporated at, say, 230 deg. fahr. responds quite readily to the addition of tetra-ethyl lead much more readily than motor gasolines or even gasolines corresponding to D.A.G. specifications. Unfortunately, this method of improving the anti-knock value of natural gasoline cannot be generally used today because certain metals used in aircraft-engine construction are attacked by the products of combustion of ethylized gasoline. This difficulty has been entirely overcome in automobile engines and is being overcome in aviation engines, but for the present it does not seem safe to market it for general use with the wide variety of equipment at present employed in military, transport, and private flying.

C. M. Larson.[6] The facts that the author has presented show clearly how progress and engineering data make it possible to overcome objectionable stipulations. By this is meant that during the World War the Navy Department specification 8-G-1-B, Sept. 1, 1917, used by both the Army and Navy Air Services, prohibited the use of natural gasolines, as shown by the following extract:

"*Aeroplane Gasoline.* Quality: To be high-grade, refined,

[4,5] Standard Oil Company (Indiana), Chicago, Ill.

[6] Supervising Engineer, Sinclair Refining Company, New York, N. Y. Mem. A.S.M.E.

and free from water. . . . No natural-gas gasolines shall be accepted nor shall they be mixed with any gasoline submitted for acceptance."

However, the objection to the use of natural gasolines in part or in whole has been dropped from all aviation gasoline specifications in effect today.

The main trouble experienced from natural gasolines when used in aviation engines is that of "gas locks." The chemical constituents of natural gasolines have been isolated and their respective vapor pressures studied, as shown in Fig. 5. By

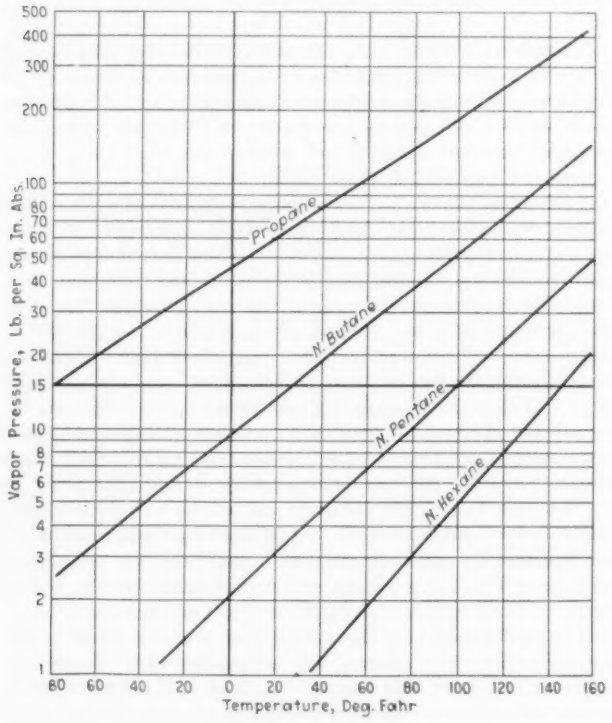

FIG. 5

knowing the constituents to remove to overcome vapor locks, and by their extraction, it is possible to control the vapor pressure of any gasoline at the desired 10 per cent over point, as plotted in Fig. 6.

The question of suitable fuel for private and commercial aircraft purposes has been a subject of wide discussion during recent months throughout the United States. From the fuel producer's standpoint, development of an improved normal fuel with a proportionate and yet reasonable increase in cost is necessary so that the engine manufacturers will be in a position to offer an improved product to the operator. Just how far and how fast this improvement in the Federal Specification Board's Domestic Aviation Gasoline Grade B (Department of Commerce Technical Paper 323B) can be made, depends on the economic distribution and availability of the product as well as the standardization of the aircraft-engine manufacturer's requirements.

The petroleum and aircraft engine industries will welcome the day when the working out through proper channels of

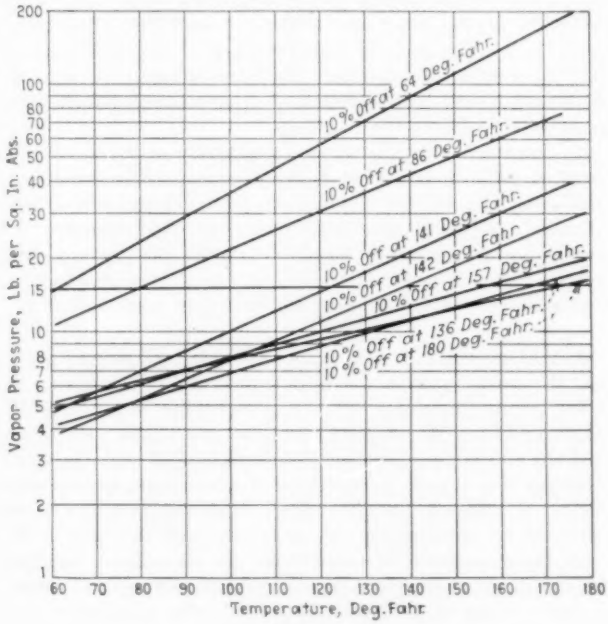

FIG. 6

specifications of two grades of aviation gasoline are arrived at—one aviation gasoline with a reasonably high anti-knock value, to be used for private flying and aerial service as well as by scheduled transport consumers, and perhaps one other, but not more than one, additional specification to cover aviation fuel for the Army and Navy and such scheduled transport lines as well as those consumers that may desire to use supercharged engines, all of whom find it necessary to go to compression ratios higher than 5.1 to 1 for air-cooled engines.

Until this is done, the oil companies c nnot afford to plan national distribution for a demand equivalent to only that used by 50,000 automobiles, as compared with the 26,600,000 automobiles operating over the same territory.

AER-53-7

Commercial Aircraft Radiophone Communication

By ROBERT H. FREEMAN,[1] OAKLAND, CALIF.

The need of dependable two-way aircraft communication has emphasized the service requirements as they are presented to the pilot. The equipment must be light and yet rugged, and as the essential parts are placed at a distance from the pilot, they must be simple of operation. The paper, without stressing the electrical-engineering side of the air-communication problem, covers the actual mechanical set-up. The mechanical and electrical difficulties encountered in shielding the ignition system and the complete bonding of the ship are discussed in detail. The placement of the component parts for ease of operation is taken up and the subsequent maintenance of the equipment is briefly outlined.

IN the last year the need of reliable two-way aircraft communication has been brought before the engineering world in a manner only too realistic and vivid. Every week situations arise which could have been foreseen and most probably avoided if there had been two-way radio-telephone communication between the aircraft and its home station or field. There have been presented many papers before different bodies of engineers detailing the great need for this service, and some of the papers have dealt with the theoretical and practical electrical-engineering side of the question, but so far little attention has been paid to the actual service problem as presented to the operator of the aircraft.

In the past engineers have sat at their desks and designed equipment to fulfil certain needs without first ascertaining the conditions under which this equipment would be used. Later nearly all this equipment has been changed to suit the operating conditions. This is even more true in the air-transportation game. As will be pointed out later, there is equipment now manufactured to accomplish certain tasks, which it will do in the laboratory, but which fails under the tests given it by the air-transport operator. He has schedules to maintain and life to protect, and cannot afford to take any undue risks in the way of poor equipment.

The requirements for apparatus to fill this general need of communication are many and varied. The equipment must be light in weight, small, compact, and rugged enough to withstand rough handling and continuous vibration. In the mail ships the essential parts of the equipment must be located at a distance from the pilot, and must be simple in operation as he is unskilled in the manipulation of radio equipment. The apparatus should be designed so as to permit ready removal, and substitution of duplicate equipment in the short space of time it takes to oil and gas a ship.

[1] Communications Engineer, Boeing Air Transport, Inc., Oakland Municipal Airport. Mr. Freeman was born May 22, 1903, in Chicago, Ill. He received the B.S. degree from the University of Colorado in 1925. He was with the Bell Telephone Laboratories in the Radio Transmitter Development Department from 1925 to 1929.

Presented at the Aeronautic Meeting sponsored by the Aeronautic Division and Pittsburgh Local Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS and the Engineering Society of Western Pennsylvania, Pittsburgh, Pa., March 12, 1930.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

PREPARATION OF THE SHIP

Shielding. Because of the low powers of the transmitters on the ground the receivers on the ship must be unusually sensitive to obtain reliable communication. The gain of the receivers must be of the order of 120 decibels. With this enormous gain the interference problem is a very serious one, and before reception may be had at a distance of greater than 10 to 15 miles using 400 watts of power on the ground, all sources of electrical interference on the ship must be eliminated.

The greatest offender is the ignition system. This must be completely covered with metal in order to cut the disturbance to a point where it no longer hinders the reception of the voice signals. Shielding equipment has been turned out by various manufacturers and most of this has been tried. In all cases the apparatus failed in one of the two following manners. Either it did not shield at the frequencies employed, which were 5660 and 3172 kilocycles, or if it did shield, it did not last more than a few hours when flown over the regular mail route from Oakland to Reno. The whole situation simmers down to the fact that the designers of the equipment did not have a first-hand knowledge of the service conditions encountered. From the theoretical viewpoint the equipment was fine, but failed miserably when applied to practice.

The air-transport operator was not in the game of designing and building shielding equipment, but was forced to it by the lack of cooperation received from the manufacturers of aircraft engines and accessories. Not being versed in the art, it was a long and tedious process, but there was evolved a harness which completely eliminates the interference from the ignition system when using a receiver having a gain of 120 decibels.

The problem divides itself into three heads: Shielding the spark plugs, shielding the leads from the plugs to the magnetos, and shielding the magnetos. Although these three were worked out simultaneously, they will be taken up in the order named.

The problem of shielding the spark plug was a hard one to attack, as it must be kept in mind that one is dealing with high voltages of the order of 15 to 18 kilovolts. Space is at a minimum where the plugs fit on the back side of the engine and the plugs must be kept fairly cool. A good many types of cans were tried in which the standard plug was placed, but these proved to be a failure, either being unserviceable or impairing the efficiency of the motor. At this time a manufacturer of aviation plugs put out a shielded plug that seemed to be the answer to the situation. It was very effective in shielding and seemed to be readily serviced. They were used on the test ship for many flights while the other parts of the system were being worked out. Then they were placed on the regular run, and the plugs failed regularly after about 40 to 50 hours of service. The idea of a can was revived, and many types were tried to obtain a device which would shield the plug, stand up mechanically under the abuse of the service crew, be light in weight, low in cost, and in no way affect the operation of the

engine. Many weeks of experimenting passed before the final model was obtained. The plug itself is only a slight change from the plug used by many air-transport operators. This change is in the design of the jamb nut which holds the plug together. The nut is run up a little over $^1/_2$ in., forming a tubular sleeve with a groove at its base. Of course this nut has to be made first and the plug built up on the nut. However, this is no drawback as the manufacturer can supply them in a short time. The cap which fits over the plug is made of nickel steel, and the prongs, which fit down over the plug sleeve, and clamp into the groove at the base of the nut, are tempered so that they hold the spring action which is imparted to them during manufacture. At the top of the cap there is a gooseneck which reverses the direction of the wire in a rather short arc and heads it back toward the direction of the harness. This gooseneck also forms a convenient handle for removing the cap from the plug. At the end of the gooseneck there is an enlargement which is split, and allows the harness to enter and then be clamped up, thus forming a good electrical shield and an oil-tight joint. Inside the cap there is placed an insulator which fits down over the center electrode of the plug inside the nut sleeving. This forms a long path for the electrical energy to jump across or leak through. In the top of the center of the insulator there is placed a small spring and screw which connect the top of the plug to the wire entering the cap. All this can be seen readily by referring to the illustration of the shielded spark plug. This plug

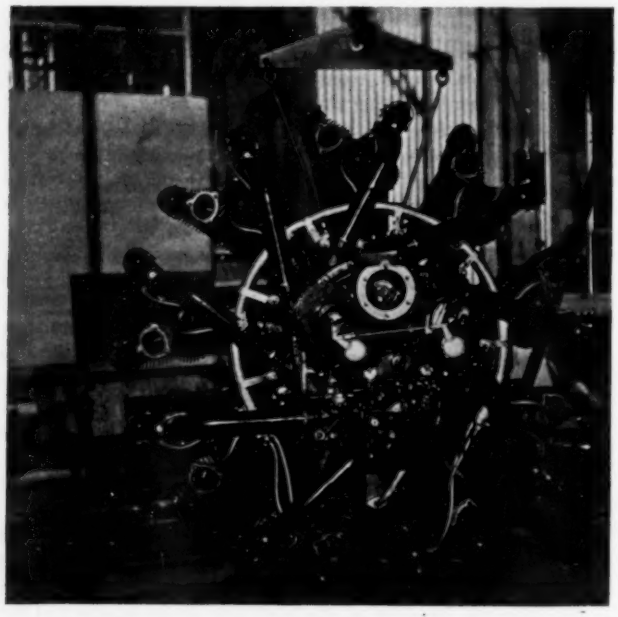

FIG. 1 OLD-TYPE SHIELDED HARNESS

is now in daily use on the lines of the Boeing System and other air-mail lines. The cost is nominal and the replacement of worn-out parts is practically the same as with the unshielded plug. The serviceability is even less complicated than with the open type of plug, for there is no need of tying the parts for safety, and upon the removal of the cap the plug can be removed from the cylinder as readily as with the regular type. As for the protection of the plug in stormy weather, there is no question as to its effectiveness. This plug is the only one to date being manufactured in quantity which is inexpensive, effectively shields the radiation of electrical energy, and will stand the "gaff" of repeated servicing by mechanics.

The shielding of the leads from the magnetos to the plugs while not so difficult was just as important. Belden braid or woven copper braid was first used to cover the wires and proved to be a very good electrical shield. However, after about 4 to 5 hr. in the air the ignition noise again became bothersome and at 10 hr. was sufficient to preclude any reception beyond about 15 to 20 miles. It developed that the cause was the oil soaking of the braid which insulated each strand from its neighbor enough to impair the effectiveness of the shielding. Many types of this woven braid were tried, but all failed after a few

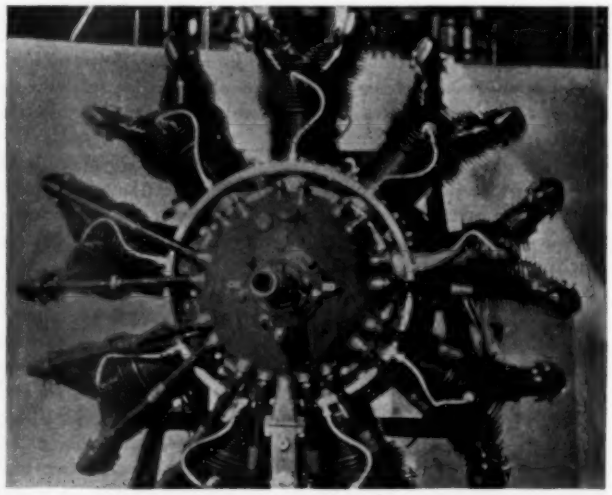

FIG. 2 NEW-TYPE HARNESS, FRONT VIEW

hours in the air or had received a few servicings by the ground crew.

The next step was the use of solid aluminum tubing which would stand a great deal of use as well as abuse. It consists of a main aluminum ring placed behind the cylinders. From this ring a small tube leads to each individual spark plug and a large "horn" carries the wires from the ring to the magnetos. To allow the servicing of the plugs and the magnetos it was necessary to use double braid from the ends of the tubes to the plugs and magnetos in order to get the desired flexibility. The braid was covered with tape and shellacked to prevent oil saturation. While this effectively shielded the disturbance it did not allow the desired ease of application of the harness or repeated servicings which are necessary in the air-transport business. The solid tubing did not stand up under the continual vibration and had to be replaced fairly often.

All sorts of flexible hose, tubing, and the like were tried, but none of them gave all the qualities desired, which were flexibility, shielding, and oil and mechanical protection to the ignition system. As the braid was a good shield and flexible carburetor hose was oil and mechanical protection, the two were combined, placing the braid inside the hose, and the long-looked-for result was achieved. The new harness still has the main aluminum ring, but with the small flexible leads running to the spark plugs, and also a large flexible tubing to the magnetos. The braid is used only where the tubing is flexible, thus saving weight and cost of shielded ignition wire with its accompanying corona losses and deterioration. This harness gave the necessary shielding, ease of application, would withstand innumerable servicings, and was inexpensive. The size of the tubing is such that if one wire becomes unusable it may be withdrawn and a new one pulled in. This is a big factor in the maintenance cost which was overlooked by several manufacturers, in that part of

their harness must be thrown away if one wire becomes damaged.

The shielding of the magnetos was a relatively simple matter. The one thing, however, that had to be kept in mind was the necessity of being able to remove all the magneto-distributor blocks without loosening or removing the magneto from the motor. This is easy to do if the motor is not equipped with an inertia starter, but as most ships now have starters of this type

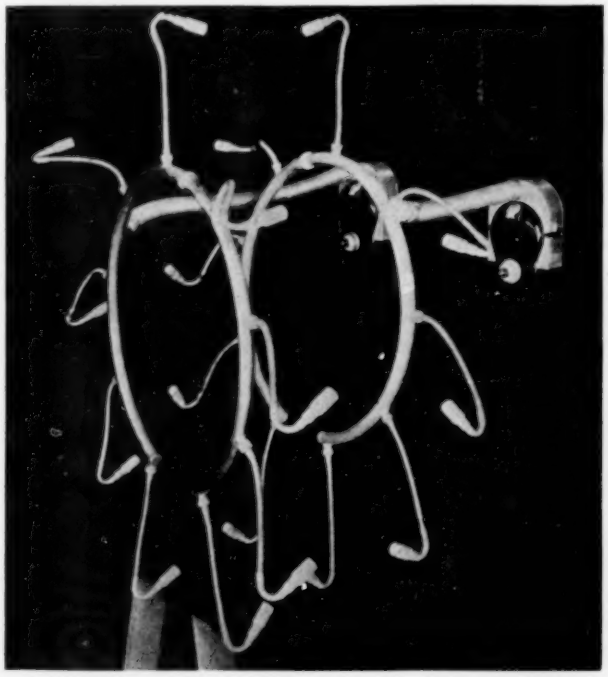

FIG. 3 SKELETON SET-UP SHOWING RELATIVE POSITION OF HARNESS AND MAGNETO AS MOUNTED ON A PRATT & WHITNEY MOTOR

some method had to be used to overcome this difficulty. The illustrations of the magneto shields are self-explanatory. The shield consists of two aluminum sheets bolted on to the magneto, and a band of spring bronze which covers the gap between the plates. In the front of the shield is a removable block with the outlet tube. This comes out when the blocks are removed to facilitate the operation and makes for a stronger shield. The booster and ground wires which have to be shielded make their exit at the rear of the shield through small tubes fastened in the rear plate. This allows the shielding on the wires to be readily attached to the magnetos. The spring band is held together with a toggle catch, making it very easy to open the shield for inspection and servicing. The cost of this shield is less than half that of any on the market and the weight is considerably reduced over the cast-aluminum type.

Thus a complete covering of metal for the ignition system is provided which suppresses the interference to a point where it is not audible in the receivers with their enormous gain. This covering does not interfere with the operation or maintenance of the ship and stands up under all the conditions encountered on the transcontinental and coastal lines of the company. It must be remembered that all this work was done using high frequencies, and does not necessarily apply to the intermediate frequencies used by the Department of Commerce for Radio-Range and Weather Services. However, a ship equipped for the high frequencies is better able to make use of the intermediate frequencies.

BONDING

Another source of great interference in the reception of the signals was the discharge of the static electricity in the different parts of the ship. It was not enough that the ship was bonded according to the Department of Commerce regulations. Every place that one piece of metal could rub on another was a source of interference. All joints had to be bypassed with a pigtail of copper braid soldered to both of the moving parts. The standard turnbuckle was replaced with a new type. This is essentially the standard type, but instead of using the brass safety wire a strip of bronze is wired and soldered on to the eye of the turnbuckle and run down past the hole in the barrel. The hole is slightly enlarged, and a specially made bolt provided with a half-moon-shaped head which holds the bronze strips from turning is inserted and fastened with a nut and lock washer. A piece of pigtail braid is soldered on to the eye, and passed across the joint to the wire or rod and is soldered there, thus making a continuous low-resistance circuit for all static charges.

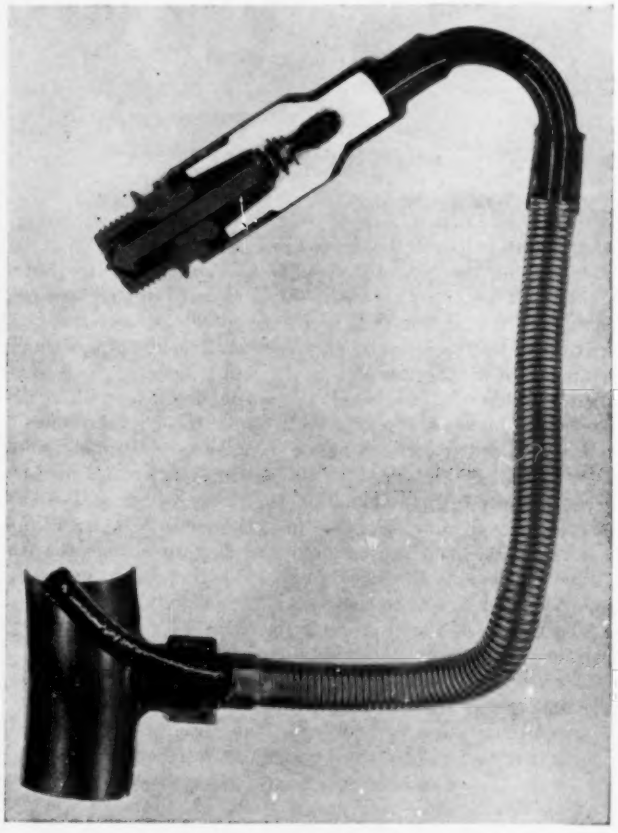

FIG. 4 NEW-TYPE HARNESS AND SHIELDED PLUG, WITH WHITE INSULATOR

All the wires in the ship are either shielded with the copper braid or else run in conduit. Wherever possible the conduit method is used as it permits the replacing of wires with the minimum of labor and expense. When the ship is equipped with a high-frequency transmitter, it is imperative that all the wires are completely covered with a grounded shield as otherwise they will pick up the energy and either burn out or at least absorb enough of the already too small energy being radiated from the antenna system.

Ship's Radio Equipment

The electrical qualifications for the radiophone equipment on the ship are easily enumerated, but not quite so readily arrived at. First, the transmitter must have as great an output, with the power input on the high-voltage side not exceeding 400 watts. Second, it must have an extremely stable frequency. Third, the percentage of modulation must be above 80. When these are combined with light weight, ruggedness, ease of operation, and compactness, one gets an idea as to what the problem is.

For phone communication the best antenna power available from the limited input is in the neighborhood of 50 watts. This

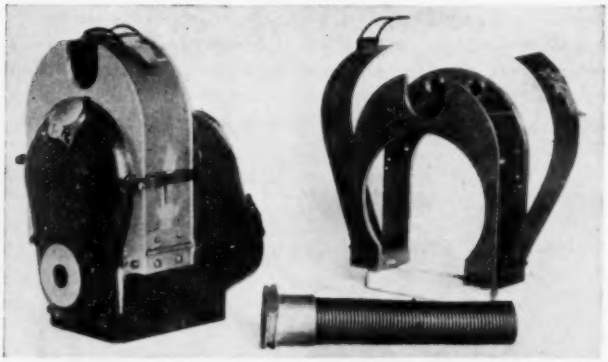

Fig. 5 Detail View of Magneto Shield

is sufficient to cover the same distance from the air that the 400 watts on the ground is capable of. To hold the frequency stable with the vibration of the ship and under such a high percentage of modulation it is necessary to employ quartz-crystal control of the oscillator. This crystal is held at a constant temperature by the use of a heater and a mercury thermostat. The crystal works at one-half the output frequency and a frequency-doubler tube is employed to obtain the desired frequency and also to act as a sort of buffer stage between the modulating tube and the oscillator. This is necessary since to obtain such a high percentage of modulation the plate voltage of the output tube has to vary from zero to twice normal value, and this will reflect back on the oscillator, tending to change the frequency. The use of this system holds the frequency as constant as is necessary to overcome distortion from shifting carrier.

The weight of the transmitter is about 32 lb., and the apparatus occupies a relatively small amount of space.

The receivers are of two types: The high-frequency one for the reception of the two-way ground transmitters, and for two-way communication with other ships; and the low-frequency one for the reception of the Department of Commerce weather stations and radio-range equipment. These receivers are extremely sensitive, as has been pointed out, having an overall gain of better than a million. They weigh 13 lb. apiece, and are remotely controlled by the use of a high-speed tachometer shaft so designed that there is very little or no backlash in the tuning of the receivers. The volume is controlled by the pilot, the units being situated just above the throttle, as can be seen by reference to the illustration. The two volume controls are at the right side and the two tuning controls at the left side. In the lower right-hand corner, the main off-and-on switch may be seen. After the equipment has been placed in the standby position the pilot merely presses a button on his stick and talks into the microphone, and to listen he removes his finger from the button. Thus the equipment is made as simple of operation as is possible so that the pilots will make ready use of the equipment and not be overtaxed trying to remember "how this new-fangled thing works."

The extent to which this simplicity of operation has been pushed can be seen from the final models of the radio helmet. The microphone is held in front of the pilot so that he has his hands free to manipulate the controls of the ship but arranged so that it can be pushed up or down out of the way. The receivers are of a special light-weight construction, weighing less than an ounce. Attached to the receivers is a molded ear-piece shutting out external noises, and putting the signal into the inner ear where it does the most good. Thus the acoustical problem has been somewhat solved. The power supply for the transmitter and receivers was given a great deal of thought, and only after trying out all the available types was the present one chosen. It consists of two dynamotors, one for the transmitter, and the other for the receivers. The transmitting dynamotor derives its power from the ship's storage battery and delivers 1050 volts at a current drain of 400 milliamperes. The smaller machine also derives its power from the storage battery, but delivers only about 200 volts. This supplies the "B" and "C" power for the two receivers.

The reason for choosing this equipment is that it is always available for use whether the ship is in the air on the ground with a dead motor. The engine-driven generator cannot be used when motor failure occurs, and the wind-driven type cannot be used to any advantage when the ship is on the ground, especially if the motor is out of commission.

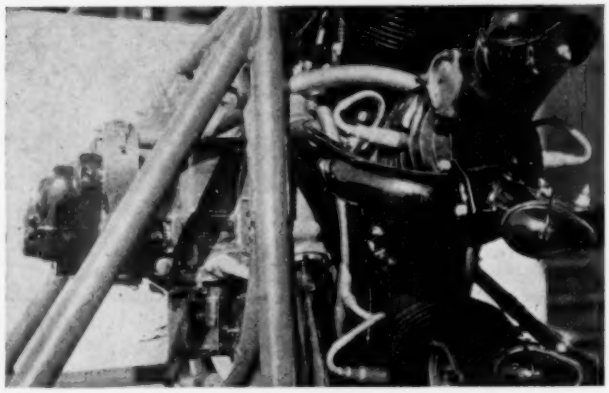

Fig. 6 Rear Ring Magneto and Shields

The two dynamotors with their control equipment and filter systems are mounted on a frame which can be removed from the ship and another inserted in about two minutes' time. The connections are made with a multi-terminal plug and jack box. All of the equipment which has a possibility of failing in service is arranged for ready removal and replacement by tested units.

Antenna System

In the past practically all radio work done on ships used the trailing-wire type of antenna. This is not satisfactory from a good many angles, as there is considerable head resistance, the lead "fish" dropping off every once in a while, and having been known to cause loss of life, and in flying the air mail from Chicago to San Francisco, many times it is necessary to fly at an altitude which precludes all possibility of any hanging wires.

The mast type of antenna is used for the reception of signals, and also for transmission on the daytime frequency which is 5660 kilocycles. When using the 6-ft. dural mast for the night frequency of 3172 kilocycles, the effective radiation is so reduced that the proper coverage is not obtained. To overcome this

difficulty two wires are run from the front-wing spar on either side of the gas tank to the top of the mast and then back to the vertical fin. With this antenna, transmission can be effected when the ship is on the ground without the pilot's running out a wire to the nearest fence post and retuning his transmitter. The wires also tend to steady the mast.

The transmitter on the ground end of the circuit is electrically the same as the aircraft transmitter with the addition of a power amplifier which boosts the power from 50 to 400 watts. It has the same crystal control and the units are interchangeable, so a smaller number of spares are needed. The power is derived from a double-voltage three-phase 220-volt rectifier. This supplies the power stage with 2500 volts, and the rest of the transmitter with 1000 volts. It makes use of the newly developed hot-cathode mercury-vapor tube for rectifying.

The transmitter and rectifier are housed in separate frames, but are placed on the operating table alongside each other. This makes a very compact set-up and has proved entirely satisfactory. The receiver is of the same type as the high-frequency receiver used in the ship. The remote tuning mechanism is removed and a knob is substituted for the ground work. Thus a smaller supply of spares is needed to take care of emergencies.

All of the stations are equipped with the teletype or telephone printer, which is a source of never-ending radio interference. After working with the installing companies for many months trying to get them to clear up the trouble it was found necessary to tackle this problem ourselves. As a result all of the machines in use at our stations are now, or soon will be, equipped

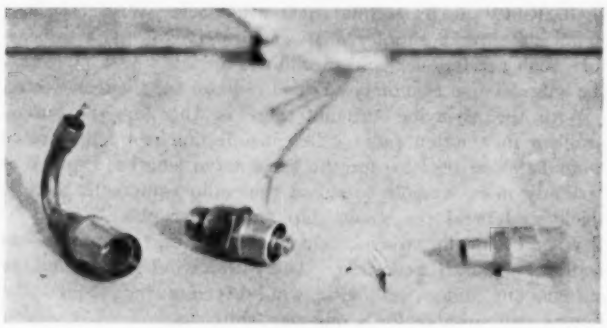

FIG. 7 SHIELDED SPARK PLUG, GOOSENECK SPRING, AND INSULATOR

with a rotating squirrel-cage type of induction motor. This removes the cause of the radio interference as the usual-type motor has five sparking contacts. The maintenance of the printer has been reduced and the reliability has not been impaired; in some cases it has been reported that the speed is more constant than with the governor type of motor.

SERVICE PROBLEMS

Each pilot fills out a card at the end of his run, giving the record of the performance of the ship and the radio equipment. If there is anything wrong with the radio equipment it is removed and thoroughly tested until the cause of the failure is found. Before a ship is allowed to be taken out on the line the radio mechanic gives the entire ship's radio equipment a test. Besides that he tests the condition of the battery and the generator. All of the readings are marked down on a form provided for that purpose, and this record is submitted to the radio man in charge. If the readings vary from the allowable limits it is the duty of the radio mechanic to find what the trouble is and fix it. No ship can go out until it has his check of approval.

If a ship comes in to one of the intermediate fields with something wrong in the radio equipment it is the duty of the operator in charge there to replace the defective apparatus with the spare and send the ship on its way. He then sends the apparatus to the nearest repair depot which is equipped to handle the repairing and testing of the apparatus. In this way there are no makeshift repairs which will lead to further grief, but a standard job is done which will stand up.

CONCLUSION

The results obtained from this system of two-way radiophone communication have more than justified the time and expense. It is a means whereby the lives of the pilots and passen-

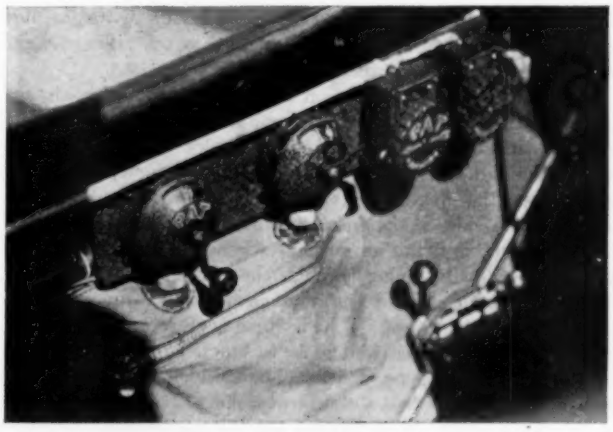

FIG. 8 REMOTE TUNING AND VOLUME CONTROLS AT LEFT SIDE OF COCKPIT ON MAIL PLANE

gers may be safeguarded and the loss of expensive equipment kept at a minimum. It is necessary to shield the ignition completely, including the spark plugs and all wires in the ship, and very thoroughly bond the ship if any reliable communication is to be hoped for.

The work as described is only the beginning of many interesting and varied problems of air-transport communication which will present themselves in the near future, but an idea is given of the problems confronting the operator of commercial planes in the installation and maintenance of two-way radiophone equipment.

Discussion

WESLEY L. SMITH.[2] The whole problem of shielding the ignition circuits is a very complicated one and it will probably be eliminated entirely as the Diesel aircraft engine comes into general use, as it now seems possible that it will. There will, however, still remain a low-voltage or combined low- and high-voltage generator whose output will need to be filtered to eliminate the high-frequency harmonics, and at the same time the electrical wiring and the battery will need to be shielded to absorb the last vestige of these high-frequency harmonics that may have got past the filters of the generator.

The all-metal airplane will eliminate most of the bonding that is now required. The control wires and all moving parts will be the only ones that need treatment in that type of plane. Radio reception in the all-metal plane is also much better than in any other type because the metal parts of the plane serve as the counterpoise or ground, and increasing the capacity of this counterpoise will automatically increase the signal strength

[2] Superintendent, Eastern Division, National Air Transport, Inc., Cleveland, Ohio.

received. This has already been demonstrated by practical flight tests in daily service operations.

High-frequency or short-wave radio communication has not proved as reliable in the eastern half of the United States as it has in the Far West, there being considerable skip distance and blind-spot effects. Because of the results that are obtained between San Francisco and Reno, they cannot be taken as conclusive for general use in this country.

The use of two separate receivers for high-frequency and intermediate-frequency reception is not now necessary since at least two manufacturers are building receivers with two systems of coils, oscillators, etc., so that the pilot, by throwing a switch, may receive in either part of the radio spectrum. This development will result in a considerable saving of weight, not only in the receivers themselves, but also in the added weight that is necessary for power supply.

Practical every-day operation for over a year with all airplanes of the National Air Transport, Inc., equipped with radio receivers has demonstrated that it is vitally necessary to have all of the radio control including tuning, volume, on-and-off switch, and the plug-in for the head phones located in one unit on the right side of the fuselage where it is easily accessible. The pilot who is flying an airplane where he really needs radio aid will usually be flying through the clouds, and then he has no time to hunt around the cockpit for the various controls that he may need to use. If he is flying in clear weather and has a lot of time to do these things, he has no need for radio.

The "Phonette" type of head phone, which fits inside of the pilot's ears, requires that a cast be made for that particular pilot's ears. As a result, these phones are not interchangeable, and were not considered for our daily operations on that account. The ordinary type of head phone that was commercially available was decidedly too heavy and too inefficient for aircraft use. However, a very light type of head phone is manufactured by the Dictograph Company for use with its dictographs. By changing the number of windings on these to get the proper impedance a very excellent type of phone results. After trying a great many methods it was finally found that these could best be mounted in pockets on the outside of the pilot's regular helmet and located directly over his ears. A small hole is then cut in the helmet opposite the opening to the ears and the results are very satisfactory. It has, however, been found very necessary to line these head-phone pockets to prevent the phones from freezing and becoming inoperative in sub-zero weather.

The matter of power supply for radio transmitters and receivers seems to be very much an open question. Batteries are heavy and a sufficient number cannot be carried for transmission purposes. A dynamotor, which is in reality a motor generator, is very inefficient because the current that is used must first be generated at low voltage and translated from electrical to mechanical energy and back again at a higher voltage in the dynamotor. There is an extra loss of efficiency in going through the dynamotor which can and does add both weight and power to the equipment that is needed. A wind-driven generator cannot be used, because its driving propeller would become unbalanced with a coating of ice in winter and thereby tear the generator loose from its mounting. The double-voltage generator which converts mechanical energy directly into the two voltages needed for filament and plate current seems to be the proper answer. A clutch and a third winding on the armature will permit its being used as a dynamotor on forced landings for power supply when the motor is dead. It is true that there are still some mechanical difficulties with the double-voltage generator, but it is felt that these can be eliminated. It is the lightest combination available that will provide the necessary power for the radio transmitter.

The radio interference caused by the motors of the teletype machines has been very satisfactorily eliminated by the American Telephone and Telegraph Company. This did cause some concern, but the proper combination of chokes and condensers properly to filter out the interference that was caused has now been found. This has all been accomplished without changing any of the motors.

It is a regular part of our radio procedure to have the radio men check the radio receivers with the motor running full on just before the plane is dispatched. A test that is made without the motor running has been found to be of little value since the motor introduces not only electrical interference, but also motor noise and vibration. The vibration may cause troubles in the radio receivers that interfere with reception and that are not present when the motor is not running. In addition to this, it has been found very necessary to check the pilot's head phones before each trip is started to be sure that these are functioning properly. Some of the trouble where receivers seemed to be weak turned out to be due to poor head phones.

C. Francis Jenkins.[3] The author's cleverness in working out the usual ignition-shielding solution of the airplane radio problem deserves commendation, but why locate the antenna in the radiation field of the engine-ignition system? There is a much better place for it, where shielding of engine and bonding of plane are unnecessary. Behind the fire-wall of the plane is an electric, interference-free shadow. An antenna located in this shadow does not, therefore, pick up any ignition trouble. And in the wake of the plane the antenna can be as long as desired, held taut by a miniature wind-sock. With this long signal collector, a simple 25,000-gain receiver is more satisfactory than a 6-ft. mast and a million-gain set. And, of course, the long antenna also makes a good radiator for the transmitter.

With the aft-flying antenna there is, therefore, no special problem in aviation radio. The installation can follow usual ground-station practice for the same wave lengths. And it is certainly more sensible to shield the radio equipment than to shield and bond the whole ship and power plant.

With a Zeppelin twisted, neutralized lead-in, the antenna can be flown as far aft as desired. And with a wind-sock to pull the antenna out, and an automatic, wind-driven rewind, the installation is still suitable for a one-man ship.

The writer flies a four-place cabin plane with a J-5 engine, 225 hp. The engine is not shielded, nor is the plane bonded in any way. With this plane to work with, the facts herein stated have been verified in actual practice.

Frankly, as a radio engineer, the writer would have felt chagrinned to have been obliged to ask the engine manufacturer to help work out his radio problems. Fortunately he did not need to do so.

Better than all else, this construction does not require the nuisance of a shielding which confessedly jeopardizes the lives of passengers by ignition short-circuits which involve forced landings. Ignition harness and plane bonding is absolutely not required in aviation communication.

Author's Closure

Since the paper was written, numerous improvements have been made on the equipment, mainly in the type of harness used on the ignition shielding. The present type of harness now consists of a double horseshoe or distributor ring, one located in front of the cylinders and the other behind, thus doing away with the necessity of running the leads for the front spark plugs over the end of the cylinders.

Instead of using the Belden braid covered with flexible conduit,

[3] Jenkins Laboratories, Washington, D. C.

a new type of flexible conduit has been developed which in itself is a very good shield. This conduit is also completely oil and water-tight. The fittings, instead of being clamp fittings as before, are now the screw type so that the whole harness is completely weather- and oil-proof. The pictures will show this very clearly.

Since using this new type of harness, the service time has been decreased appreciably. After original installation, it is not necessary to service this type of harness until it is removed from the motor at time of overhaul. The condition of the wire as removed from the harness, after a 300-hour period, is such that it can be used for at least another 300 hours. If it is necessary to rewire one of these harnesses, a man that is acquainted with the method can readily do this in two hours' time. This is a decided improvement over the former type, where it took one man eight hours to rewire the harness. There are many other advantages to the new type which are self-evident.

There have been small improvements made on the rest of the equipment, but nothing of great note. A few of these are shown in the pictures, however.

AER-53-8

Plywood in the Aircraft Industry

By JAMES R. FITZPATRICK,[1] CHICAGO, ILL.

Although plywood is used for nearly all parts of airplanes, its most general use is in wing construction. It is used for wing covering, leading edges, spar webs, gusset plates, cover plates, nose pieces, and tail pieces. The author in this paper tells of joining methods, results from use of plywood in shear, and takes up typical examples of its use in airplane construction.

IN WOOD, nature has given to mankind a light, strong, and stiff material of construction. These characteristics, together with workability, beauty, durability, and abundance of supply have made it a favorite with artizans ever since the dawn of civilization.

Various fabrication methods of wood have been developed, both for artistic and structural purposes. These methods of fabrication have been characterized in general by an overabundance of strength of the individual wood members and by comparatively weak jointing of the several members. With the advent of the present-day development of light-weight transportation mediums, notably in the automotive, electric-railway, ship, and aircraft industries, more balanced constructions have been needed and found. The weights of individual members have been reduced, and the strength of the ties between members increased.

As examples of this change may be mentioned, (1) the use of molded-plywood panels for the roofs of buses and street cars, (2) the use of plywood panels for stateroom partitions on ships, and (3) the use of diagonal plywood panels for the webs of aircraft spars.

Laminated wood and plywood were originally developed to increase the artistic appeal of furniture. Thin veneers of figured woods were glued to ordinary woods, and often successive slices were matched together to give an attractive grain pattern. This art has been well developed and is much used today. The glues used for this purpose, however, were satisfactory only because the finished product was usually well protected from extreme atmospheric changes. They did not possess good weathering qualities.

[1] Vice-President and Secretary, Haskelite Manufacturing Corp. Mr. Fitzpatrick received his education at Cornell University and Rensselaer Polytechnic Institute, graduating from the latter school with a degree of Civil Engineer. He was construction engineer with an automobile company in Detroit, later vice-president and general manager of the Grand Rapids Hydraulic Company. During the World War, he was factory manager of the Haskelite Manufacturing Corporation, which turned out aircraft plywood for the United States, England, and France. Mr. Fitzpatrick is a section Vice-President of the Aeronautical Chamber of Commerce, is chairman of the Accessory-Material Section, and is a member of the Show Committee and Membership Committee. He has been on the aviation committees of the Illinois Manufacturers Association, Chicago Association of Commerce, and the Chicago Rotary Club. He has just completed a term as chairman of the Manufacturers Section of the Automobile Body Builders Association, and was recently made a member of the executive committee of the American Electric Railway Association. A former trustee of the Rensselaer Polytechnic Institute, he is also a member of the Society of Automotive Engineers, American Society of Civil Engineers, and the Aeronautical Chamber of Commerce.

Presented at a meeting of the Aeronautic Division with the Chicago Section, Chicago, Ill., August 25, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Plywood as an Engineering Material

Plywood is, of course, no stronger than the glue which binds its veneers, and it was not until the introduction of water-resistant glues that plywood could be considered an engineering material. It is understood that an engineering material has definite physical properties, such as weight, strength, elasticity, and hardness. It will have properties which can be relied on to such an extent that structural and other parts can be designed from this material so that their strength and other properties will be appropriate to the loads which the parts are expected to carry or to the service which they are expected to give. For example, shingles are not used in design to carry particular loads; they are not structural parts and cannot be considered an engineering material. On the other hand, the rafters that support the roof are made sometimes of one size and sometimes of another, depending upon the loads that must be carried and upon the manner in which they are to be supported. Rafters are structural parts and they may be considered engineering materials.

Wood is a non-homogeneous material. Laboratory experiments show that the strength of wood along the grain averages about seventeen times as great as the strength across the grain. This fairly characterizes wood in its ordinary dry condition just as it is found anywhere. The purpose of plywood is to meet this deficiency by cross-banding, which results in a redistribution of the material. Thus in a plywood panel with a large number of plies the mechanical properties in the direction parallel to the face grain are almost the same as those at right angles, and the greater the number of plies, the more nearly homogeneous is the finished product.

A glue bond has been developed with blood-albumin glue which gives a shear-test value, an average taken from thousands of tests, of 370 lb. per sq. in. in dry shear and 240 lb. per sq. in. in wet shear (after the test specimens have been soaked for 48 hr.). With an adequate glue joint and selected veneers it is possible to predetermine the physical characteristics of any given construction of plywood. Engineers have found it admirably suited to carry an appreciable load in any direction. A few of plywood uses in transportation fields were mentioned before, and in every case it has replaced heavier and less adequate constructions.

In the aircraft industry, although plywood is found in practically all parts of a plane, its most common applications are in wing construction. It is used for wing covering, leading edges, spar webs, gusset plates, cover plates, nose pieces, and tail pieces.

Joining Methods

Fig. 1 shows a joint in a wing covering at a rib. It illustrates the use of plywood for gusset plates and wing covering. A simple lap joint is used for transmission of tensile stresses by means of shear. If a joint of this type is used, and it is desirable to make the joint as strong as the plywood, it is necessary to have enough gluing surface in the overlap to make the ultimate strength in shear equal to the ultimate strength of the plywood in tension. Ordinarily a joint of this type would be backed up by other structural members rigid enough to prevent

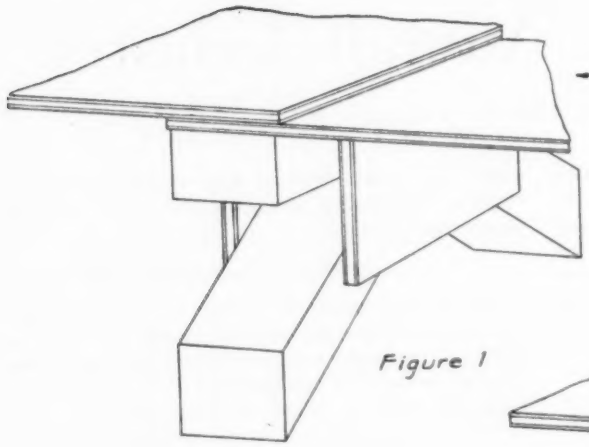

Figure 1

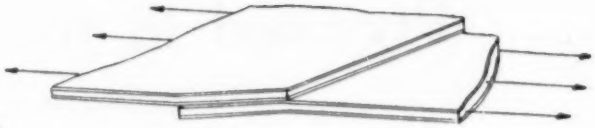

Figure 1-a

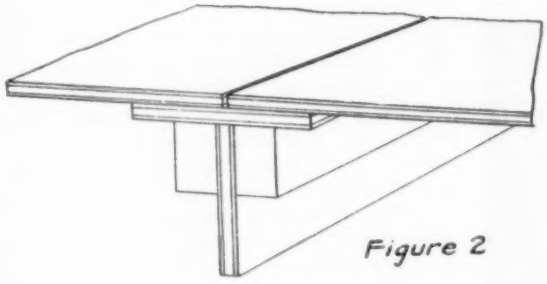

Figure 2

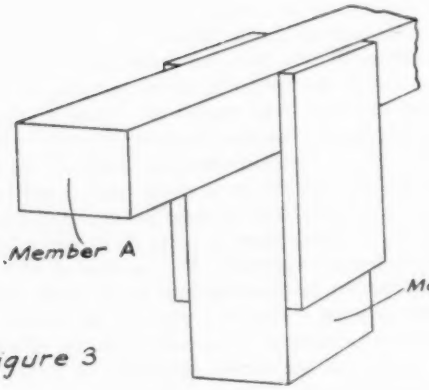

Figure 3

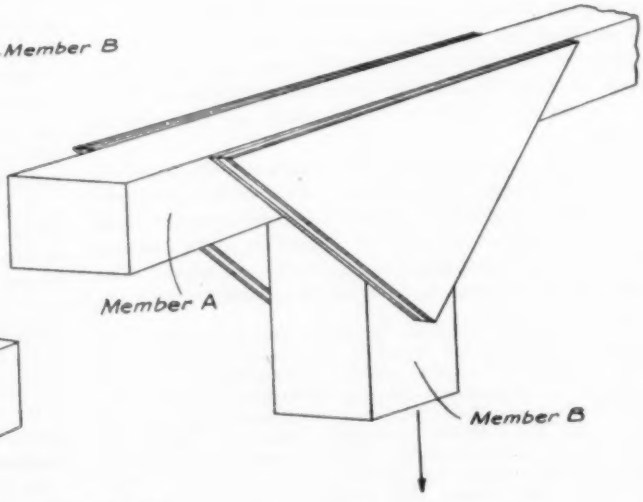

Figure 4

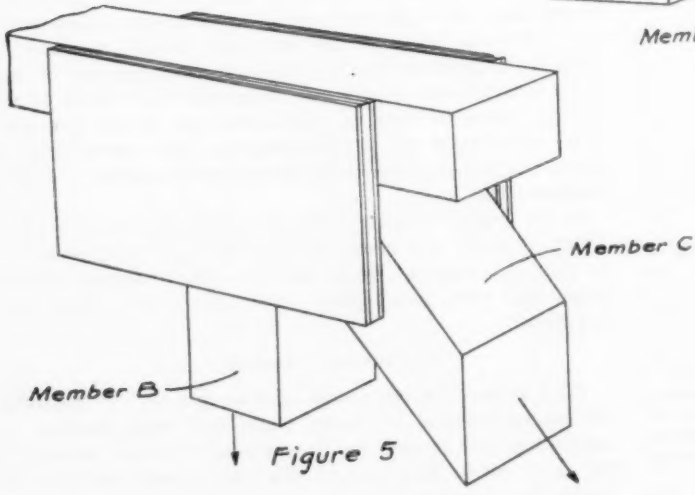

Figure 5

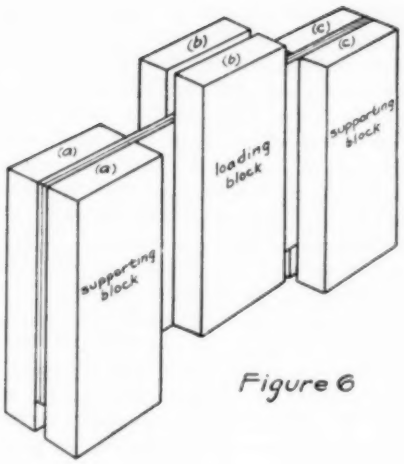

Figure 6

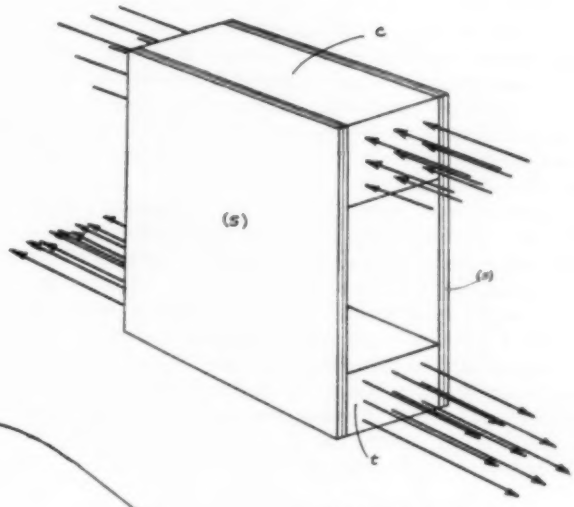

Figure 7

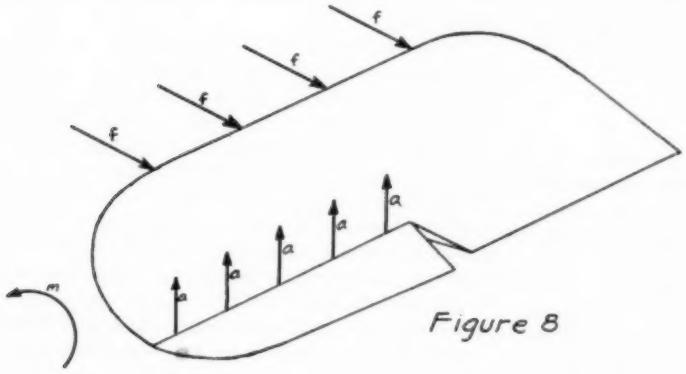

Figure 8

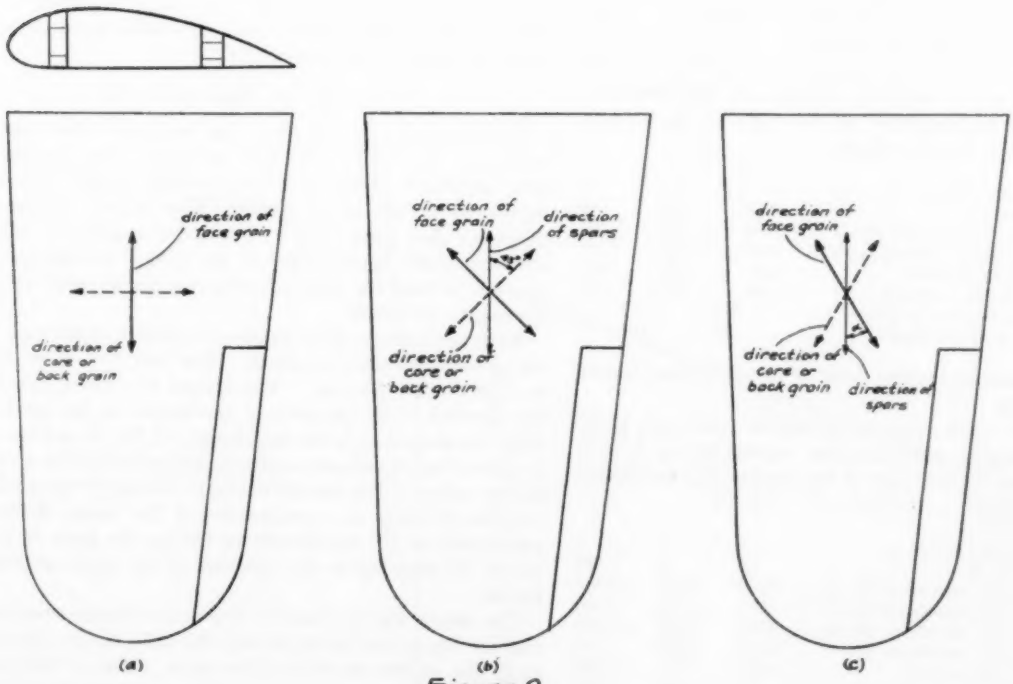

Figure 9

the bending shown in Fig. 1*a*. When such bending takes place, it increases tensile stresses on one side of the plywood near the joint.

Fig. 2 shows plywood used as a wing covering, a cover plate, and web of a rib section. It shows another method of transmitting tensile stresses from one sheet of plywood to another. The use of the cover plate decreases the bending moment and is an addition to the flange of the rib. Although this joint has the structural advantage of mitigating any transmission of bending moments into internal structural members, it is slightly heavier than the joint illustrated in Fig. 1.

Fig. 4 shows plywood gussets joining two members of a wing rib. This is a typical simple application of plywood carrying load from one structural member to another. For simplicity's sake, let it be assumed that member *B* is in tension. The gussets should be large enough so that they can transmit whatever load member *B* is to take either in compression or tension.

If it is attempted to make gusset plates from thin strips of wood, the construction would be similar to that represented in Fig. 3. It apparently has insufficient gluing surface between member *A* and the gusset plates, but the use of a wider plate would be inadvisable because of the inability of wood to carry shear.

Testing Plywood in Shear

Reference has been made to the ability of plywood to carry shear. To test this assumption, the following experiments were performed: Plywood panels were glued to wooden blocks, as shown in Fig. 6. The panels were 6 in. wide, and either 4, 6, or 8 in. long. Supporting blocks *aa* and *cc* were $^1/_2$ in. longer than the panel, and were glued to each end of the panel. Loading blocks *bb* were of similar length to *aa* and were glued to the middle of the panel. In testing, the specimen stood on the platform of the testing machine, the lower ends of the supporting blocks acting as legs, and loads were applied to the upper ends of the loading block *bb*. The clear distance between the loading blocks and the supporting blocks was $^3/_4$ in. The upper parts of *aa* and *cc* were connected by 2-in. strips of $^1/_8$-in. plywood glued to their faces, but not touching the blocks *bb*. These bracing strips are not shown in the sketch.

The results with $^1/_8$-in., two-ply mahogany plywood glued with blood-albumin glue in the ordinary manner, i.e., with the grain running parallel or perpendicular to the edges of the loading and supporting blocks, were as follows:

Height of plywood panel tested, in	4	6	8
Length in single shear, in	8	12	16
Maximum load, pounds, specimen No. 1	1240	1700	2750
Maximum load, pounds, specimen No. 2	1450	2140	2210
Average maximum load, pounds	1345	1920	2480
Strength, lb. per in. in single shear	168	160	155
Load increase for 2 in. increase in height	575	560	
Strength, lb. per in. in single shear	144	140	

The foregoing table shows the result of six specimens, two in each of three heights.

The results with $^1/_8$-in., two-ply mahogany plywood, glued with blood-albumin glue, with the grains running 90 deg. to each other and at 45 deg. to the edges of the loading and supporting blocks, were as follows:

Height of plywood panel tested, in	4	6	8
Length in single shear, in	8	12	16
Maximum load, pounds, specimen No. 1	3250	5075	6535
Maximum load, pounds, specimen No. 2	3410	5515	5000
Maximum load, pounds, specimen No. 3	3085	4360	7250
Maximum load, pounds, specimen No. 4	2240	4435	7810
Average maximum load, pounds	2996	4846	6649
Strength, lb. per in. in single shear	374	404	416
Load increase for 2 in. increase in height	1850	1803	
Strength, lb. per in. in single shear	462	451	

The preceding table shows the result of 12 specimens, four in each of three heights. The object of using three heights was to obtain a value for shearing strength which would be largely independent of the form of the test specimen.

In the lower part of each table, two estimates of the shearing strength are obtained by comparison of maximum average loads by different heights of panels. The final results for shearing strength obtained from these tests may be recorded as about 140 lb. per in. in single shear when the grain of the plies was parallel to the edges of the loading blocks, and about 450 lb. per in. in single shear when the grain of the plies made an angle of 45 deg. to the edges of the supporting blocks.

It is believed that this value is low as an average if it is to be used for a basis of designs for box beams, in which all edges of the panel are well glued. Each test specimen has four free edges; the strength near these edges should be smaller than elsewhere. This variable has been partly eliminated by taking differences as mentioned in the foregoing paragraph. In a test specimen, however, the stress is likely to be largest at the top and bottom.

The deflections in the two experiments were also taken, and they seemed to indicate that the deflection due to shear in the case of a diagonal web grain is not more than half the deflection in the case of ordinary plywood. It is interesting to note that $^1/_8$-in. solid mahogany would have roughly 100 lb. of shearing strength parallel to the grain. The strength of plywood, especially diagonal plywood, is used to advantage in the box-type spar as illustrated in Fig. 7. The tension and compression in such a spar is mainly taken care of by means of the spruce longerons *t* and *c*, while the shear is taken care of by means of the two-ply diagonal plywood *s*. Constructions of this type have been found light, stiff, and strong. Although diagonal plywood is particularly appropriate for spar webs because of its strength and stiffness for carrying loads in shear, it is not always found advisable to use it with a uniform thickness from end to end of a panel. It is evident that the shear is not uniform in some wing beams, particularly those of a monoplane, and some manufacturers meet this problem by increasing the strength of the web in various parts. This is done by adding extra ply or plies where the extra thickness is wanted.

Plywood for Wing Covering

Plywood for wing covering was originally developed as a substitute for fabric. At first extremely thin constructions were developed, some with plies as thin as 0.01 in. It was considered merely as a covering with greater strength and toughness than fabric, and no attempt was made to utilize its strength in the construction of the wing. At present $^3/_{64}$-in. plywood is used for wing covering and its physical properties are used to advantage.

There are four groups of stresses to which plywood wing covering is simultaneously subjected. The first is a stress induced by direct wind pressure. The second is tension, considering the plywood as an extension of the flanges of the spars. The third is a shear due to the drag forces *f* of Fig. 8, and the fourth is a shear due to moment *m*, developed by forces *a* as a result of aileron action. The tensile strength developed by considering the wing covering as a continuation of the flanges of the spars would indicate the importance of having the grain of at least one of the plies run in the direction of the spars, as shown in Fig. 9-*a*.

The shears due to drag and due to the aileron action seem to indicate the advantage of having the grain of the plywood run at 45 deg. to the direction of the spars. This is shown in Fig. 9-*b*. A combination effect might be produced by having the angle of Fig. 9-*c* less than 45 deg.

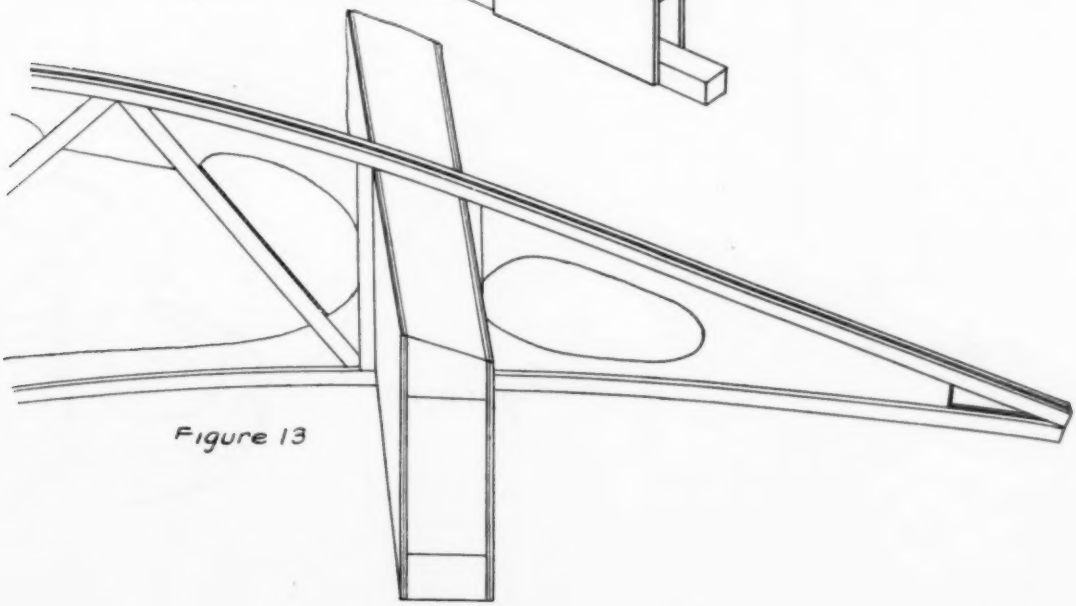

Figure 13

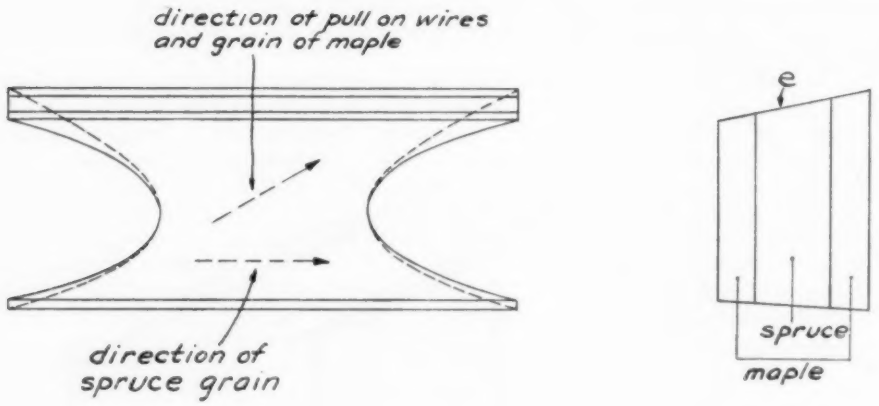

Figure 14

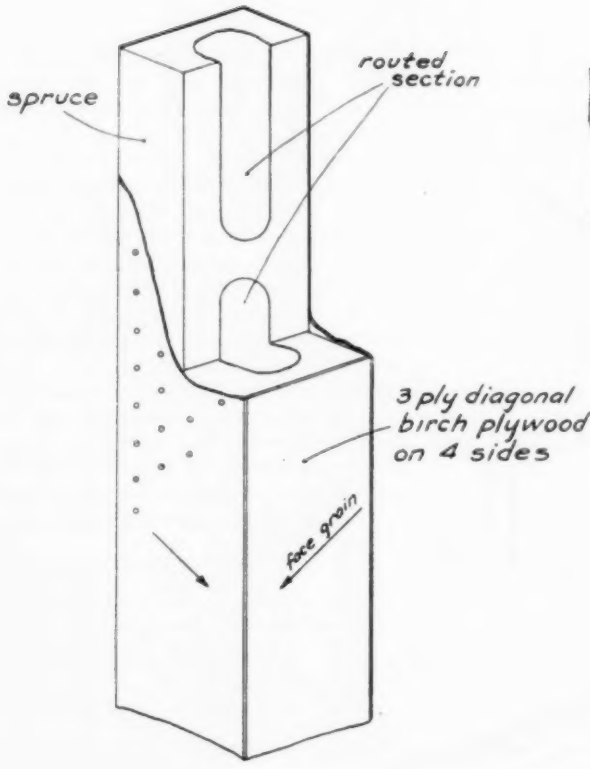

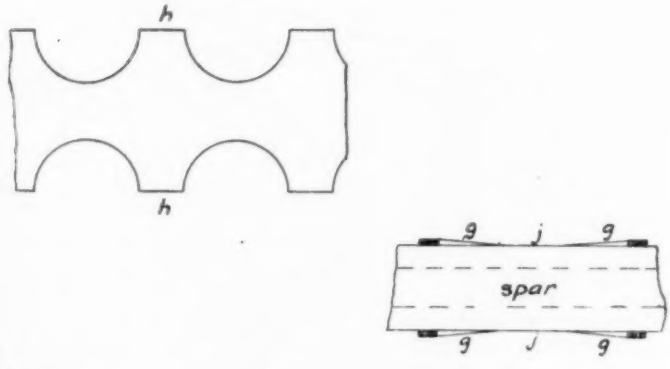

Figure 15

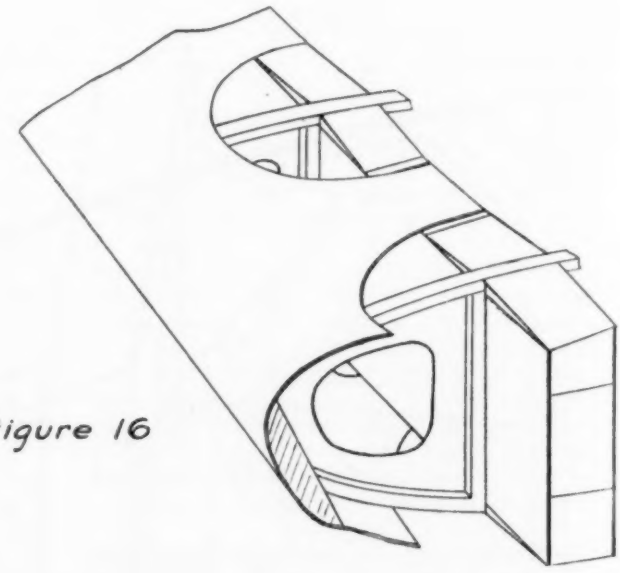

Figure 16

Typical Examples of Plywood in Wing Construction

Fig. 10 shows a typical wing-nose construction, consisting of a solid nose piece *n* tied to the ribs by means of blocks *b*, and covered at least to the front spar by a plywood leading-edge covering *p*. Such constructions have been considered capable of resisting impact of solid particles which may be in the air, and similar constructions have been found successful by a large number of the airplane manufacturers.

At the beginning of the paper, the importance of plywood as a medium of transmitting loads from one member to another was emphasized. Fig. 11 shows a very good example of such a use of plywood; *t* and *c* show the flanges of a spar, while *s* shows the diagonal plywood webs of the spar; *b* is a spacer block, and *p* is a plywood reinforcing member. Through the entire beam, hole *h* is drilled for a bolt fastening. Plywood reinforcing members *pp* are used to prevent splitting of spruce members adjacent to them. They transmit the load from the bolt to a much wider loading surface.

Fig. 12 shows a wing-rib construction and its attachment to a spar. Plywood is used for gusset plates in the rib and for webs in the spar. Fig. 13 shows another wing-rib construction and its attachment to a spar based on the same principles illustrated in Fig. 12, but different in appearance. It illustrates another method of utilizing plywood as a shear-carrying member of a rib.

Fig. 14 illustrates a spacer block used between the upper and lower flanges of a spar. It is designed to carry a load from the spar to other structural members. This particular type is used at the point at which the strut and lift wires are applied. It is a built-up three-ply member. The face plies are of maple with the grain running in the direction of the pull of the lift wires. The core is spruce with its grain running along the axis of the spar. This connection member shows the importance of large gluing surfaces. The load is transmitted from the flanges of a spar to the spruce core of this spacing block over the large surface of *e* and from the spruce core to the maple faces again over a large surface. The loads are taken through bolts, mainly from the maple of this block, to another structural member. The reason for this is clear when it is considered that even though the bolts run through the entire block, the load carried along the grain of the maple will exert much larger stresses on the contact surface of the bolt and the maple than on the contact surface of the bolt and the spruce whose grain is not in the direction of the load.

Fig. 15 shows a section of a rudder beam. It must carry shear and bending moments applied from all directions. It consists of a spruce beam with a rectangular cross-section, partially routed out in the center and covered on the four surfaces by three-ply diagonal birch plywood. The spruce carries the tension and compression of the bending moment while the diagonal plywood carries the shear. The resulting beam is extremely strong and light.

Where fabric is found for wing covering, plywood is usually employed for a leading edge. An interesting example of the manner in which plywood is cut for this use is shown in Fig. 16. The protruding parts *h* are glued to point *j* of the spar between the small filler strips *g*. These are glued to the spar in order to taper the fabric gradually from rib to spar. The result is a nice, smooth airfoil section. Plywood leading edges present a smooth contour and permanently retain their shape under any weather conditions. The face grain is parallel to the edge, and the cores are made slightly thicker than those used in ordinary construction in order to give the desired stiffness. Leading edges are given a desired curvature by boiling the plywood in water for a suitable length of time and then bending it wet around special forms. These forms have a system of clamps for holding the panel in place. When the panel dries on the form it has acquired the desired shape and will not change under ordinary conditions.

In this paper only a few of the uses and possibilities of plywood are touched on. If an attempt were made to list all of its applications, such a list would contain at least 50 different uses. Plywood is found in some of the earliest planes. In the World War it received a decided impetus along with other aeronautical constructions. Since that time it has been used in increased quantities from year to year in spite of inroads of other materials. With the advent of the all-metal ship, it was thought by many that other constructions were doomed, but plywood has maintained its place. Plywood wings are used with some all-metal fuselages and even in all-metal ships it is used in combination with metal for interior paneling and flooring. Plywood with metal glued to its surface is stronger than sheet metal of the same weight and in addition it provides insulation against both heat and sound. Although plywood has been mentioned in this paper principally as a structural material, it is widely used in transport ships for decorative and insulating purposes. These additional uses are mentioned merely to indicate plywood's wide scope. Its importance in the aircraft industry is due to the fact that it is an engineering material whose physical properties are known and can be depended upon to perform the tasks for which it is intended.

The Layout and Design of Modern Airplane Plants

By G. W. PLAISTED,[1] SEATTLE, WASH.

Plants for the manufacture of airplanes are in their design subject to the same general principles as are applied to all factory buildings. They must meet the requirements of straight-line production, flexibility, ample daylight, analysis of material handling, and the special needs of individual departments. Changes in methods of manufacture or changes in conditions should not affect a building so laid out originally as to permit of a flexible straight-line production process nor affect the maximum return on the investment. The author exhibits the general plant layouts and flow diagrams of four existing airplane plants and a typical cross-section of an economical factory building that might be converted to airplane manufacturing.

THE fundamental principles applied to the design of all factory buildings are obviously also applicable to the airplane manufacturing industry. The essential requirements that must be satisfied in the design of all manufacturing buildings are as follows:

(1) Straight-line production
(2) Flexibility
(3) Ample daylight
(4) Analysis of material handling
(5) Special needs of individual departments.

The objective of the design of an airplane plant or any other modern manufacturing plant is, briefly, to provide a straight-line production process so flexible that the buildings can be used satisfactorily in spite of change of conditions and methods of manufacturing, at the same time providing housing for the industry which will result in ultimate maximum return on the investment.

The factors involved in the design of an airplane factory may seem to the layman so numerous that it would be practically impossible to attain the ideal, and yet it has been proved in many industries, including aircraft manufacturing, that the ideal can be closely approached if the fundamentals are carefully analyzed.

The Curtiss plant, designed and constructed by the Austin Company in 1917 for the manufacture of airplanes for use in the war, was so flexible that not only could it readily be used for the manufacture of airplanes today, but the design is such that it could be used successfully for many other industries.

Building "A" of this plant was composed of nine aisles approximately 100 ft. wide and 700 ft. long. The side high aisles in Building "A" could either be equipped with crane runways or with a mezzanine over either part or over the entire area. These side aisles could be used for assembly or, in fact, almost any part of airplane manufacturing. Furthermore, these aisles would accommodate the assembly, crating, storage, and shipping of ships in crates on flatcars.

This plant stands out rather conspicuously for the way it has anticipated manufacturing requirements of even today. The reason for this is that this plant layout was so flexible that all kinds of airplane manufacturing in either wood or metal could be carried on in Building "B" and all kinds of assembly, crating, storage, or shipping could be done in Building "A," and, conversely, Building "A" would make an ideal building for ware-

Contributed by the Aeronautics Division and presented at the National Aeronautics Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Seattle, Wash., May 28 and 29, 1930.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

housing, for receiving, storing, and assembling ships for local fly-away delivery. (See Fig. 1.)

The aircraft factory designed and constructed for the Navy Department at League Island Navy Yard at Philadelphia in 1917 was similarly flexible and satisfies the requirements of the manufacturing of airplanes of all kinds today, with minimum change during the period since it was constructed, almost as well as it did when originally occupied.

The problem of the airplane manufacturer during the past 15 years has been the problem which has existed and confronted every new industry. It has been impossible for the industry as a whole to foresee accurately the opportunities for profit ahead of it, and it has been extremely hazardous to attempt to forecast the volume of business that would be available even twelve months ahead.

Companies like the Boeing Airplane Company, leaders in the industry today, were started with a group of three or four aviation enthusiasts who were willing to take a sufficient gamble on the future to invest their capital while the industry was in its infancy.

At the beginning of this period the problems of housing the manufacturing utilities of the industry were minor and were little considered, as the objective was the design and the construction of the airplanes themselves. Government orders during the war and since that time to a considerable extent furnished sufficient volume in the industry, so that the number of ships produced annually in the manufacturing plants of the country required more attention to production costs than before.

It is true that the demands of commercial aviation have increased remarkably during the last five-year period, and with

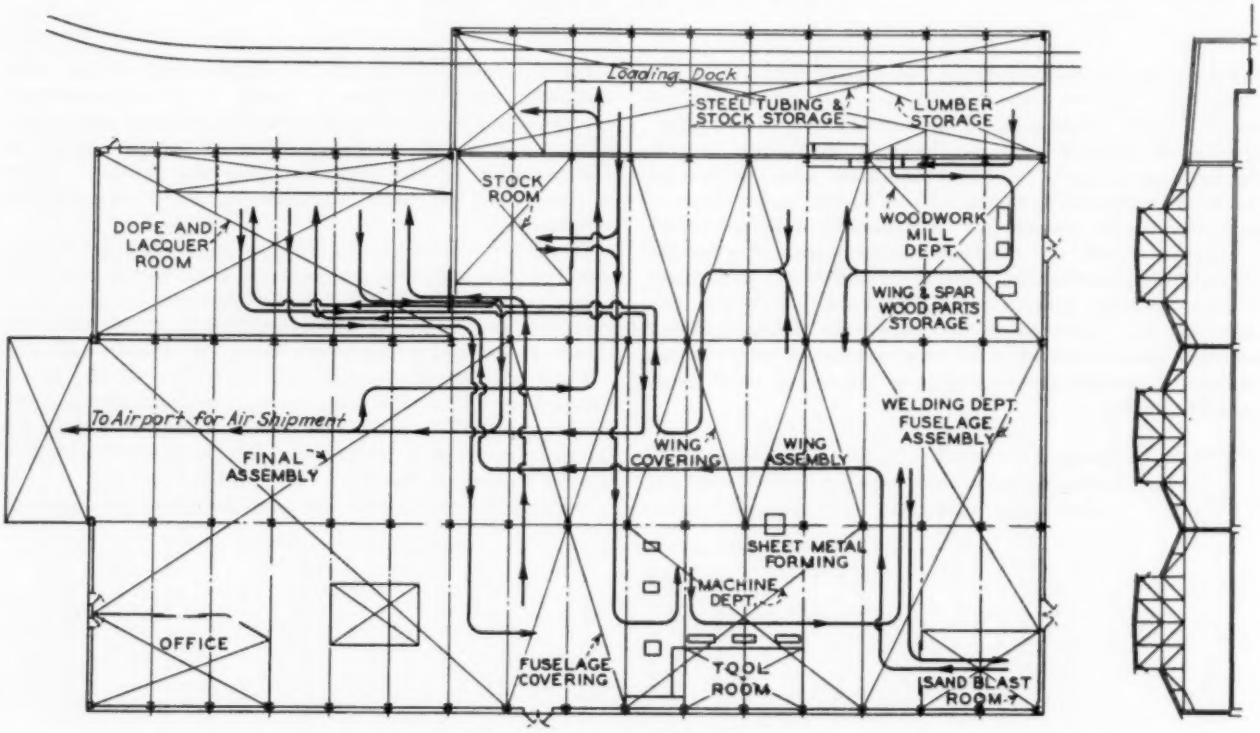

FIG. 2 TYPICAL PLANT "A" FOR 1500 AIRPLANES ANNUALLY

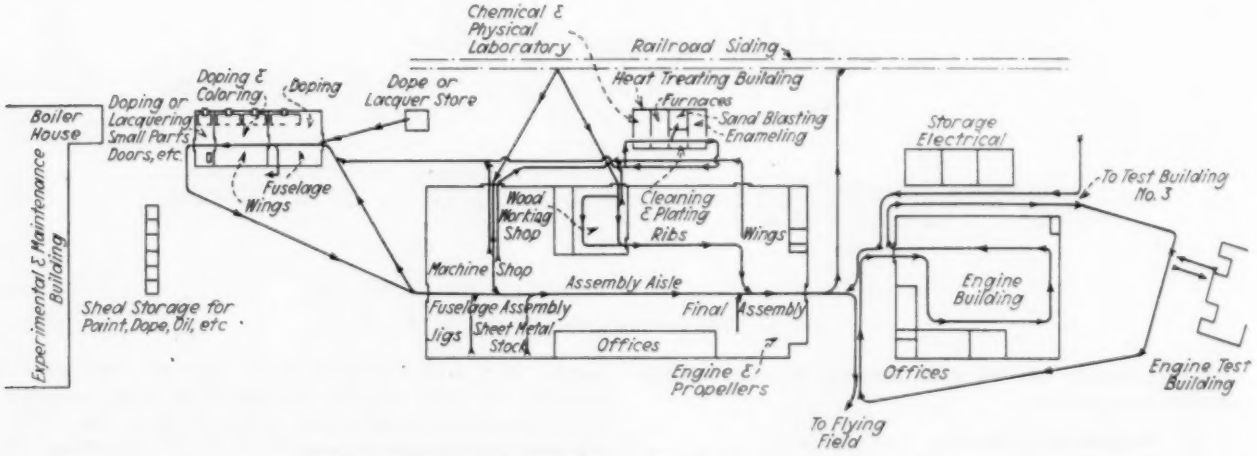

FIG. 3 TYPICAL PLANT "B" FOR 2200 AIRPLANES ANNUALLY

this condition very naturally came the problem of increased competition, and this condition in turn tended to fix the selling price ever closer to the cost. Mass production, in the real sense of the word, as it is applied to the automobile, however, has never been reached in the airplane industry, and there has been a considerable tendency on the part of airplane factories to neglect to a large extent the important factors which tend to lower production costs.

This condition may be more readily seen by an analysis of the plant layouts of a few of the manufacturers of commercial planes.

Plant "A" is designed for a maximum production of approximately 1500 commercial airplanes annually, with about 300 employees. It will be noted from the flow sheet that the main plant building is practically square, resulting in a complicated routing system as the material moves through the plant toward assembly, involving considerable back-tracking. The flow sheet indicates quite clearly that the fundamental condition of straight-line production was not satisfied in this plant. At the same time it must be recognized that this square building results in minimum building costs on account of the small wall area per square foot of floor space. (See Fig. 2.)

Plant "B" is designed to produce 2200 commercial planes annually. This company manufactures engines and cabin planes at this plant, also a considerable number of custom-built planes. The layout of this plant is an example of the other extreme, with too many buildings for specific purposes and with the obvious disadvantages resulting from handling between buildings, as well as a layout which is not as flexible as when the industry is housed in one large building. Moreover, this type of layout is wasteful of land, and the large wall area per square foot of building area obtained results in increased capital expenditure for a given amount of manufacturing space. This flow sheet clearly indicates again that the conditions of straight-line production have not been satisfied. (See Fig. 3.)

Plant "C" is designed to produce approximately 1100 commercial airplanes annually. It is composed of several buildings in parallel with closed passageways between the buildings. The system of manufacturing is departmental, as is indicated by the flow sheet. The amount of back-tracking is comparatively small. The flexibility provided in this layout is obviously better than in Plant "B," though it is not as great as in Plant "A," and the production process in general is the most logical of the three layouts presented. For a given type of building the investment is large on account of the large wall area per square foot of floor area, and it is safe to say that the ground could have been more economically used and more provision made for expansion by housing the industry in one building or in two buildings connected with loading docks. (See Fig. 4.)

Plant "D" is designed to produce approximately 300 commercial monoplanes annually. The flow sheet indicates practically straight-line production and the housing of this small industry essentially in one building, and from a layout standpoint this small airplane plant satisfies more of the conditions than any of the other layouts shown. The principles of straight-line production indicated clearly in the layout of plant "D" can be applied successfully and satisfactorily to airplane factories whose business requires much larger production. (See Fig. 5.)

It must be realized, however, that the restrictions placed on engineers designing airplane factories today involve the use in most cases of existing facilities, and it is seldom practical in the design of additional buildings to increase the production of existing plants to satisfy all of the conditions of this ideal layout. As

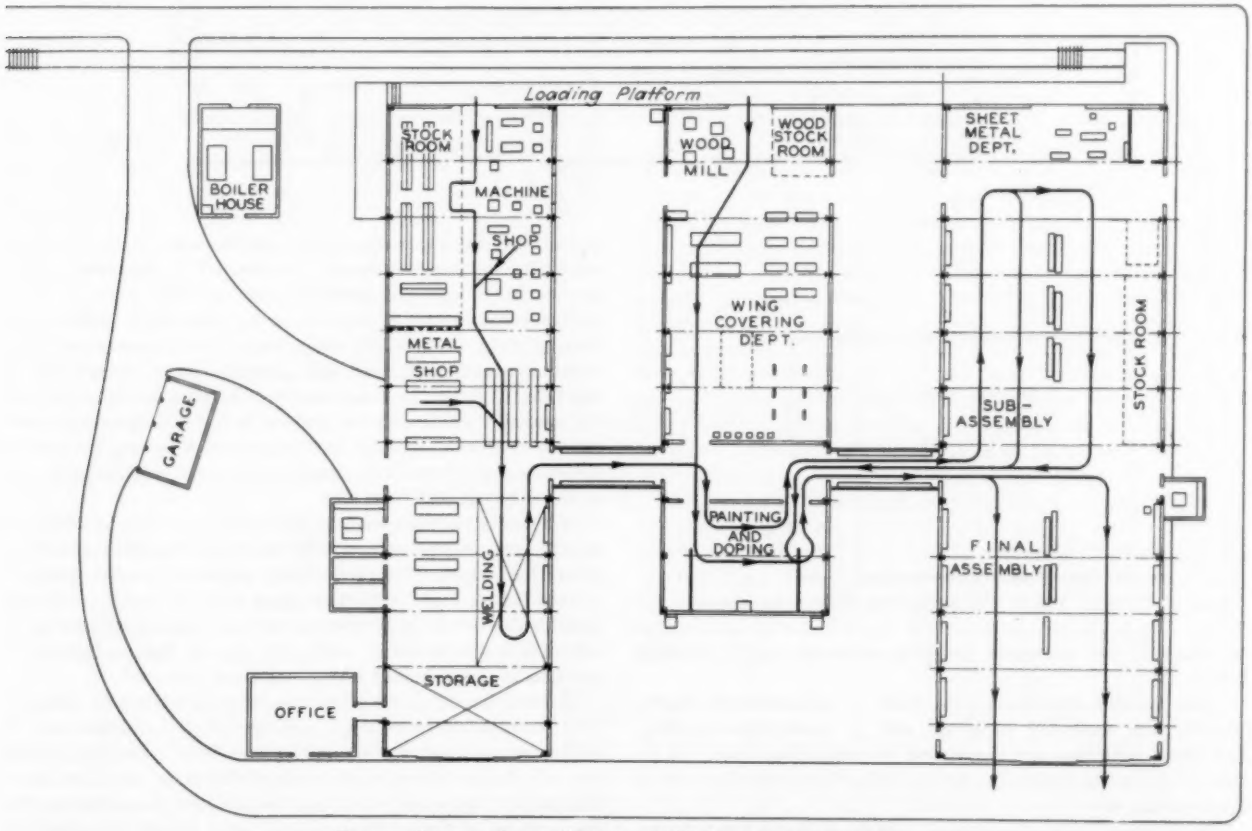

FIG. 4 TYPICAL PLANT "C" FOR 1100 AIRPLANES ANNUALLY

the industry grows, however, it is true that there will be new plants built on vacant property where all factors of the ideal layout can be considered and attained, and while it is impossible to foresee at this time whether the manufacture of airplanes will even approximate the production conditions of the automobile, it is interesting to refer to one of the most modern automobile plants and consider it for a moment as an airplane plant.

The 1000-cars-a-day plant of the Pontiac Division of General Motors is an outstanding example of close coordination of straight-line operations with material-handling equipment. This is said to be the largest factory constructed in the United States during the year of 1926. There are 35 acres of floor space. Lost motions are avoided, aisles are wide, and assembly lines in various

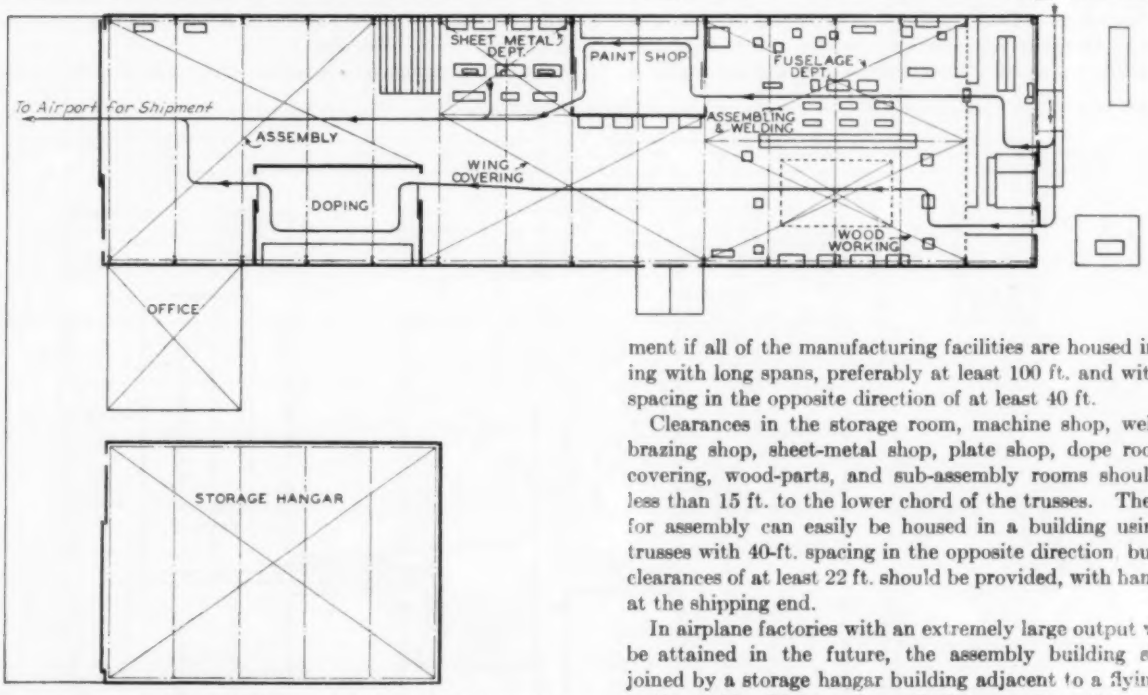

FIG. 5 TYPICAL PLANT "D" FOR 300 AIRPLANES ANNUALLY

departments are arranged to give workmen ample working space.

Three parallel structures were built—a motor-manufacturing building, an assembly building, and a car-storage building. The three buildings are connected by unloading docks 75 ft. wide for incoming material. A third unloading dock is located on the receiving side.

The diagram showing the layout clearly indicates the arrangement adopted, and it is not beyond conception to imagine this plant being converted to the mass production of the airplane instead of the automobile, in so far at least as the preliminary layout is concerned. The primary conditions of straight-line production, flexibility, ample daylight, material handling by conveyors, and special requirements of individual departments have been carefully studied and satisfied, and the plant has actually attained a production in excess of the 1000 cars per day for which it was designed originally.

Perhaps the most outstanding factor of this plant is that everything is under one roof from the time that the freight cars loaded with parts and other materials reach the unloading docks until the finished automobiles leave the shipping department.

The principles of the layout of airplane factories have, it is believed, been established, but even though an excellent layout is adopted the design of the buildings is equally important to assure economy of investment and a maximum return on the investment. The first principle to be applied to the design of the buildings themselves is flexibility.

No industry is changing so rapidly today as is airplane manufacturing. The receiving end of the plant and the storage of most materials may be provided at minimum expense in buildings of 40-ft. or 50-ft. span with column spacing in the opposite direction 20 ft. apart. The machine shop and welding and brazing may well be housed in structures using spans from 30 to 50 ft. and with column spacing 20 ft. apart in the opposite direction, but the plant will be more flexible and will represent a better investment if all of the manufacturing facilities are housed in a building with long spans, preferably at least 100 ft. and with column spacing in the opposite direction of at least 40 ft.

Clearances in the storage room, machine shop, welding and brazing shop, sheet-metal shop, plate shop, dope room, wing-covering, wood-parts, and sub-assembly rooms should not be less than 15 ft. to the lower chord of the trusses. The facilities for assembly can easily be housed in a building using 100-ft. trusses with 40-ft. spacing in the opposite direction but vertical clearances of at least 22 ft. should be provided, with hangar doors at the shipping end.

In airplane factories with an extremely large output which will be attained in the future, the assembly building should be joined by a storage hangar building adjacent to a flying field or testing field. Light and ventilation may be satisfactorily provided in all buildings by the use of continuous steel sash in the sidewalls and in monitors which will provide light to the interior portions of the buildings where long spans are used.

Material handling, fire protection, insurance costs, as compared with the required investment, and light studies and space studies in the various departments must be considered. Heating, plumbing, and locker rooms must be given the same consideration in this industry as in any other, and the problems in connection with the location of the washrooms and toilet rooms will materially affect the production cost of any plant.

It may be the simplest thing to do to provide the same heat in all departments; but the design of the heating system, while it must be made flexible, as must the system of illumination and power wiring, must take into consideration the special demands of the various departments, for it must be quite possible, for example, to maintain a temperature of 90 deg. in the dope room for satisfactory results, while a temperature of 60 deg. in cold weather in the machine shop will prove entirely satisfactory, providing proper ventilation is supplied.

The standardization of modern factory buildings makes it possible to provide the building structure itself, including the foundations, walls, and roof, at a minimum expense, satisfying the conditions of daylight and ventilation at the same time.

In conclusion, it is evident that the straight line to profits in manufacturing today is found in straight-line production methods. Many concerns have moved ahead of their industry by taking full advantage of this fact, while others have waited until forced to do so by competitive conditions. With the fundamentals of proper design and layout of airplane plants satisfied, the handicap of selling price approaching cost, as is the tendency today, is minimized. All signs indicate that the industrial concern which comes to the end of this year without a completely modernized plant will be seriously handicapped in doing a profitable business. Soon this urgent problem may mean complete new plants, perhaps in entirely different locations.

Discussion

GARDNER W. CARR.[2] Without attempting to criticize the paper, it is believed that certain points can be profitably amplified or explained. To do this a survey of this company's problem will be enlightening. Four years ago the Boeing Airplane Company was manufacturing an airplane the structure of which consisted of a welded tubular steel body with wings manufactured of mahogany plywood and spruce, covered with fabric. The following year the same type of wing construction was used by the Boeing Airplane Company, but the body structure had been changed, supplementing a considerable number of welded steel tubes with bolted dural members. The following year found a reactionary change in the body construction, although the wings remained the same. The forward section of the body was of welded alloy-steel tube construction, but the rear section of the body was made up of bolted rectangular dural tubes. The fourth year, that is, 1930, finds a still farther and more radical departure from previous practices. The wings are now fabricated from dural sheet, the ribs, spars, and covering being metal. The body, although it still retains the steel forward section, is also metal covered, the covering being applied over a skeleton of bolted dural tubes. Quite a change has taken place in the shop organization. In 1927 there was a large amount of electric welding and work in steel tubing, with the wood shop manufacturing spars and ribs and the wing room manned by cabinet makers who could handle the assembly of wood structures. The year 1928 increased the load in the machine shop, where the dural tubes and terminal blocks had to be made up, while the load in the welding shop decreased. The year 1929 found a still greater load in the machine shop, with the welding problem almost eliminated and replaced by a new type of work, that of assembling bolted dural structures. This year, 1930, brings up a problem involving almost nothing in the welding shop, a normal load in the machine shop, and a tremendous burden in the sheet-metal department. A plant not laid out to give this flexibility would have rendered the manufacturing problem extremely uneconomical if not prohibitive.

Another phase to be considered is that of size, and particularly over-all height or clearance under the roof trusses. As long as small airplanes are being built, little overhead clearance is required. In this plant, however, airplanes have been manufactured ranging in weight from 2500 to 27,500 lb. and in wing spread from 27 to 120 ft. The latest design has wings of such size that they could no longer be assembled in a horizontal position, and vertical jigs were constructed. Although the assembly department in any plant will require head room, the probable size of units to be produced in other departments must be given consideration.

From an observation of the industry and the changes which have taken place in the last ten years, the writer believes that a plant laid out in the shape of a letter E or with wings leading into a main building offers the greatest advantage. There are two problems connected with the manufacture of airplanes which require isolation of equipment—that is, electroplating or anodic process equipment, and doping or enameling. Either electroplating or anodic process involves a problem of ventilation and heat control not required in other operations. The doping or enameling processes require not only heat control and ventilation, but special protection against fire hazard. The problem of isolating these functions seems easiest to solve by housing them in a wing offset from the main building. The experience of the Boeing Airplane Company indicates that such a unit can be placed between other departments to advantage, thereby simplifying the flow lines and eliminating backhaul. In construction this wing should not be radically different from the other wings of the plant, as these requirements seem to be changing quite rapidly, and particularly the doping operation may be eliminated in the near future.

The foregoing comments are offered not as a criticism but rather to emphasize the author's point that no plant should be laid out that will not be flexible and capable of handling the varying types of construction and new manufacturing problems which are constantly appearing in the particular branch of engineering where progress is exceedingly rapid and radical changes occur almost over night.

Stability and Controllability in Free Flight

By PAUL E. HOVGARD,[1] BRISTOL, PA.

Making the airplane pleasant to fly is discussed by the author in this paper. Strength, durability, and performance of airplanes are determined quite accurately by analyses and tests, but the ease with which a particular plane can be maneuvered is often left to chance. Stability at cruising speeds and balance with the throttle closed and open are essential for ease of control. The author tells of various methods that can be used to test flying characteristics and make certain that airplanes will perform as desired.

IT IS NOW becoming possible to choose an airplane in much the same manner as one chooses an automobile, that is, by picking out from a directory the type and size that suit the needs, scratching off a few because they are too slow, and of the remaining, buying the one that is the most pleasant to operate. If one finds the operation of the airplane not to his taste, he will know from automobile experience that it is useless to ask the manufacturer to modify something to eliminate the queer feeling he gets coming out of a turn, but will step into the next hangar and buy a competitive airplane almost identical to the first except that he likes the way it flies better.

In one case three pilots from different parts of the country and strangers to each other informed the author that the proper way to make a turn in a certain popular cabin monoplane was to start by pushing the rudder hard in the direction of the desired turn, and when the airplane had reached a sufficient degree of bank, relieving the pressure on the rudder. The plane continued to turn without further attention. As soon as it was headed in the desired direction the top rudder was to be pushed till the airplane straightened out. The ailerons were to be used only for rough weather take-offs and landings. Such haphazard design may be tolerated when airplanes are hard to purchase, but with the strong competition in selling now in vogue, such an airplane has little chance.

While the strength of an airplane can be determined by stress analysis or static tests, the durability by service tests, and the performance by flight instruments and a stop-watch, the "flyability" is too often left to get along the best it can, and when finished is expressed in such vague terms as to have no meaning to the designer. In some cases the test pilot is reluctant to find fault with the airplane for fear others will think it was just getting the best of him, and on that, of course, he cannot afford to take a chance. Making an airplane pleasant to fly requires close cooperation and intimate understanding between the test-flight and design sections. The stability and controllability forms used by the Army and Navy serve well the purpose intended, but are of little help to the designer in this respect. The Department of Commerce instructions are very indefinite and in some cases even incorrect, as an airplane would have to be spirally stable to pass either their directional or lateral stability tests.

Determination of longitudinal stability is the most straightforward test of all; yet even there mistakes are made especially in large airplanes. The stabilizer must first be set to trim the airplane at the given engine speed, and the air speed for that engine speed recorded. The throttle and stabilizer setting remain constant throughout the test. The airplane is then nosed over to increase the air speed 5 m.p.h. and held in the required position until the air speed is constant. If upon releasing the control column the nose returns toward its original position, the airplane is stable. The test is repeated for an air speed 5 m.p.h. below the cruising speed.

Quantitative results may be obtained by measuring the forces on the control column required to hold the airplane constant at given air speeds and the results plotted or by finding the center-of-gravity location at which the airplane is neutrally stable. If a revision of any kind is made on the airplane, one or both of these methods should be used to determine the effect of the change on the stability. In case the tail surface is changed the test should be made with both the old center-of-gravity location and the new, as quite often the increase in weight of an enlarged tail plane will move the center of gravity far enough to the rear so that the stability at or close to cruising speeds will remain unchanged, though usually the stable moments will be increased at very high and very low speeds.

If the airplane is found to be statically stable by the above tests, its dynamic stability is next determined. To do this the airplane should be dived or climbed and the control column released. If the oscillations decrease and dampen out, the airplane is dynamically stable. There are very few airplanes that are statically stable that are not also stable dynamically.

Besides the stability at cruising speeds the power "on" and "off" balance should be determined. This can best be given in terms of air speeds with throttle closed and wide open with the stabilizer set for cruising and no pressure on the control column. Ordinarily, the greater the stability, the higher the power "off" air speed, a rather unpleasant condition. It is possible to maintain a constant air speed for all throttle setting regardless of the vertical position of the engine except for rapid movements of the throttle. Such an airplane will invariably be longitudinally stable.

The amount of longitudinal control necessary varies with the purpose of the airplane. All airplanes should have enough elevator to raise the tail on the take-off by the time 50 per cent of the stalling speed is reached and with the stabilizer set for cruising.

Small airplanes should have enough elevator control to get the tail fully down when landing without changing the stabilizer setting, though this feature is not necessary on large airplanes because the pilot expects to take more time for the approach preparatory to landing. It is not necessary that a large airplane be able to make a three-point landing when only partly loaded even by the use of the stabilizer as long as the landing speed in this condition is not greater than the landing speed with full load.

The lateral stability of an airplane is determined by its ability to bank itself for a turn and to level itself from a turn without the use of the ailerons, the turn being made with rudder alone. The rudder action for this test should be quite slow, and a certain amount of slip during the maneuvers must be expected.

---

[1] Research Engineer, Keystone Aircraft Corporation.

Presented at a meeting of the Aeronautic Division with the Chicago Section, Chicago, Ill., August 25, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The amount of lateral stability an airplane should have can be set by no definite rule and must be determined by compromise. Too much lateral stability is much more unpleasant than too little. Too much means dangerous take-off and landing characteristics in gusty weather or cross wind and, worse than that, causes the airplane to be very rough and sickening in bumpy air. Too little lateral stability means mainly that the pilot must be a little more careful with the aileron control when maneuvering. There should be enough so that the pilot can follow a straight course by using the rudder alone.

The lateral control must serve two functions; overcome inherent lateral stability and provide sufficient maneuverability. If an airplane can be flown on its side at speeds not over 10 m.p.h. above the stalling speed in this position, it has ample aileron control for the first condition. The aileron control for sufficient maneuverability cannot be determined definitely, but is a matter of judgment.

The directional stability is the most difficult of all to determine accurately, and it is possibly fortunate that very few airplanes are directionally unstable. For the test a bank-and-turn indicator is very helpful. The rudder should be either held rigidly in the center or entirely released and the maneuvers made with aileron alone. The pilot must bear in mind that there will be a yaw due to the ailerons which must be accounted for in the test.

The airplane should first be banked in one direction by the ailerons. This should be done very slowly and for this start it is better to counteract the yaw of the ailerons by applying the rudder in the direction of the turn. The ailerons should then be applied in the other direction until the airplane is approximately level and the turn indicator shows zero turn. Ailerons are then either entirely released or held rigidily in neutral. If the airplane turns into the direction of the slip it is directionally stable.

It can be seen from this that the test is made with wings horizontal and the airplane side slipping either to the right or left but not turning. The test should be made with various degrees of slip as shown by the ball of the bank indicator and should be made both to the right and to the left.

The degree of directional stability can best be given by the position of the center of gravity on the mean chord at which the airplane is directionally stable with the rudder held in neutral and directionally unstable with the rudder free. Difference in stability, rudder held or free, with a balanced rudder is surprisingly small so this position can be definitely located within about 1 per cent of the mean chord. Ordinarily this position is 10 or 20 per cent to the rear of the full-load center-of-gravity position.

The rudder area required depends for the most part on the degree of directional stability except in cases of airplanes without brakes where the determining factor is the ability to taxi on the ground. The rudder area and directional stability should be so proportioned that the airplane can be flown on its side at low speeds with full top rudder and without stalling in this position. In the case of multi-motor airplanes the rudder should be powerful enough and well enough balanced so that the airplane can be flown straight with one engine idling and the other engines wide open without overexertion on the part of the pilot.

For spiral stability an airplane must have small directional stability as compared to the lateral stability and whether or not the airplane should be spirally stable is sometimes questionable because of the small amount of directional stability or the excessive dihedral required to obtain it.

To test for spiral stability the airplane is put into a normal steady turn and the controls released. If the airplane recovers from the turn it is spirally stable and if not is spirally unstable. Tests should be made both to the right and to the left, and either the vertical fin should be adjusted or the spring attached to the rudder to make the airplane act the same in right and left turns. In multi-motor airplanes the outboard-engine tachometer should be carefully checked to be sure the engines are synchronized before making the test.

For normal flying the spiral stability is closely tied in with the yaw due to the ailerons. Because of the small directional stability, pilots invariably over-rudder an airplane that is spirally stable. If aileron yaw is high this rudder movement is necessary for normal flying and the pilot is at ease. It is advantageous at times to use unbalanced rudders on airplanes that are spirally stable to reduce the tendency to overcontrol.

One of the most important considerations in making an airplane pleasant to fly is the coordination of the three control surfaces. A normal flying airplane will be defined as one which requires an approximately equal pressure on the rim of the wheel or top of the stick and the rudder to start and recover from turns, the pressures being applied or released at approximately the same time. In spirally stable airplanes a very fine degree of relationship must exist between directional stability, lateral stability, and yaw due to ailerons without making the airplane fly abnormally. Spiral stability therefore should not be required in an airplane, but of course excessive instability is not desired. Even though an airplane were spirally stable the action would be so slow that the pilot would not care to wait for it.

It is impossible to fly airplanes above a given size without balance of some type on the control surfaces. The overhang balance gives satisfactory results for elevator and rudder at small angles of attack of the surfaces, but has very little effect when the surfaces are moved through more than about 10 deg. It is possible to design a partially hidden balance that will give excellent results over the entire control movement. Frize type balance for ailerons with hinge line at about 18 per cent or 20 per cent of the chord gives excellent results and is generally acceptable.

It is quite possible that at some time in the near future the method of controlling airplanes will be entirely changed and one of the controls eliminated. Until this time comes, however, it behooves the manufacturers using the present system to so refine it that the best results possible will be obtained.

Discussion

HALL L. HIBBARD.[2] I believe that the paper is very much to the point. The modern airplane can have stability and controllability not thought possible several years ago. Aircraft properly proportioned and designed are in existence which have good stability and controllability, but there are still a larger number which do not have these desirable features; especially is this true of stability. It has been the writer's experience that many pilots are unable to discover accurately whether an airplane is stable or unstable. It is for this reason that the author's "Methods for Determining Stability and Controllability" should be studied and tried by pilots. Many of the war-time pilots became accustomed to the airplanes used during the war. As a rule these craft, although quite controllable, usually lacked stability. Numbers of these pilots, however have become accustomed to this unstability, and when buying a modern plane pay little attention to this important item. Not long ago attention was called to a pilot who had been flying an airplane which was laterally unstable and which had to be "flown" all the time. He was asked to try out the stability of a particular airplane which happened into the field and which he had never flown before. This airplane was known to have poor or no lateral stability. When the pilot returned from the test flight he was questioned about the lateral stability, and much to the surprise of all he reported good lateral stability.

[2] Project Engineer, Stearman Aircraft Co.

The answer is that he been accustomed to poor lateral stability and was unfamiliar with the method of testing airplanes for this quality. It is for such pilots that the paper is recommended.

H. RAWDON.[3] Control and stability in general cannot be expressed quantitatively, and one is usually compelled to accept the qualitative or descriptive statements of test pilots. At least there is very little in the way of generally accepted units of measurement.

It is exceedingly difficult to find a test pilot who has a sufficiently clear idea of what he is to look for and to give an interpretation and presentation of opinions of his observations. This fact imposes difficulties on the design staff, since under the circumstances the pilot will probably change his mind later on, on his first impressions, or since it is difficult to get two test pilots with a common opinion. The difficulty could be helped if engineers in general would take greater interest in flying themselves.

The Keystone Company is fortunate in having a man who is both a capable pilot and engineer.

Regardless of size, it is always desirable to have an airplane that can be landed three points under any condition of load within the range for which the airplane was designed. There is no practical reason why this should not be possible to accomplish.

Spiral stability is generally of the least value. However, excessive spiral instability is not desirable by any means. A case is known in which the directional stability was deemed insufficient and a small amount of fin area was added. The resulting directional stability was satisfactory, but the airplane was objectionably unstable in a spiral without using a prohibitive dihedral in the wings. This was a case for compromise.

A measure of control which seems desirable to obtain is the ability of the airplane to make a turn at a speed something below that of stalling speed without the aileron action causing the wing to drop. The lateral control required here would be greater than in the case cited by the author.

A. A. GASSNER.[4] The paper covers the subject thoroughly. One misses, however, the mentioning of two criterions of the stability of an airplane:

1 A ship should be longitudinally balanced in such a way that, with stabilizer and throttle setting at cruising speed, closing of throttle would bring the ship in a glide and opening of throttle would bring the ship in a climb.

2 The behavior of the ship in a stall. If small-sized planes slide off one wing when brought in a stall and go in a spiral, which is sometimes mistaken for the beginning of a stall, or if they actually go into a spin, the forces required to stop this movement will not be excessive and recovery is possible. It is, however, of imperative necessity to test all large-sized planes for their behavior with engines partially or totally throttled. A ship which behaves well in a stall, i.e., goes into a straight dive when all controls are released, can be termed as safe playing.

WILLIAM H. MILLER.[5] The author is to be commended for inviting attention to a series of very simple tests by means of which airplanes may be compared as regards stability and controllability. The mere definitions of these quantities are too often misunderstood or confused by both pilot and engineer.

From a strictly academic viewpoint the author has not drawn a sharp enough distinction between stability with free controls and with locked controls; that is, "hands off" and "hands on." However, in actual practice, the former quantity is generally the easier to determine by such tests as the author describes, and, except in the case of spiral stability, it is usually the criterion of the latter.

Although the author criticizes the standard flight-test forms of the Army, Navy, and Department of Commerce as being of little help to the airplane designer, one must venture to say that his subject article may be criticized in the same respect. For any case of instability or deficiency in control the changes in the airplane necessary to correct the condition should have been mentioned. As an example, dynamical instability with free controls may be caused by any one of the following items:

(*a*) Center of gravity too far aft
(*b*) Center of gravity too far above thrust line
(*c*) Moment of inertia in pitch too great
(*d*) Too much area of horizontal tailplane in slipstream
(*e*) Elevator area too large a proportion of total tailplane area (where the control surface is unbalanced).

Generally, items (*d*) and (*e*) are the easier to change after flight tests indicate longitudinal stability. Simply increasing the aspect ratio of the horizontal tailplane, keeping the total area constant, and increasing the area out of the slipstream will usually greatly improve longitudinal stability.

Occasionally, in military aircraft, a rearrangement of the useful load, in order to reduce the moment of inertia in pitch, will remedy an unstable condition caused primarily by item (*b*).

It can be shown theoretically that the difference in elevator angle to trim, for the same airspeed, "power on" and "power off," is a function of the built-in wing incidence. The effect is theoretically small except, for example, in the case of a tractor biplane seaplane, with wings set 3 or 4 deg. to the thrust line for quick take-off. The relation of wing incidence to difference in trim for the aforementioned conditions ought to be given considerable attention by the designer. In this connection he must of course take account principally of the relative positions of propeller and wing.

An airplane which is stable statically in pitch or yaw with fixed controls, but unstable with free controls, can be made stable sometimes in either case by the addition of a small amount of balance to the control surface in order to reduce the hinge moment.

It is most important of all, in so far as yaw is concerned, to provide sufficient rudder moment to counteract the yawing moment with fully deflected ailerons at the stall with power off. Incidentally, this is a quite difficult condition to obtain (with conventional ailerons), and at the same time maintain spiral stability at low speed, unless the airplane has a large amount of sweepback.

From the standpoint of preliminary design, all satisfactory stability calculations should take account of slipstream downwash and velocity. Many designers do not realize that these effects are so pronounced in some tractor airplanes that they account for a difference of from 15 to 35 per cent in effective tail area required to give equal degrees of stability with free elevator, for "power on" and "power off" conditions.

G. G. BUDWIG.[6] The author states that a particular airplane, the name of which is not mentioned, is guilty of being haphazardly designed because it can normally be turned with the rudder only and without applying the aileron control at all. In view of the fact that such characteristics are very difficult

[3] Chief Engineer, Travel Air Company, Wichita, Kan.

[4] Chief Engineer, Folker Aircraft Corporation of America, Hasbrouck Heights, N. J.

[5] Assistant Chief Engineer, Berliner-Joyce Aircraft Corporation, Baltimore, Md. Mem. A.S.M.E.

[6] Director of Air Regulation, Department of Commerce, Washington, D. C.

to predict, he is probably correct in his assumption that the turning characteristics were the result of accident rather than design. However, it appears that this particular feature was rather a happy accident than otherwise because it would tend to make the airplane in question much more pleasant to fly. The reason for the author's condemnation, therefore, is not entirely apparent.

When the author accuses the Department of Commerce instructions of being "very indefinite, and in some cases even incorrect," it is assumed that he is referring to Inspection Service Memorandum No. 1, which was published and circulated October, 1929. This memorandum is fairly lengthy and was written for the sole purpose of acquainting the manufacturers in as much detail as possible with the routine procedure followed by inspectors when they test an airplane for conformity with the Air Commerce Regulations. The instructions contained in the memorandum do not in any way guarantee that an airplane which meets those requirements will be the best possible airplane of the particular type, but for the purpose for which the memorandum was written it is believed that it is both definite and accurate. If there are parts of the memorandum which are not clear, we would be very glad to have any one point them out specifically, so that we might clarify them.

It is stated by the author than an airplane would have to be spirally stable to pass either our directional or lateral stability tests. This is not correct, because during the directional stability tests the wings are held level by means of the ailerons, and during the lateral stability tests the airplane is held level by means of the rudder. No part of either of these maneuvers has a remote resemblance to spiral flight, and airplanes which successfully pass these tests are not necessarily spirally stable. In fact, an airplane with sufficient stability will usually dive out of a turn and assume a level flight attitude if the controls are released.

When the author states that a faster power-off glide results from longitudinal stability, it is difficult to follow his reasoning. A longitudinally stable airplane has a negative lift on the stabilizer, which builds up rapidly as the speed increases. Of course, as the down load on the tail increases, the nose of the airplane comes up and it flattens out, at the same time decreasing its speed. It is therefore not only apparent but true that the greater the longitudinal stability, the quicker a dive will be checked. A stable airplane therefore, cannot build up an excessive diving speed. An unstable airplane, on the contrary, will frequently get its nose clear under in a dive and will fall at terminal velocity if allowed to do so.

An excessive amount of lateral stability is unpleasant in several ways, particularly in a cross-wind, as the author says. However, it is believed that an insufficient amount of stability in this direction is even more unpleasant and more dangerous when one is called upon to fly in rough, gusty air. Fighting with an airplane to keep it on an even keel is far from being the ideal in flying. The writer agrees with the author that the coordination of the three controls is a very important consideration which is too frequently neglected.

JOHN C. NULSEN.[7] There is no question that the author is correct in his contention that airplanes should be so designed as to be easy and comfortable to fly. The necessity of this feature will of course grow in importance from the manufacturer's standpoint as competition increases. Nothing is more disagreeable from the pilot's standpoint than to get into a ship and find on maneuvers that it is light on the ailerons and heavy on the flippers, or vice versa. Such conditions are due simply to lack of attention to details.

[7] General Manager, Ryan Aircraft Corp., Anglum, Mo.

Stability about the various axes is a subject that should receive very careful consideration, and a conclusion should not be jumped at. It can without question be overdone. As the author points out, too much lateral stability is hard on the passenger prone to air sickness; likewise locating the center of gravity too far forward in an attempt to make the longitudinal stability extremely positive is detrimental to the full efficiency of the ship.

There is no good reason that the writer can see to try to balance the ship so that it will recover rapidly from a power-off dive after having been balanced at cruising speed, if it means that in normal flight sufficient negative setting must be carried on the stabilizer to cause a sacrifice of maximum performance.

Maneuverability is also a safety factor in tight places, and a careful balance between this feature and stability must be arrived at. This brings up a question that is, or has been, before every manufacturer; namely, the attitude of the individual engineering inspector of the Department of Commerce. As the author brings out, the department's instructions relative to the foregoing points are indefinite. The department unquestionably deserves the appreciation and thanks of all in the aviation industry for the splendid work that has already been done toward making aviation safe. However, the writer feels that the department could help matters still more by impressing upon the individual inspectors the necessity of approaching the subject of stability very conservatively. Because a sufficient amount cures, it does not follow that more will cure faster.

AUTHOR'S CLOSURE

It is easily possible in some types of airplanes to so design it that it will balance at the same air speed for any throttle setting. In other designs this is quite difficult, and for rapid movements of the throttle is impossible without going through a series of oscillations before reaching steady flight. It is of course desirable. This was discussed in the paragraph on power on and off balance which stated, "This can best be given in terms of air speed, throttle closed and wide open, with stabilizer set for cruising and no pressure on the control column." Mr. Gassner's other comment on the behavior of the ship in a stall is well taken. Attention is invited to the fact that an airplane goes into a straight dive when all controls are released only when stalled in straight flight. Since, except during demonstrations, airplanes are most often stalled while turning, this feature is not as important as it may at first appear.

The author did not intend to make a sharp distinction between stability with free controls and locked controls, because, since no airplanes are equipped with devices to lock controls, why should one be interested in the stability in this condition. If the pilot attempts to hold controls in neutral for stability, it is not only an unnatural procedure, but he has one chance of being right and an infinite number of chances of being wrong.

It was the purpose in writing the paper to assist the test pilot and designer in understanding each other and not in assisting the designer to correct faults found by the test pilot; the latter is purely a design problem in which the test pilot is usually of little assistance. The remainder of Mr. Miller's discussion, therefore, being beside the point, will not be answered.

In order to answer Mr. Budwig's discussion it will be necessary to repeat and expound some of the material given in the original article and to comment upon Inspection Service Memorandum No. 1.

In explaining the normal manner in which a certain airplane was to be flown, the author stated that the rudder must be pushed hard in one direction; by hard was meant to put both feet on the rudder pedal to try to bend it. It was impossible to push the pedal more than 2 inches in either direction without waiting for

response; while the airplane is making a turn it is impossible with both feet to even get the rudder pedals into neutral, much less the rudder. This point was brought out, not as a measure of lateral stability, but to show a lack of coordination in control forces. The aileron control could be moved to any position with one finger only, with absolutely no exertion.

Mr. Budwig stated in his discussion that "During the directional stability test the wings are held level by means of the ailerons and during the lateral stability test the airplane is held level by means of the rudder." Had this been stated in Memorandum No. 1, the author's statement that "Department of Commerce instructions are very indefinite and in some cases even incorrect," would not have been made so broad. As requested by Mr. Budwig, the author will point out specifically parts of the memorandum that are indefinite or incorrect.

Their instructions to determine longitudinal stability read as follows: "Whether or not an airplane is longitudinally stable at any given load or power condition can be determined by balancing the airplane with the stabilizer for level flight and then nose the airplane over approximately 15 deg. and release the control column. The airplane on being pointed down should increase its speed and the nose begin to come up." This is a very good test for dynamic longitudinal stability, but will not assist the designer in determining statical longitudinal stability, although this memorandum does not distinguish the two. According to these instructions, the test is started while the airplane is rotating about the axis of pitch, is at the moment 15 deg. to the horizontal, and the air speed is slightly above cruising speed, but actually unknown, and the angle of incidence is unknown. How far the nose continues to go down will depend upon the moment of inertia about the axis of pitch and the stable righting moment. The moment of inertia being so much larger, it is impossible to tell whether the aerodynamic moment is positive or negative.

The test for lateral stability reads as follows: "Lateral stability is determined by setting the controls for normal flight and then by purposely dropping either wing. If either wing tends to return to horizontal with the controls released, the airplane can be considered laterally stable. If, however, either wing stays wherever you put it, the airplane is neutrally stable. If the condition becomes worse and either wing keeps coming up or down, the airplane is laterally unstable. All airplanes must be at least neutrally stable laterally." Contrary to Mr. Budwig's statement, lateral stability test is made with controls released, if made according to instructions. If the top rudder were used to bring the airplane level, the test would be correct.

The next paragraph in the memorandum, that on directional stability, shows a similar fault.

Mr. Budwig's statement that "In fact, an airplane with sufficient stability would usually dive out of a turn and assume level flight attitude as the controls are released," is not entirely correct, since, if an airplane is going to recover from a turn, it will lose speed instead of diving before assuming level flight.

Mr. Budwig has somewhat confused the author's statements on stability and power on and power off balance. The "negative lift on the stabilizer, which builds up rapidly as the speed increases," as quoted from Mr. Budwig's discussion, may be built up from the slipstream as well as from increased speed.

It is quite common for pilots to say an airplane is stable when they mean its flight is stable. The more stable an airplane is, particularly in roll and yaw, the more unstable will be its flight. The necessity to fight controls in rough, gusty air is due to excess of directional and lateral stability and not to an insufficient amount.

AER-53-11

Opportunities for Aviation Training

By JOSEPH S. MARRIOTT,[1] WASHINGTON, D. C.

In this paper the author endeavors to set forth the possible methods of obtaining adequate instruction and training to enter the aviation industry either as a pilot or in a ground capacity. The article is written from the practical viewpoint of training facilities available in the industry itself rather than opportunities presented by strictly educational institutions such as secondary schools and universities. The author also points out some of the advantages and disadvantages that are apparent in the existing means of obtaining aviation training.

THOSE who have kept in close contact with aviation in the past three years realize that it has emerged from a babe in arms, passed through the creeping stage, and is beginning to take an important place in national industrial development. The continued expansion and development of this new industry can be accepted without question. Along with this progress and expansion is found a variety of opportunities likewise increasing for those who are adequately trained and qualified to find employment and fill responsible positions. While it is possible for some of these positions to be filled by men from other allied industries, a majority of the opportunities are such that specialized training or a background of experience is required. Since men who have had any previous experience are practically all connected with the industry in some capacity, the operators are faced with the necessity of calling on those who have been trained, since the expansion of the past few years has made the need for additional trained personnel evident. Therefore, an important part of the industry itself is the training facilities which are available for preparing men and women to take their places in the responsible positions of the aeronautical field.

Since it is the purpose of this paper to discuss the opportunities for training which exist as a part of the industry itself, only passing mention will be made of the facilities provided by strictly educational institutions such as secondary schools and universities. It is, however, worth while to mention that probably one of the best ways of preparing for a life work in aviation is by the route of an aeronautical engineering course. Courses of this nature are offered by a large number of our leading universities, considerable impetus having been given to the institution of such courses by the Daniel Guggenheim Foundation. In addition to the university courses the report of the survey made by the Daniel Guggenheim Fund Committee on Elementary and Secondary Aeronautical Education shows that an ever-increasing number of secondary schools are teaching aeronautics in some phase. True enough, a number of these courses are of general information value only, but a small group of polytechnic and trade schools are offering courses of such a nature that they could be classed as vocational education in preparation for ground positions.

For a first rough classification of opportunities existing in aviation the types of positions may be divided into: (1) Operations requiring flying ability and experience, and (2) operations of a ground nature. In the first group are commercial pilots operating aircraft on scheduled mail runs; passenger and express airlines; aerial taxi service; passenger hopping and miscellaneous operations; governmental pilots functioning as inspectors for the purpose of examining and testing pilots for license; aircraft salesmen demonstrating planes for sale; instructors in flight-training schools; test pilots testing the products of aircraft factories; specialized pilots operating some specific industrial mission such as aerial photography, mapping, crop dusting, aerial advertising, etc.

The second group includes the engine mechanic, airplane mechanic, maintenance superintendent, ground-school instructor, airport manager, traffic agent, airport engineer, aeronautical engineer, research engineer, airways mechanicians, airways keepers, weather observers, radio operators, parachute riggers, instrument repair men, airport lighting specialists, and a host of others requiring some technical or specialized training.

In addition to the above two groups, a third group might be added which would include the personnel engaged in the business phases which closely interlock with the activities of the ground and flight operation personnel. In this phase are minor executives and managers of such activities as aerial photography and surveying, aircraft sales and distribution, aerial advertising and promotion, airport development and management, accessories specialists, insurance experts, factory and office executives. It is evident that this third group is being supplied to the industry mostly from other allied industries and the business world. Therefore, no particular study has been made of the opportunities available for training in these fields because of the fact that the average individual entering such a field will have had previous business, sales, or engineering experience fitting him for the position involved, and he will find it entirely possible on his own initiative to acquire the general aeronautical information necessary for the executive duties involved in that type of position.

It will be seen readily from the preceding classification that the different positions in the field of aeronautics demand various types of training and experience. However, education in certain basic lines will lay the foundation upon which the individual

---

[1] Chief, Inspection Service, Aeronautics Branch, Department of Commerce. Mr. Marriott graduated from Leland Stanford, Jr., University in June, 1917, and was commissioned First Lieutenant, Aviation Section, Signal Corps, in December, 1917. He was stationed at Park Field during the war, and at the conclusion had passed through the stages of dual instructor, flight commander, officer in charge of second solo, and officer in charge of flying. Entered commercial aviation as manager of the Memphis Aerial Company and two years later was made head of the science department of the Tamalpais Union High School, Mill Valley, Cal. He remained there five years, during the last two of which he was vice-principal in addition to his other duties.

Mr. Marriott joined the Aeronautics Branch, Department of Commerce, in 1928. He was an inspector in and later supervisor of the New York district. In 1929 he went to Washington to take charge of the school inspection and regulation work as an assistant chief of the inspection section, and was advanced to Chief, Inspection Service, in October of that year.

Contributed by the Committee on Education and Training for the Industries and presented at the Annual Meeting, New York N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

may acquire specialized information leading to other and higher positions provided the person possesses the proper qualifications and necessary basic training. The desirability of adequate preparation cannot be overemphasized.

Opportunities for Flight Training

In view of the fact that the entire first group requires ability and experience as a pilot, investigation should be made of the various avenues through which a person desiring flying training as a preparation for aeronautical work may acquire this instruction and training. The different means of acquiring flying training may be subdivided into: (1) Military schools, (2) commercial flying schools, (3) individual ownership and purchase of instruction, and (4) flying clubs.

Military Schools

The army, navy, and marine corps operate primary and advanced flying training schools for the purpose of providing officers and flying personnel for the particular branch of the service involved. The fact remains that these services do not require the permanent employment of all the graduates of their schools and, although each branch of the service requires that the graduates of their schools undergo a period of active duty after instruction is completed, a large number of the men so trained do eventually leave the service and enter commercial aviation. In view of the fact that the navy, marine corps, and army select the applicants for these schools with a view to their fitness as officer personnel as well as their fitness to become pilots, the educational requirements are somewhat stricter than are required in commercial aviation. These requirements are such for the navy and marine corps that only applicants with the equivalent of four years of college training stand an appreciable chance of being accepted. The army will accept applicants who have satisfactorily completed at least two years of college or who are able to pass an examination which is equivalent thereto. For all branches of the service, there is a minimum and a maximum age requirement and strict physical qualifications. Providing an applicant is able to secure an appointment to one of these military schools, there is, of course, no question regarding the quality of the training which he will obtain. However, it is only natural that this training will have the emphasis of the military phase of aviation, and the graduate of such school, while he will have had adequate flying training, will, in the beginning, be somewhat handicapped in commercial aviation due to his lack of knowledge and familiarity concerning the problems relative to commercial operation.

Commercial Flying Schools

It is believed that the commercial schools which have been issued approved-school certificates by the Department of Commerce provide the most complete and adequate training available in the industry itself for preparation as a pilot. The air-commerce act of 1926 was amended February 28, 1929, by the passage of the Bingham bill authorizing the Secretary of Commerce to inspect and rate civilian schools giving instruction in flying when such schools applied for approval.

Under the provisions of this amendment school regulations were formulated and inspection and rating of commercial schools were under way in June of that year. At the present time 43 schools are operating under approved-school certificates issued by the Department of Commerce. The results obtained by these approved schools have been thoroughly gratifying. The improved methods of instruction are decidedly apparent in the greater capability of the graduates whom they are presenting as applicants for Department of Commerce pilot's license. This can best be shown by the figures obtained from the Department of Commerce records regarding the examination of pilots for license. A comparison of the number of student permits issued, which are not over a year old, with the number of the holders of such student permits who have applied for higher grades of license indicates that 60.6 per cent of those issued student permits continued their instruction to the point where they applied for some grade of pilot's license. It is believed that this can be accepted as a fair figure for comparison because of the fact that the department's study shows that less than 5 per cent of those who hold a student permit for over a year ever apply for a higher grade of license. In comparison, or rather in contrast with this figure of 60.6 per cent, it is found that 91.6 per cent of the students enrolled in approved schools actually complete the course and obtain a higher grade of license. The remaining 8.4 per cent includes not only those who discontinued their instruction voluntarily or were dropped from enrolment by the school, but also those who completed their course, but were subsequently disapproved for license. This comparison shows conclusively that the methods of instruction as well as the attendant conditions at an approved school decidedly decrease the factors which influence an individual to discontinue his training before completion.

Further proof of the value of approved-school instruction methods is obtained by comparing the figures of all applicants for pilot's license. For the first half of the year 1930, Department of Commerce figures disclose that 20 per cent of all applicants for pilot's license were disapproved. During the same period, the figures of approved-school operation show that only 7.34 per cent of the applicants for license from these schools failed to pass the test for license, which means that 32.66 per cent of those applying from other than approved schools failed to obtain license. Here again, the percentage is greatly in favor of the approved-school instruction. This comparison is even more favorable to the approved school when the fact is taken into consideration that a larger number of the approved-school graduates are applying for the higher grades of license, that is, industrial, limited commercial, and transport, than is the case of applicants on the outside. By this is meant that a large number of those receiving instruction from other than approved schools acquire only enough instruction to obtain a private grade of license, the test for which is less difficult than the examination for the advanced grades. The present number of approved schools and their locational distribution throughout the United States make it possible for any one desiring to learn to fly to enroll at such a school with a minimum of inconvenience and travel expense. As an explanation of the reason for the results which it has been possible for the approved schools to obtain, it should be borne in mind that approved schools are required to give the student a complete course in ground instruction in addition to the flying training. Also, the student is required to have instruction on a number of different types of aircraft, which increases his capability and broadens his experience prior to the time when he actually enters the industry. The thorough instruction which the approved school is required to give the flying student has naturally increased the operating cost of the school. Certain advantages accrue to the approved school such as advertising the fact that they have governmental approval and the counting of a portion of the dual instruction flying time as solo flying experience. However, the approved schools are required to meet the serious competition of the unapproved school which can operate without providing a ground school or a variety of equipment.

As stated in the foregoing section, it is not compulsory for a school to obtain a Department of Commerce approved-school certificate in order to operate. The matter of applying for a

rating is entirely optional with the operator. Because of the necessity of meeting certain definite requirements such as providing a field of adequate size, several different types of aircraft, and maintaining a ground school as well as a flying school, a number of operators have continued to conduct their schools on an unapproved basis. The quality of instruction being offered by such schools may be of a high standing. However, there is no assurance that such is the case, and a careful investigation of the facilities, equipment, personnel, and reputation of the institution should be made before a person decides to enroll. After enrolment, the student will find that, under Department of Commerce regulations, only his solo-flying experience counts toward eligibility to apply for a pilot's license. Consequently, in all probability, he will receive only a limited amount of instruction in accordance with whatever restrictions the contract with the school calls for, and his solo-flying experience must be built upon his own initiative without adequate check time and advanced instruction. In other words, any check time or advanced instruction will have to be paid for in addition to the solo time, which very often results in the advanced instruction not being acquired at all. The persons involved, therefore, usually apply for license without adequate instruction and with the possibility of having acquired faulty flying habits which, even though they may not be dangerous, will be expensive to eradicate and will certainly affect the pilot's competency and his ability to obtain a worthwhile position in the industry. He also runs the chance of being in the 32.66 per cent group with those who are disapproved for license on the first examination and who, on that account, are required to wait 90 days before being eligible to reapply. This causes considerable embarrassment, loss of time, and expense for additional instruction. While it is possible for a student flier with the proper aptitude for assimilating flying instruction to obtain his training and experience in an unapproved school, he may, in the long run, find the course more expensive than the approved course would have been, which course carries with it a practical guarantee of being able to obtain the pilot's license.

Individual Ownership

When an individual is so financially situated that he can purchase his own airplane and hire a pilot to teach him to fly, or can reverse the process, that is, hire a pilot to give him instruction and, at the completion of the course, purchase an airplane to build up his flying experience, he is in a position to acquire thoroughly satisfactory training if he is sure of the competency of his instructor. The trend of aviation appears to be such that in the future a number of sportsmen pilots and individuals who purchase airplanes for their own private use will receive their preliminary training leading to a private pilot's license from the factory or sales agency from which they purchase the airplane. Teaching the purchaser to fly will be a part of the purchase price of the airplane. If the individual who desires to fly only for his own pleasure or to use an airplane as a means of his own personal transportation learns to fly by this method, the result will be that the established schools, both approved and unapproved, will be training centers for professional pilots only. In this case, the tendency would be for the schools to lengthen their courses beyond the present requirements for transport grade of license in order that they might provide specialized phases of instruction preparing pilots for air mail, passenger, and airline operation and other types of pilots' positions. In fact, one or two of the approved schools have already offered advanced courses of this nature. One school in particular offers a 500-hr. course for pilots for definite preparation for scheduled airline operation. This is in contrast to the customary 200-hr. course for transport license, which is the highest one the average approved school is now giving. The group of individuals who are able to purchase airplanes and employ pilots to give them private instruction is, at the present time, relatively small. Also, a relatively small number of this group are interested in entering commercial aviation in a flying capacity. This group is, therefore, not a particularly important factor in the nation's aviation training program.

Flying Clubs

The flying club offers an excellent opportunity for a person to build up his flying experience and keep his hand in after having acquired his preliminary instruction. Particularly is this the case if a person is not able to purchase a plane as an individual or is unable to obtain a position requiring flying duty immediately after obtaining his primary instruction. The flying club also offers an opportunity for an individual to obtain his elementary flying instruction if conditions are favorable and the club is organized properly with a membership including men who have sufficient experience and qualifications to serve as instructors, or providing the club is in such financial position that it can employ the services of a competent instructor. However, it should be pointed out that the limited amount of equipment and the usual lack of facilities for maintaining and servicing the club airplane usually make the matter of learning to fly by this method a long drawn out process. Also, when the flying instruction is so spread out, the individual finds difficulty in maintaining progress and, in most instances, takes a greater number of hours in the air to acquire satisfactory skill in manipulating the airplane. This may cause discouragement to the student flier and influence him to give up the experiment before he has reached the place where he can obtain a license and become a producing part of the flying fraternity.

The foregoing four methods, as outlined, now constitute the principal opportunities for flying training existent in the country today. The selection of the method of training should be made with the advantages and disadvantages of all the four available methods in mind, particularly as they apply to the individual himself.

While there has been some talk in the past six months to the effect that there is now an overproduction of pilots in the industry, a careful analysis of the situation discloses that a very large percentage of the pilots now out of employment are those whose capabilities and experience as pilots do not meet the standards set by the industry itself or they are lacking in certain other qualifications which render them unsuitable for a given phase of work. Unquestionably, with the present healthy growth of commercial aviation operations such as the extension of scheduled passenger-carrying airlines, the pilot who has been adequately trained and who has the proper qualifications will be able to find a position commensurate with his capabilities. In this connection, it might be well to add that the industry does not look upon the graduate of a school, even though that school be approved, as a comp'etely trained product. Ability to fly aircraft under varying conditions of weather and other emergencies can only be acquired over a period of time and cannot be crammed into the school course, regardless of how intensive the course may be. In addition, any specialized type of work, such as the variety of type of positions specified in group one, will require additional preparation if the individual does not have knowledge of same prior to taking the pilot's training. At the present time, very little has been done toward providing these specialized courses in commercial aviation schools. Some courses are available for aircraft salesmen, aerial photographers, and flying instructors, but the demand for such instruction has not been great enough to warrant the institution of many courses covering these fields.

Opportunities for Ground Training

Opportunities for training of a ground nature in connection with aircraft operation as they now exist are: (1) Trade and technical schools, (2) practical experience as apprentices in the industry, and (3) combination of aeronautical courses and practical experience.

A representative group of the trade and technical schools is offering courses in preparation for ground positions in aviation. However, the nature and the value of the instruction are as divergent as the number of schools. This is due to the fact that there are no established standards for any of the courses of this type, which means that the kind and quality of instruction depends entirely upon the initiative, capability, and viewpoint of the instructors and operators of these schools. A greater portion of the trade and technical schools attempt to prepare a person for a position in the mechanical phase of aviation ground operation. This school preparation, if adequate in any sense, prepares an individual to take a position as an apprentice mechanic working on the maintenance and repair of aircraft under the supervision of licensed personnel. After having acquired sufficient practical experience, the apprentice mechanic is eligible to apply for a Department of Commerce mechanic's license, of which there are two types, the airplane mechanic's license and the engine mechanic's license. In addition to the trade and technical schools, quite a number of the commercial schools, especially the approved ones, are offering courses for mechanics. There is no provision at the present time for the rating of such courses by the Department of Commerce. Consequently, little can be said about the quality of the instruction being offered or the uniformity of instruction as given by the different schools.

The army air corps conducts schools for mechanics for its enlisted personnel. This army course is a combination of theoretical and practical training. Together with the subsequent experience obtained during the three-year enlistment period, it produces thoroughly competent mechanics provided they have the necessary aptitude and qualifications to begin with. The army air corps also conducts at Chanute Field a school for parachute riggers. To date, the graduates of this school have furnished practically all of the army as well as commercial parachute packers. In view of the recent Department of Commerce parachute regulations which require a parachute packer to hold a Department of Commerce parachute rigger's license if he is to pack parachutes used in commercial aviation, this type of position will become increasingly important in civilian aeronautics.

New York University has done some valuable work in developing a course for ground-school instructors. This activity has been conducted under the supervision of the Daniel Guggenheim Committee on Secondary Education. So far as is known, this is the only school offering a course preparing ground instructors for positions in approved schools.

Practical Experience as Apprentices in the Industry

By far the greatest number of men serving in a ground capacity in connection with the operation of aircraft have obtained the position which they now hold as a result of previous practical experience. These men, particularly the airplane and engine mechanics, served with the air service during the war or with the barnstorming pilot since the war and have developed their knowledge of airplane maintenance and repair from the "University of Hard Knocks." The work of an aviation mechanic is rapidly developing into a trade of its own. The men without previous experience or with a mechanical experience from other fields are, in many cases, entering aviation groundwork by the apprenticeship method. If the individual is fortunate enough to obtain a position where he can, by applying himself, learn the various phases of work in connection with the mechanical repair of aircraft, it is possible for him to acquire sufficient knowledge to enable him to obtain a mechanic's license, and with the proper qualifications, to progress to a responsible position supervising this type of work. In many instances, however, the apprentice finds himself working under a mechanic who obtained his knowledge and experience in the early days of the industry and who, although thoroughly capable himself, is all too often unwilling or unable to impart his knowledge to the apprentice. Factories are hiring from time to time inexperienced employees and training them on some portion of the aircraft construction work. These men are not required to hold a license because they are not working on the maintenance and repair of aircraft, but rather on the construction of a component part under the supervision of competent engineers. Such men, while they have an opportunity to work into factory production, will have some difficulty in getting into aviation operation because their training has been entirely limited to one phase of airplane construction. As the factory production increases and as commercial operation expands, increased opportunities for men to work as apprentices and learn their trade will become available.

Combination of Aeronautical Courses and Practical Experience

The aviation ground man who obtains his training solely by practical experience will be limited in the advancement which he can make in the industry. This is true, because he will have learned to do certain things, but will not have learned the why and the wherefore. He will have no theoretical or technical background, and will have to rely entirely upon his experience of having done a job before or having seen it done in order to be able to do it himself. Therefore, probably the best method of training for aviation ground positions is a combination of some aeronautical course which will provide the theoretical instruction regarding the position which the person desires to fill combined with the practical experience in work of this nature. Whether this aeronautical course is taken before or during the time when practical experience is being acquired is not necessarily essential, although if it can be taken in conjunction, the theoretical training will be more easily assimilated by the student. If the person is to follow this method, it will probably be necessary for him to attend night courses or take correspondence courses in order to enable him to work and obtain his practical experience during the day. The selection of a ground course should be made only after a careful investigation of the reputation of the school and the facilities available. For courses of a mechanical nature, the amount of modern demonstration equipment provided for laboratory or maintenance and repair instruction is an important factor. The value of a correspondence course is dependent, to a great extent, upon the application of the person taking such a course and his ability to apply practically, in his daily work, the principles which he is studying. Earlier in this article, it was stated that there was a lack of uniformity in ground courses and that no standards existed for relative comparison of such courses. There has been a standard set up by one governmental agency for courses which are designed for the instruction of airplane and engine mechanics. The Federal Board of Vocational Education has issued a bulletin setting forth the phases of instruction essential for each of these two courses. The bulletin gives the duties of the airplane and the engine mechanic, and includes in the course outline a complete set of typical jobs for practical instruction. It is believed that the combination of theoretical and practical experience is the soundest means of preparation for any ground aviation position.

The necessity for some theoretical and technical instruction is conclusively indicated in the high percentage of failures by applicants for mechanic's license who apply with only a background of practical experience.

New Ground Positions Developing

The provision for the licensing of parachute riggers, which has already been mentioned, is an example of the new types of specialized positions which are developing in the ground operation of aviation. Another example is the necessity for competent instrument repairmen on operating airlines. Still another is the development of radio in connection with aircraft and the necessity for radio operators to handle such equipment on the airplane.

The radio division of the Department of Commerce has established a new grade of radio operator's license known as commercial third class which is specifically designed to take care of men operating radio-telephone or radio-telegraph installations on aircraft. This license or a radio operator's license of a higher grade will entitle the holder to serve as a licensed airman in connection with licensed aircraft.

In closing, the fact should be pointed out that the acquisition of proper training for filling a definite ground position in connection with aviation depends, to a large extent, upon the ability of the individual to make the most of the facilities which can be obtained. His success or failure will be governed by his initiative and persistence in following through to a conclusion the course of instruction which he maps out for himself. In addition to the theoretical training, the practical experience is equally as important. The selection of the place to obtain this initial experience should be made with consideration given to the opportunities which are available for progress rather than the amount of salary which is involved. While it may appear that the opportunities for aviation training for ground positions are limited, it is, nevertheless, possible for any one with the proper qualifications to equip himself adequately for a successful future in this work. Information relative to the names of schools offering aeronautical courses, either for ground or flight instruction, can be obtained from Department of Commerce bulletins. The department has recently prepared a new bulletin on the entire subject of aviation training which will be of value to any one interested in acquiring such training.

Discussion

T. A. Sims.[2] After reading this paper there are several thoughts which may or may not be of any value. The writer knows little about commercial aviation beyond the average military pilot's knowledge of the commercial game gleaned from several years' experience in flying around the country visiting civilian fields as well as military. However, the writer formerly was stationed at the Air Corps Advanced Flying School at Kelly Field, Texas, as a flying instructor and is familiar with the present system of flying training in use by the Army Air Corps. It is this system which he would like to recommend to the industry.

An enormous expansion of commercial aviation in this country is being held up simply because the public is still skeptical, and rightly so, about the safety of flying. Although the large air lines have a very low accident rate, the general public forms its opinions of aviation in its entirety, and every accident exerts its disquieting influence on the whole industry. So it behooves the whole industry to take drastic steps to demand safety in flight; to convince even the insurance companies by cold statistics that it is safe to fly. Now every one knows that approximately 75 per cent of the accidents are caused by errors in pilotage. So let us begin at the pilot factory and nip these errors in the bud.

The standards of commercial schools at present are far below what they should be for the best interest of commercial aeronautics in that they have no tendency to eliminate the inferior student. Any man who pays his tuition fee for a 200-hour flying course, for instance, can complete the entire course regardless of his progress in flying ability, which may or may not be satisfactory. The schools should be honest enough to eliminate the student when he has reached his ultimate limit of learning, beyond which further instruction is useless. To graduate such a student is a crime against the aviation industry, for this man is handicapped from the beginning, and lacking the normal safety factor he stands more chance of becoming a casualty.

Imagine the condition at West Point if we had no method whereby the deficient cadet could be eliminated. About fifty plebes per year would just be wasting their time when carried to more advanced classes, because the subject matter would be so far over their heads that they would be completely lost. This is the condition that exists in the commercial flying schools today. Instead of turning out a smaller number of safe, dependable pilots, they have entered mass production of a larger number of pilots of the questionable variety. Compare this with the Government flying schools, which perhaps swing the pendulum the other way and graduate about 25 per cent of a class, eliminating any one the instant he fails to show satisfactory progress and becomes dangerous to himself and others. It is only fair to the student that he be eliminated when he reaches this stage. Unfortunately, some of these eliminated students will not believe that they are incapable of further flying, and will enter the commercial game. Handicapped as they are by the "lack of inherent flying ability," they will eventually become a casualty. They should be forever prevented from touching the controls of an airplane in flight.

Now the writer realizes that there is at present a vast difference between commercial and military flying. As he understands it, the military pilot must be able to use his airplane as a military weapon; that is, the actual technique of flying to him is secondary to the proper use of the military weapons at his disposal. He must possess "inherent flying ability" or, in plain language, the ability to operate the airplane automatically by his subconscious mind while his main mental effort is directed toward his enemy, his machine guns, bombs, camera, radio, his tactics and strategy, and countless other tasks. On the other hand, it would seem at first glance that the commercial pilot needs very little of this "inherent flying ability" because he can devote most of his mental effort to the actual technique of operating the plane. However, it is this "inherent flying ability" that the writer believes should be a requisite of the commercial flier as well as the military. What may happen to the pilot without it? He meets an emergency sooner or later wherein he is required to look for a landing field or make his choice between several courses of action, or in other words, to use his mind for something other than concentration on the technique of operation. He does one or two things, both wrong; he either neglects the technique and allows the plane to fly itself, which, together with his natural tenseness on the controls, will cause the plane to fall off into a spin, or he neglects the headwork or judgment end of his forced landing, and the chances are that he crashes. The possession of "inherent flying ability" is an enormous safety factor, and the industry will do well to follow the lead of the military schools and demand it in their pilots.

Now some people might question this and bring out the fact that the military accident rate is as high as the commercial. This is true, and the reason for this lies in the type of flying that the military services are required to perform and which to be of any tactical value whatsoever are far more difficult and danger-

[2] Second Lieutenant, Air Corps, U. S. A., West Point, N. Y.

ous than most commercial missions. Were the military services required to reduce their accident rate to the minimum, it would be necessary to dispense with formation flying, for instance, but at the expense of the effectiveness of the Air Corps as a military arm.

Another thing, the writer thinks the 200-hour requirement of the Department of Commerce is really no fitting criterion for a transport pilot's license. A student's knowledge depends not upon the amount of time spent in study, but upon what he gets out of the study, on the quality of time in the air rather than quantity. Quoting from the paper that "Graduation from a 200-hour course in an approved school carries with it a practical guarantee of a license," the writer has seen some schools where the students were merely counting flying hours in building up to that coveted 200; they were doing the same thing day after day (acrobatics) without much thought toward improvement of flying ability. The writer has seen one school where the bulk of the students were airplane factory workers, who would save out their $5 from their weekly pay roll and spend it for 15 minutes of flying instruction, a slow and tedious course, without any hope of sequence or any instruction in a phase of flying that took more than 15 minutes to complete. The knowledge of either of these two types cannot be compared to that gained by a student who completes his course of supervised instruction within a year's time, who has flown in various types of airplanes, made cross-country flights, or perhaps flown as co-pilot on transport lines. The writer thinks that a stiff flight check by the Department of Commerce covering everything an embryo transport pilot should know is a far better criterion of flying ability, and too much should not be taken for granted upon presentation of 200-hour credentials.

The third opportunity for aviation training, that of individual ownership, is relatively small due to the large financial outlay it takes at present to purchase, maintain, and operate aircraft. However, with the advent of standardization and mass production this cost will diminish in the future, and this group will become more important. To insure safety it will be necessary to rule this group with better regulations than are in existence today. This group is controlled mainly by the various state laws governing flying, just as automobile licenses are controlled today. These laws lack uniformity; in fact, some states have no laws, and it is possible in these states for a man to purchase an airplane, get in, and fly it away with little or no flying experience, when the same man would be arrested for driving his car without a license. It appears that the only solution rests in more stringent and uniform state regulations. So much for pilot training.

Obviously, the graduate of any school is not a finished product. Under present conditions the only way a pilot can learn anything more is through the "school of hard knocks," his own experience over a period of time. The pilot has several real forced landings, and finally learns that he can "walk away from them" if he flies at a safe altitude, so that he has plenty of time to think and plenty of room in which to maneuver. Finally, flying at a safe altitude becomes a habit. However, these lessons by personal experience are sometimes fatal, if the pilot makes the wrong decision when he gets into some predicament that he has never experienced. In fact, the first year after graduation is the most dangerous one of the pilot's career. The various statistics on aircraft accidents emanating from the Chief of the Air Corps and the Department of Commerce are extremely valuable to a person who understands statistics and who studies them thoroughly. By these means we learn from the experience of others. However, it is the writer's opinion that there is a considerable amount of information on aircraft accidents that is going to waste because it cannot be expressed by statistics and graphs. By this is meant all the various details of an accident, the conditions under which it happened, what was done by the pilot, what happened, and a statement by an expert on what the pilot might have done to avoid the accident. Such information never gets into print and is consequently lost. The Navy gets considerable information on landing accidents by having a moving-picture camera trained on the approaching airplane, and taking the photograph when an accident looks possible. Obviously this is impractical for the mass of accidents, but the essential information could be reproduced by drawings and pictures. This information might be broadened to include personal experiences of reputable men. To be specific, suppose a pilot in a land had a forced landing, with the choice of landing either in the woods or in a river. Certainly the great collection of data on aircraft accidents could give some indication of the best line of action in this case. Also certainly some experienced pilot could be prevailed upon to explain the technique of landing a land plane on water. In the military services a common mistake of the inexperienced pilot having motor trouble while flying in formation is to pull up and out of the formation in a natural reaction to gain more altitude. He flies directly across the path of the succeeding elements in the formation, and sometimes a collision results. This happens several times each year. If these collisions were represented pictorially and repeatedly published to the services every time such an accident happens, it would soon teach every one to dive out of a formation instead of pulling up. Some Government agency should be prevailed upon to publish this detailed information as an addendum to the statistics.

Perhaps quoting a few statistics will tend to verify some of these contentions. In the paper, "Opportunities for Aviation Training," it is noticed that 7.34 per cent of the applicants for license from accredited schools and 32.66 per cent of the applicants from other than approved schools fail to obtain their license, whereas the writer knows not a single case of a graduate of the Army flying schools failing to obtain a transport pilot's license.

To summarize, it has been attempted to show that:

1 The standards of commercial schools at present are far below what they should be for the best intent of commercial aeronautics
2 The 200-hour requirement of the Department of Commerce is really no fitting requirement for a transport pilot's license
3 Better state laws are needed to cover cases not controlled by Federal Interstate Commerce regulations
4 Some Government agency ought to publish and distribute detailed information of an educational nature about airplane crashes and the technique of flying.

The foregoing are the writer's personal views.

J. S. A. Johnson.[3] The author has not only described in a comprehensive manner the present opportunities for training in aviation, but also has outlined fully the methods of broadening these opportunities and creating others.

Of the two kinds of training, flight and ground, the former will appeal most strongly to the more adventurous natures. Accordingly, with the gradual increase of aerial transportation an increasing number of regulatory measures must be introduced for safeguarding not only pilots and passengers, but also the general public. As small a number as possible of such means of regulation should be of the "thou shalt not" type, but all of them should be designed to contribute toward the safety, comfort, and convenience of both fliers and those upon the earth. In

[3] Professor of Applied Mechanics and Experimental Engineering, Virginia Polytechnic Institute, Blacksburg, Va. Mem. A.S.M.E.

congested areas aerial traffic regulations therefore will doubtless open up an ever-increasing number of opportunities for employment, along with which will proceed increased opportunities for training in both flying and ground work. The aerial traffic officer of the future must possess not only great courage and skill, but also tact and general resourcefulness. The installation and operation of aerial signs and signals such as beacon lights and possibly buoys, together with effective weather forecasting and indicating equipment, will provide opportunities for numbers of well-trained and skilful pilots and other aerial employees.

Especially significant are the author's statements regarding the necessity of proper general qualifications and the thoroughness of basic training and preparation of the pilot and the flight mechanic. In many cases those who know least concerning the principles and mechanism of the automobile become the most skilful chauffeurs after a few lessons in manipulation and steering. In case of failure to function, the car can at least be stopped until aid is secured. Not so with the airplane, however, when failure immediately to locate and correct trouble may result in disaster. It would appear, therefore, that in time all agencies giving instruction in flying must be chartered, at least by the respective state governments, or come within the classification of the approved schools.

With the increase of aerial transportation owners of airplanes and other aircraft will be required, doubtless, to secure accident insurance for the benefit of passengers and employees, and this would involve a corps of aeronautical experts in various capacities, thereby offering additional opportunities for those trained in both flight and ground schools.

In connection with flight schools, especially those under governmental control, it is probably that consideration should be given to the establishment of Reserve Officers' Training Corps units in aeronautics at certain technical schools, together with aerial summer camps for R.O.T.C., possibly at least one of each in every state, depending upon general conditions, such as population, climate, and topography.

For training in ground work the opportunities would appear to be limitless because of the need of development of materials, fuels, mechanisms, and methods of construction. A broad field in design and research is accordingly opening up for any one with technical training and research ability. As in any industry, there have been many, and there will be many more, impractical suggestions and "inventions," and it will become the duty of those with technical training to pass upon them. For such investigators, especially as the author suggests for those who intend making aviation their life work, the best preparation would be the completion of a course in aeronautical engineering at a standard technical college.

R. Burdette Dale.[4] The author has confined his paper principally to the opportunities which exist within the aviation industry for those who are connected with operation and maintenance. He has given but little consideration to those who are engaged in the planning and design of the airplane structure itself. He did mention the aeronautical engineer whom he has classed in the group whose operations are of a ground nature.

A survey of the industry would probably disclose that not all those employed in the engineering department are aeronautical engineers. The industry rightly makes use of many young men with a basic engineering background who have not had the advantages of a specialized course in aeronautical engineering. This is a customary procedure in the general engineering field. For example, not all technical men in the engineering department of an organization engaged in the manufacture of steam turbines are turbine engineers, but many of them are apprentices or cadet engineers with a mechanical engineering background. These young men deserve special training to enable them to take their proper place in the industry and to fit them to carry on the responsibilities of the future.

The aviation industry is at the forefront of this forward-looking movement. It has observed that those industries which have not been active in recruiting and training promising young men are today suffering for their neglect. This is particularly true in the case of planning activities. Every industry must look forward to the future if it intends to maintain its position with the highest efficiency.

At least one organization in the New York district provides special out-of-hour training for their engineering apprentices. Advancement in the organization is predicated on technical examinations which are held every six months. Their engineering designers and draftsmen are encouraged to attend evening classes in airplane design offered in technical institutions in the city. In selecting the general run of designers and draftsmen, preference is given to the young man with a sound, fundamental engineering training rather than to graduates of aeronautical engineering courses. The industry itself assumes the responsibility of providing the required specialized training either within its own organization or through other agencies.

For the past three years, Pratt Institute has offered an evening course in airplane design. This has been very successful. Most of the students are actually employed in the industry, though a number have prepared themselves to enter the industry by taking the course. The enrolment is limited to twenty members, and these are carefully selected for their suitability and qualifications. Many are college graduates from a general course in engineering or from a specialized course in aeronautical engineering, but membership is not restricted to college graduates. The instructor is a practical and experienced airplane-design engineer who is employed in the industry. The objective is to give intensive and practical but highly technical training which will be of immediate and useful application in the industry.

Roland H. Spaulding.[5] The author has given a splendid paper on the opportunities for aviation training to be found in the industry itself. It may be of interest to know that approximately 500 public schools are giving some form of aeronautical instruction. In about 50 of these the instruction is on the vocational level. The Daniel Guggenheim Fund Committee on Elementary and Secondary Aeronautical Education, with headquarters at New York University, has been aiding the public schools in this instruction for the last two years by its research work and its facilities for the training of teachers, both for ground schools and for public schools. One may obtain the publications of this committee gratis.

The Educational Committee of the Aeronautical Chamber of Commerce of America is also sponsoring the development of educational opportunities in aviation. Last year, in cooperation with the Daniel Guggenheim Fund Committee, it held the First National Conference on Aeronautical Education in St. Louis. The next one will be held in April in Detroit, coincident with the International Aircraft Exposition.

Author's Closure

I wish to take exception to Lieutenant Sims' statement that the standards of commercial schools, at present, are far below what they should be for the best interests of commercial aeronautics in that they have no tendency to eliminate the inferior students. I would call attention to the fact that the approved schools, in order to hold their certificate, are required to maintain

[4] Department of Machine Design, Pratt Institute, Brooklyn, N. Y. Mem. A.S.M.E.

[5] Professor, New York University, New York, N. Y.

a standard that will guarantee that nine out of ten of their graduates qualify for license. This requirement has resulted in the approved schools eliminating inferior students from their enrolment prior to graduation. In fact, most of the schools have adopted the policy of eliminating such students as soon as their unfitness for flight duty becomes apparent. Statistics for the first year of approved-school operation definitely show that the standards of instruction in commercial aviation have been greatly improved.

The Secretary of Commerce is charged with the duty not only of regulating commercial aviation but also of fostering and promoting its development. The approved-school set-up, therefore, was made as nearly ideal as possible without being impractical from a commercial operating standpoint. As a matter of fact, it was made so nearly ideal that, although it improved conditions so far as student training is concerned, the approved schools have found it difficult to maintain their required standards and, at the same time, make a profit.

It is believed that the transport graduate of an approved commercial school is a thoroughly competent pilot. Furthermore, in contradiction to the opinion of the discussor, it is believed that the commercial pilot must possess inherent flying ability and does. He is called upon to fly a wider variety of weights and types of aircraft than the military pilot, under all sorts of weather conditions, and, in the case of air transport pilots, must be able to maintain two-way radio communication with the ground while in flight. Along this same line, Army Air Corps officials freely admit that commercial aviation has done more to develop instrument flying than the military branches.

The author agrees with the critic that too large a proportion of aircraft accidents are caused by errors in pilotage. Therefore, anything that can improve pilot training by having the embryo pilot gain his experience under a variety of operating conditions and thus better qualify him to fit into commercial operation, would be of great value to the aeronautical industry.

Lieutenant Sims points out that the two-hundred-hour requirement of the Department of Commerce is not a fitting requirement for a transport pilot's license. While it is agreed that a certain number of hours does not indicate a pilot's ability, it might be pointed out that the two hundred hours constitute a minimum requirement and all applicants for license are required to undergo a flight test to determine their actual ability. It also might be worth while mentioning that the graduates of military schools have little more than the two hundred hours' total solo flying time upon their graduation.

The author is heartily in accord with the critic's statement that better state laws are needed to cover causes not taken care of by Federal Interstate Commerce regulations. He also is in accord with the suggestion that more publicity of an educational nature concerning airplane crashes and the technique of flying would be of value.

Mr. Dale has pointed out one of the methods whereby the industry may recruit men with a technical background and assist them in obtaining additional technical training needed for the duties involved in connection with a position in the aeronautical industry. His discussion bears out the suggestion that practical experience, supplemented by theoretical instruction, is sound means of advancement.

Prof. J. S. A. Johnson's suggestions for the further development of opportunities in aviation, particularly as they apply to the allied ground opportunities, are excellent. Undoubtedly, as the various phases of the aeronautical industry become better organized, their development will require the services of a large number of men trained in specialized fields.

FIG. 1 AIR VIEW OF LOS ANGELES METROPOLITAN AIRPORT—THE DARK CROSS IS THE SODDED RUNWAY

Management and Operation of a Large Airport

BY WALDO D. WATERMAN,[1] LOS ANGELES, CALIF.

The policies and methods outlined indicate how an airport may be managed so as to take care of all interests. The author covers relations of the airport management with transport companies operating large fleets, with air-service operators having fleets of taxi and charter planes, with schools, with dealers and distributors, with manufacturers, with private owners of airplanes, with individual owners of single airplanes or small fleets for business purposes, and with the general public. Figures are given showing how a successful business has been built.

THE management and operation of an airport presents many interesting problems both serious and difficult. Perhaps the most difficult of these is the maintenance of the proper relationship between the management and those located on the airport.

In an analysis of the situation each individual class of operators must be considered as the problem of each is often greatly different from that of the others. For such an analysis the various operators should be grouped so that each case can be studied individually:

1 Transport companies operating large fleets of planes
2 Air-service operators operating fleets of taxi and charter planes
3 Schools
4 Dealers and distributors
5 Manufacturers
6 Private owners
7 Individual owners of aircraft operating one airplane or small fleets for business purposes, such as oil companies, accessory manufacturers, etc.

Speaking for all classes there are a few fundamental rules which it is believed are necessary in the successful operation of any com-

[1] General Manager, Los Angeles Metropolitan Airport.

mercial airport upon which diversified operations are taking place. The first of these is that all commercial activities must of necessity be given every chance to operate at a financial profit or it is certain that a time will eventually come when they cannot pay their bills and the airport will be the financial loser. With this in view it is highly advisable for the airport management to exert considerable effort in publicizing the field and the operators thereon in as many ways as the particular case makes advisable.

It is the policy of many airport organizations to engage in commercial aviation activities to as great an extent as is financially profitable. Many such airports reserve for their own organization passenger-carrying and charter rights, repair facilities, and the marketing of supplies, gasoline, and oil, etc. Although engaging in such activities is unquestionably in many cases lucrative, it is not a function of the airport operator. It is certain that many plane operators would be drawn toward such an airport if they were permitted to participate in such activities. If airplane operators conduct such businesses in competition with the airport operator, the situation would be very undesirable, although such cases are occasionally found. In an ideal set-up the airport management should be in such a position that it cannot favor any particular operator over another, whether he be an airline, a school, a dealer, or service station. Under such circumstances a spirit of good business and clean competition can be built up among the operators, which is the basis upon which true modern American enterprise is developed.

Rules and regulations, in addition to Department of Commerce rules, must be promulgated; but only such rules as are absolutely necessary to the safety of aircraft operation and those that will prevent an injustice to other operators should be in force. The enforcement of airport rules is a difficult problem, as every airport manager experiences minor infractions which under the particular circumstances render no hardship or hazard to any one, yet seriously impair the morale of the pilots. Such penalties as grounding or otherwise punishing such offenders can very quickly cause considerable friction between the pilots and the airport management. A new idea is now being used on the Los Angeles Metropolitan Airport, which has so far solved this rather difficult problem. A "kangaroo court" has been established, having its judge, prosecuting attorney, and clerk selected by the operators appointed by their own group. At periodic meetings the offenders are given a fair trial and, if found guilty, are fined in small amounts. The proceeds of the fines thus derived are used for development or social purposes participated in by all of the operators. This is being found to make the worst offenders an excellent policing body. The system has thus far proved very effective, and any hard feelings that would otherwise be felt toward the management are eliminated.

With such a system there is still nothing to prevent the management from taking any steps which it may see fit along disciplinary lines, but naturally such authority would be unwisely used unless the offense was a serious one and the kangaroo court could not adequately take care of the matter.

It has been found that periodical meetings between the operators and the management are of great benefit. At such meetings many things can be explained and the reasons thereof enlarged upon by the management, thereby preventing cause for dissension. Many constructive ideas can be obtained at such meetings from the operators, and many petty grievances such as exist on all flying fields can be aired and usually amicably settled.

One of the most essential things to make it possible to maintain the proper relationship between the airport management and the operators is to have the original fundamental set-up between the management and the operators of such a nature that certain relationships can be established and maintained. Without this proper foundation there is always room for discord and strife. There may be many set-ups that can be used to advantage, but there are certain things which, if included in the original set-up, make the airport management's future job much less complex. These are briefly outlined as follows:

Fig. 5 Ruckstell Corporation Building Where Service and Repair Work Is Done

The granting of an exclusive privilege of any sort to any operator, even though he pays well for it, is a constant source of trouble. If a certain firm has the exclusive passenger-carrying rights on the airport and another operator is seen by him to load in what is apparently, but not in reality, a load of pay passengers, there immediately arises in his mind the thought that he is being deprived of something which is rightfully his, and nothing will cause trouble and dissatisfaction more quickly than such a feeling. Unjustly the airport management immediately receives the blame and bears the brunt of the ill-will thus incurred. If an airport grants unrestricted commercial privileges to all those basing on the airport, it then only becomes the management's problem to see to it that planes based at other ports do not encroach upon the home plane operators' rights, which is a comparatively easy matter.

The more nearly approaching ownership of hangars and hangar sites that can be developed the simpler the airport management's problems will be, for it is natural for every one to take pride in ownership and look at things from a much different point of view. If an operator owns his own hangar or still better his hangar and the site upon which it stands, together with an interest in the flying area, he feels that he is part of the airport organization and will be more careful to guard and promote its interests. It also encourages him toward a more permanent development and a better standard of operations. He becomes a permanent function of the airport, and, although spasmodically perhaps not so lucrative, is in the long run a much greater asset than a tenant who is here today and gone tomorrow.

One of the most necessary policies in airport management is to make each operator feel that those in charge of the airport take a personal interest in his activities and evidence a desire to be of help in developing his business or of assistance in solving his problems. A much closer relationship can be established along these lines if the airport manager or at least some of his staff are recognized pilots. If such is the case many incidental problems can be dealt with more intelligently and the opinions of the airport management are likely to be more highly respected. Being a pilot, although desirable, is by no means the only qualification that members of airport managerial staffs should possess. They naturally have many problems of construction, engineering, and general business with which to cope, which require a diversified experience.

With an airport built on the foundations outlined the problem of maintaining an amicable relationship between the aircraft operators and the airport management is greatly simplified. The author is frank to admit that with the fundamental set-up which

FIG. 6 FACTORY OF BACH AIRCRAFT COMPANY AT LOS ANGELES AIRPORT

FIG. 7 SERVICE, STORAGE, AND REPAIR DEPOT OF ANGELUS AERO CORPORATION AT THE AIRPORT

exists on many airports throughout this country a harmonious organization would, at many times, be very difficult to maintain. In these cases the fault does not necessarily lie with the management, its personnel, or the operators, but rather with its policies which are basically wrong. Unfortunately many airports have been developed by political administrators with little thought except that of building a monument to their administration or have been developed by private capital with little thought of what the future held in store for them.

To make a drastic change in policy, although apparently for the better, even in an airport's infancy is oftentimes disastrous. This has been tried in the cases of privately owned airports which have been taken over by municipalities. As an example, a certain large midwestern airport which was privately owned permitted all operators to market gasoline. Upon the acquisition of the airport by the city near which it was located, the new management of the airport decided that the revenue derived from the sale of gasoline should go rightfully to the city, and immediately took steps to bring about this change. When the operators were not only deprived of this revenue, but also had to pay a larger price per gallon for the gasoline which they themselves consumed than they did before municipal control, immediate dissension resulted. Although in some cases these operators carried on extended operations with bases at other airports where they were not permitted to market gasoline and were perfectly content with the arrangement there, yet it was one of these operators in particular that raised the biggest protest. The result has been a belligerant attitude between the operators and the municipal management, although in the minds of both they are entirely justified in the stand which they have taken. In the long run it may be found that although considerable revenue can be gained by the city in the sale of the gasoline the loss of good-will more than counteracts this apparent gain.

This is cited just as one case of scores that may arise in a change of policy. The airport that is intelligently built with an eye to the future, instead of merely looking two or three years ahead, will always have fewer operator-managerial problems.

Individual consideration must be given to various classes of operators as outlined in the opening paragraph.

(1) *Transport Companies Operating Large Fleets of Planes.* Such an operator is one of the backbones upon which the industry is built. His demands are many and in most cases do not dovetail well with the activities of other types of operators. One of his principal difficulties is in merchandising. His clients are paying prices for transportation considerably in excess of other means and therefore feel entitled to all possible courtesy and comforts while at the airport. It is therefore highly necessary that the airports from which transport companies operate have suitable terminal facilities available at which various conveniences are to be had. A comfortable waiting room is necessary, with clean and modernly equipped restrooms. Conveniently situated, should be also a clean restaurant where good food is served at reasonable prices, and tobaccos, confections, and current periodicals should be obtainable. Some one should be at hand at all times when airline passengers are present, competent to give full information on the many questions likely to be asked. There is no branch of service that will mean more to the airline operator than judicious attention to all of their clients' needs.

Air-transport hangars should be so located and fenced that the general public has no access to them and so that they are not bothered by the usual airport hangers-on.

Many airports ground all other flying activity upon the arrival or take-off of transport planes. This may be very satisfactory from the transport operators' point of view, but works an unnecessary hardship upon all other operators. When the flying area of the particular airport in question is of sufficient size, the enforcement of the Department of Commerce rules requiring that all ships in the air remain at least 300 feet apart and the granting rights of way to transport ships in the vicinity of airports should be entirely sufficient. Care should be taken, however, that traffic does not interfere with the activities of transport ships on the ground to the extent that they may be delayed in approaching the passenger terminal, and congestion, if any, at that point should be eliminated, as close operation to schedule is highly important to the success of the air-transport operator.

(2) *Air-Service Operators Having Fleets of Taxi and Charter Planes.* Such operators depend largely for their business upon the solicitation of customers from those drawn to the airport through interest in aviation and general flying activity, and of course the repeat business derived from their clientele. Their problem, as of the transport operators, is principally one of merchandizing, and they should be accorded every possible opportunity of contacting those that visit the airport. For this purpose parking areas should be provided at locations giving a good view of the general flying and as free from unpleasantness as possible. It is highly desirable, but oftentimes impractical, from an operation and safety point of view, to permit the spectators to get as close to the operating planes as possible.

On almost every airport it will be found that the spectators are likely to congregate at certain spots, and each operator feels that if he can park his plane nearest that spot he will be advantageously located. As airports grow this will of course be impos-

sible, and it has been found that rather than lose the good-will experienced in the past through a change in policy along such lines it is advisable to require all operators to park their planes in some area immediately in front of or adjacent to the hangar in which their equipment is stored. With this definitely understood in the development of an airport from its start, much future hard feeling can be eliminated.

A public address system operated by the airport company for the benefit of all of its commercial operators or for those who subscribe to its maintenance can do much to build up the trade.

(3) *Schools.* The problem of intensified student training on any airport where transport operations take place, particularly if the port is of limited size, is a serious one. One of the customs frequently practiced during the giving of landing practice is for the instructor to give his student verbal instruction immediately upon landing out in the middle of the field prior to another take-off, this instruction lasting in some cases several minutes. The pilot of a plane in the process of landing often questions whether this standing plane with idling engine is going to take off again or turn to go back to its hangar. This oftentimes confusing situation can be prevented by requiring all ships headed in a downwind direction to keep moving. If they wish to remain stationary, they must head upwind, incidentally giving the pilot vision in the direction of approaching and landing planes.

Certain very definite lanes within the immediate vicinity of airports should be prescribed for the flight operations of student planes. The carrying of tape streamers attached to the rudder by solo students prior to securing a private license easily designates the plane as one piloted by an amateur, and right of way should be given to such planes by all except transport ships.

Hangars in which school operators are based should be easily accessible to the public, and it is oftentimes desirable that they may be thrown open to the public, for many schools obtain their students from casual airport callers.

FIG. 8 AIRPLANES AT NIGHT ILLUMINATED BY FLOOD LIGHT

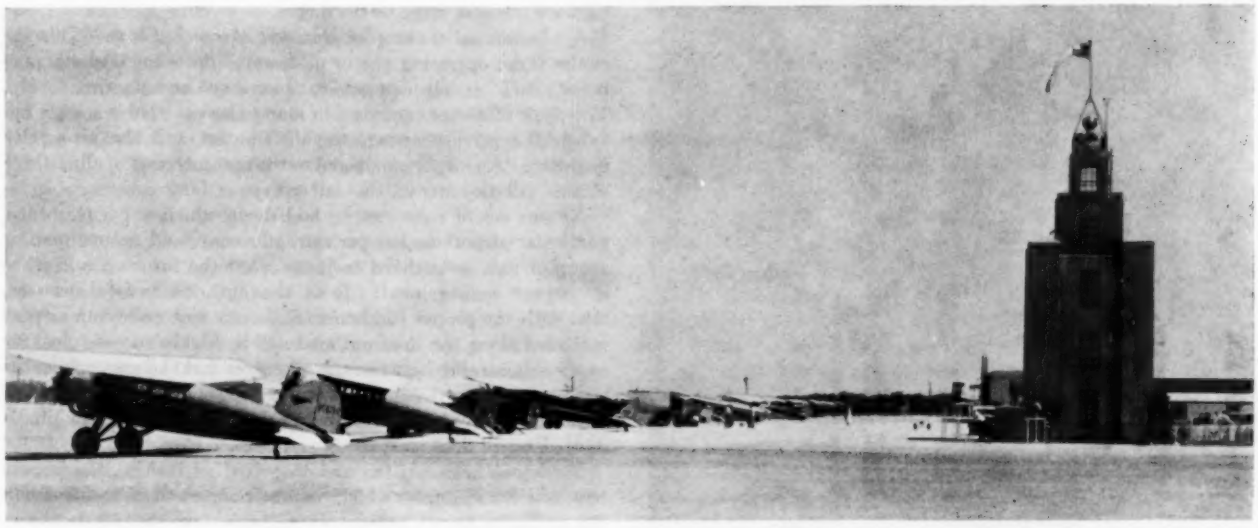

FIG. 9 LINE OF PLANES IN FRONT OF CONTROL AND ADMINISTRATION TOWER

(4) *Dealers and Distributors.* It is greatly to the advantage of dealers and distributors to be located on a port where intensive selling activities are taking place. The modern purchaser of aircraft no longer buys the first plane that he sees which is satisfactory and at the price he wishes to pay, but he will spend considerable time looking at various makes and models. The port having the distribution of the largest variety of planes will attract more buyers than any other. This is being fully realized by many distributors in that the tendency has been lately for them to concentrate as much as possible on one large major airport. The airport fortunate enough to get this type of business soon becomes recognized as a leading aircraft merchandizing center and quickly attracts the other dealers who did not have th e forethought to locate on it in the first place. However, such a situation on an airport immediately makes more problems for the management. Care should be taken that distributors are not located so close to each other that there can be any feeling that

one may steal another's prospects. It is essential that the public at large have easy access to the distributors' quarters and display rooms. He must be provided with office space and given sufficient opportunity to display his merchandise. Airport hangers-on should be discouraged from interfering in any way with the distributors' clients.

While on the subject of hangers-on, this type of individual, although seemingly at many times obnoxious, is an asset to the industry. These people are usually super-airminded and are often the go-between in many deals. They usually give a willing

FIG. 10 FACTORY OF COMMERCIAL AIRCRAFT CORPORATION AT LOS ANGELES AIRPORT

FIG. 11 CONTROL AND ADMINISTRATION TOWER WHICH HOUSES METEOROLOGICAL INSTRUMENTS, DISPATCHER'S ROOM, AND FIELD OPERATIONS OFFICES

hand when called upon and can be made generally useful. Of course, there are the out-and-out airport bums who certainly are not assets, and steps must necessarily be taken to eliminate this type of individual.

(5) *Manufacturers.* On airports where industry is encouraged, manufacturers of aircraft, engines, and other commodities are usually found. It is well that such industries be so located that they do not come in direct contact with the other airport activities. Their premises should be suitably fenced and protected.

There are many facilities which an airport can well afford to install for the use of aircraft manufacturers and others, such as weighing scales capable of weighing large aircraft as units, compass-swinging bases, etc. Not only the manufacturer but the dealer and distributor finds railroad trackage essential. Restaurants should be provided which serve good meals at low prices for factory employees. Given these conditions in a good labor market, together with suitable airport test facilities, one has the principal requisites which an airport management should provide to attract manufacturers. Of course, the geographic location of the airport is also a prominent factor.

(6) *Private Owners.* The needs of the private owner are varied. He wants his plane stored where it will not be tampered with by others and where it may be kept clean and ready to go at all times. Service should be supplied which makes it possible for him to have his plane on the line, warmed up, and ready to go at any designated time. He also wants his friends to be shown the proper deference when they come to the airport, either with him or calling for him. He usually has a certain personal pride in his plane and wants his acquaintances to see it and know that it is his. Particular care should always be exercised by hangar crews in handling all planes between the line and into the hangars, not only of private owners, but of all ships. All airport operators have been confronted with the problem of an occasional minor damage to aircraft in this process, and it is money and effort well spent to repair such damage at the airport's expense and immediately report same to the owner.

(7) *Individual Owners of Business Aircraft Fleets.* This includes those operating one or more small fleets for business purposes, such as oil companies, accessory manufacturers, etc. This type of owner can come in many classes. He is a cross between the private owner, the distributor, and the air-service operator. An airport managed to the best interests of all of these classes will also attract this latter type of business.

No one set of rules can be laid down which will govern any particular airport to 100 per cent efficiency, and no one man or group of men is qualified to judge what the future has in store in airport management. It is the author's belief, however, that with the proper fundamental set-up and policy an airport managed along the lines outlined will be highly successful so far as the relationship between the operators and the management is concerned. The business is in a highly experimental stage, however, and only the future can determine the correct procedure along all lines.

Much has been written and theorized on making the airport pay, but the examples which may be pointed to of such cases in this country are at present exceedingly few and far between. Perhaps an outstanding example along these lines is the rapid growth and development of the Los Angeles Metropolitan Airport.

This project was originally conceived and backed by the finances of a group of Los Angeles and Hollywood business men. The ideal of their conception was a port planned and operated to meet all needs of commercial aviation. In the short space of thirteen months after the port was opened for operation it has been placed on a paying basis. When it is taken into consideration that the entire plan and layout had been developed with the future rather than the present in view, this rapid progress can be considered unusual. There are many fundamental theories upon which the airport has been developed, the strict adherence to which has been largely responsible for its success.

The first of many problems which had to be considered was that of location, and the site of 394 acres located in the heart of the San Fernando Valley was purchased only after a careful analysis of its merits with respect to accessibility to the center of the buying power of the metropolitan area, meteorological con-

ditions, cost of the land, and cost of preparing the land for airport purposes.

The next problem was that of laying out the field in such a manner that it would adequately serve all requirements imposed upon it for future flying activities and building development without the unnecessary waste of any acreage.

It was then necessary to install needed improvements, such as runway surfacing, hangars, lighting equipment, restrooms, restaurant, and administration facilities, in conformity with the scope of potential business. No effort was made to install any improvements for the sake of display or effect, but purely those that were essential to the contemplated activities, with the thought continuously in mind as to what the future might hold in store.

The next step, then, was merchandizing the airport. In order to do this effectively, it was necessary to have a set-up which was not only diversified but fundamentally sound. The plan of development made it possible for manufacturers and operators and other allied industries to procure sites for their activities by either lease, lease with an option to purchase, purchase for cash, or on time. Such a plan enabled those locating on the Los Angeles Metropolitan Airport to get actual title to the property on which their buildings were located if they so desired. For those not wishing to put up their own buildings the airport company is supplying the necessary buildings on a lease or a lease with an option-to-purchase basis. This diversified plan has enabled enterprises and allied industries to avail themselves of the airport's facilities in whatever manner most suited to their particular requirements.

The next problem has been that of exploitation. The airport was dedicated on December 16, 1928, with a suitable program which was publicized through the press as extensively as possible. This launched a year's program of letting the public and the aviation industry of this country hear of the Los Angeles Metropolitan Airport with great frequency.

In order to do this, it was felt that among other things it would be highly desirable to obtain as many record-making flights at the port as possible. At no time did the airport, however, in any way sponsor any such flight, but it was felt, as was later justified, that if facilities were made available and equipment installed that would tend to make such record flights more successful if attempted at this port than at other ports, activities of that nature would naturally be attracted.

The first of a series of such records to start from the port was the famous flight of the "Question Mark." Before this was completed, Miss Bobbie Trout took off and established the world solo endurance record for women. A few weeks later, Captain Frank Hawks took off from the Metropolitan Airport for his first transcontinental non-stop record, and early in the spring Herbert J. Fahy broke the men's solo endurance record here. In the month of June, Frank Hawks again used the Metropolitan in establishing his non-stop round trip record between New York and Los Angeles. The following month the writer was fortunate enough to establish a new record for altitude, carrying 1000 kilograms pay load, using a Bach Air Transport. The month of August saw the start of Henry Brown, Lee Shoenhair, Roscoe Turner, and the ill-fated John Woods in the Los Angeles-to-Cleveland non-stop air derby. At the close of the year, Misses Bobbie Trout and Elinor Smith established a world refueling endurance record for women, and a few days later Amelia Earhart established a new women's world record for speed by attaining an average of better than 184 miles per hour over the mile course at the port.

The establishment of nine records recognized by the F.A.I. during the year in no small way contributed largely to the exploitation of the port. Exploitation was further developed by building up a friendly relationship with the various newspapers, magazines, and news services. Every single item of news, no matter how small, was immediately transmitted to the press. No attempt was made to cram "publicity" down their throats, with the result of building up a very friendly relationship with the press. A conservative advertising program was carried out through the distribution of literature, the advertising in trade magazines, and occasionally by newspaper advertising.

Business has not been built at the Los Angeles Metropolitan Airport merely by exploitation. So far as has been possible, every branch of the aviation industry and allied industries, whether apparently suitably located or not, has been interviewed by representatives of the airport company with the idea of selling them on locating at the port. These activities have not only been local but in some cases national in scope.

Getting business is one thing and keeping it is another. The

FIG. 12 GOODYEAR BLIMP AT SANDERS SERVICE STATION, LOS ANGELES AIRPORT

airport company has stayed out of all commercial activities which in any way might be competitive with those located here on the port and is therefore in an admirable position to remain neutral on the many problems which daily arise in the operation of all ports.

Every month has shown an increase in business. Starting in with nothing on December 1, 1928, the Los Angeles Metropolitan Airport on January 1, 1930, could claim the following: There were 95 airplanes permanently based at the port; six hangars capable of housing 125 planes; two airplane factories; one engine factory; dealers and distributors representing 14 makes of aircraft, who have sold twice as many airplanes in the last six months as have been sold at any other airport west of the Rocky Mountains; four schools; four gasoline filling stations; three service and repair shops; and many private owners.

Revenues have been derived from many sources, the principal source of income being from the rental or lease of hangar space, hangars, and ground space. Other income has been derived from rental of the restaurant, refreshment stand, office, and shop space. Revenue in no small amount has been obtained from motion-picture companies while on location at the port. This form of activity has also proved quite lucrative to the various operators, shops, and restaurants. Certain portions of the airport which are held for future development bring a fair revenue from farming.

The year of 1929 showed an operating cost of approximately $52,000, with an income of approximately $42,500. Contracts at hand and business located on the airport as of January 1, 1930, show an income of approximately $60,000, with little reason for much increase in operating costs over the preceding year. Without any increase in the present business, a profit of $8000 for the year 1930 can reasonably be expected.

An analysis of the income of Metropolitan Airport shows that approximately 75 per cent of the revenue is derived from rentals, the remaining 25 per cent being the revenue from sales of land to manufacturers and operators, less the cost of improvements and alterations.

At this time, approximately 140 acres of the flying area are being sown to alfalfa, which from time to time during the coming year will be irrigated and cut. Of course, it will be necessary to cut this alfalfa much more frequently than if grown for agricultural purposes, yet it is anticipated that revenue from this source and other agricultural activities will approximate $20,000.

Fully 80 per cent of the floor space erected by the airport company is occupied, and with the same increase as has in the past been enjoyed it will in a short time be filled to capacity. The investment in buildings and improvements on the part of the airport company represents $130,000, while there is an investment slightly in excess of this amount which has been spent in building improvements on the part of companies located at the airport.

There has been no one single factor which has been responsible for the financial success of the Los Angeles Metropolitan Airport, but the many contributing factors as previously outlined have all had their place in doing their share toward the development.

Airplane Instrument Vibration

Report of the A.S.M.E. Special Research Committee on Airplane Vibration With Special Reference to Instruments[1]

THE problem of airplane vibration with special reference to instruments is one of vital interest to both aircraft manufacturers and operators, since safety in flying depends to such a large extent on accurate instruments. The present investigation is one of a preliminary character only, and had for its purposes: (1) The securing of information on difficulties encountered in practice, (2) the collecting of opinions as to possible remedies, and (3) formulating suggestions for research.

With these purposes in mind, the committee sent out a questionnaire to pilots, airplane operators, aircraft manufacturers, aircraft instrument makers, and others in the aviation industry.

Questionnaire and Analysis of Replies

The questionnaire and analysis of replies follow:

1 *Have you experienced any difficulties with airplane or airplane-engine instruments due to vibration?*

Almost every reply stated that instrument difficulties due to vibration had been experienced.

2 *If so, on what types of airplanes?*

The airplanes on which instrument vibration occurred covered all types, the reply as to type being dependent upon the particular operator's experience. It is safe to say that instrument vibration difficulties are not limited to any one type, or to a few types, of airplanes.

3 *What was the general construction of the airplane in which such difficulties were experienced?*

Such difficulties were not limited to any one type of airplane, nor were they limited to any one type of fuselage construction. Difficulties were experienced in all types of fuselage construction, whether of welded steel tubing, riveted dural, or composite metal and wood. All phases of structure were evidently covered in the replies and no particular type of fuselage structure seemed to be free from vibration difficulties.

4 *What was the character of engine mounting?*

The engine mount was constructed of the same material, generally, as the fuselage. Some engine mounts were detachable, while others were not. Wooden engine bearers were employed with some engine mounts, while others had the engine mounted on rubber blocks.

5 *What engines were employed?*

All engines, whether radial, in-line, vee, etc., were used on the planes which had instrument vibration troubles. Those who had experience with both radial and other types of engines stressed the fact that radial engines gave the greater trouble, while the six-in-line gave less trouble. These comparisons were made with engines in different airplanes; no particular investigation was made to determine if the trouble still persisted if a different type of engine was substituted in the same airplane. Nevertheless, since the airplanes are more or less similar in construction, the diagnosis as to which type engine gave the better results may be assumed as correct.

6 *What p opeller was used?*

Both metal and wooden propellers were used. If excessive instrument vibration trouble occurred due to the propeller, it was usually traced to propeller unbalance and therefore could easily be corrected. In no case was instrument vibration difficulties thought to be due to some inherent fault in propeller design.

7 *Where was the instrument board mounted?*

The instrument board location aft of the engine was generally dependent upon the location of the cockpit. The conventional place was slightly in the rear of the fire wall. (The fire wall was usually located as close to the engine as possible.) The instrument boards were usually suspended between the two upper longerons.

8 *What was the distance from the instrument mounting board to the engine mount?*

The distance from instrument board to engine varied from 7 in. in the rear of the fire wall (which was the closest of all cases cited) to as far away as 10 ft. The average distance in the rear of the engine mount was about 2 ft.

9 *What were the material and thickness of instrument board?*

Aluminum or duralumin were the common materials used in the construction of the instrument boards. A few instrument boards were reported to be of plywood construction, while one operator mentioned basswood. The common thicknesses for metal boards were either 0.020 in., the thinnest used, or 0.050 in., the most common thickness, or 0.091 in., which was the thickest used.

10 *What was the method of attaching the instrument board? Were mountings flexible or rigid?*

A few instrument boards were bolted directly to the longerons or cowling of the fuselage, while a few were mounted on felt washers or sponge rubber. The majority of the instrument boards were rigidly mounted, although one or two were reported to be flexibly mounted.

---

[1] The personnel of the Committee is as follows:

Klemin, Professor Alexander, *Chairman*, Daniel Guggenheim School of Aeronautics, New York University, New York, N. Y.

Aldrin, Captain E. E., Manager, Aviation Department, Standard Oil Development Co., New York, N. Y.

Backus, Harold A., Metallurgical Laboratory Inc., Philadelphia, Pa.

Baugh, Lieut.-Commdr. H. V., General Inspector of Naval Aircraft, Eastern District, New York, N. Y.

Budwig, G. G., Chief of Inspection Section, Department of Commerce, Washington, D. C.

Campbell, C. W., Cambridge Instrument Co. Inc., New York, N. Y.

Colvin, Charles H., President and General Manager, Pioneer Instrument Co., Brooklyn, N. Y.

Depew, Captain Richard H., Jr., Sales Engineer, Fairchild Airplane Manufacturing Corp., New York, N. Y.

Durand, William F., Emeritus Professor, Mechanical Engineering, Stanford University, Cal.

Hagenberger, Lieutenant A. F., Instrument and Navigation Unit, Matériel Division, Air Corps, Wright Field, Dayton, Ohio.

Ileman, E. A., Chief Engineer, Consolidated Instrument Co. of America, Inc., New York, N. Y.

McCarthy, C. J., Chance Vought Corp., Long Island City, N. Y.

Newell, Floyd B., Engineer in Charge of Aeronautical Instrument Division, Taylor Instrument Co., Rochester, N. Y.

Smith, Wesley L., Superintendent, Eastern Division, National Air Transport Inc., Air Mail Field, Cleveland, Ohio.

Presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

11 *Did the instrument board form part of the fire wall?*

In the majority of cases, the instrument board did not form part of the fire wall. One operator replied that it was impractical to have the instrument board form part of the fire wall.

12 *What was the exact character of the instrument trouble experienced?*

Excessive vibrations caused oscillations of the compass card so that it was practically impossible to read. All instruments having indicating pointers were difficult to read since the indicator vibrated so badly that readings were inaccurate.

In some cases, continued and excessive vibrations caused the indicating hand to drop off if it was not held in place securely by a small cotter pin.

13 *If the trouble was eliminated, how was it eliminated?*

The answers were few on this subject, probably indicating that either the trouble had not generally been overcome, or no particular attempt had been made to overcome it. The difficulty in trying to eliminate instrument vibration usually lay in determining the real cause.

A few eliminated the trouble by flexibly mounting the instrument boards, while others did the direct opposite and rigidly mounted the boards. One eliminated the trouble by changing engines, but this method is not expedient.

14 *Was the vibration difficulty experienced at all engine speeds, or at specific engine speeds?*

Difficulty was generally experienced at all engine speeds. Some noticed difficulty at varying engine speeds, and still others found that vibration difficulties were experienced at one or two engine speeds.

15 *Did all instruments vibrate at the same or at different engine speeds?*

There were very few replies to this question. Two correspondents found that various instruments vibrated at different engine speeds, while three found that the instruments vibrated at the same engine speeds.

16 *With what instruments was vibration difficulty experienced?*

The compass seemed to be affected most severely of all instruments. Altimeter and tachometer readings were also affected by vibration.

17 *What was your diagnosis of the trouble?*

The diagnosis by the correspondents were equally divided among five causes:

1 *Faulty Engine Mounts.* The engine mounts were either too rigid or too flexible. There seemed to be no agreement among the correspondents.

2 *Faulty Instruments.* Improper balancing for dynamic conditions were thought to be the cause of inaccurate readings.

3 *Faulty Instrument-Board Mountings.* The boards were considered to be of cheap construction, and improperly mounted, either too rigidly or too flexibly.

4 *Engine.* Some engines have inherent vibration weaknesses which affect the entire aircraft structure.

5 *Propeller Balance.* Wherever propeller unbalance was found to be the cause of instrument vibration, the operator was able to remedy the difficulty, so that this may not be considered an inherent fault.

18 *What are your general recommendations as regards elimination of instrument vibration difficulties?*

(*a*) *Structure.* A few suggested that the fuselage structure might be made more rigid by more bracing; the structure in the vicinity of the instruments especially should be well braced. Changes in structures, if made at all, should only be made if all other methods have failed.

(*b*) *Engine Mounting.* Rubber or fiber mounting for engine bearers were generally favored in order to obtain a slightly more flexible engine mounting.

A few consider a more rigid engine mount desirable.

(*c*) *Mounting of Instrument Board.* The consensus of opinion was that a flexible instrument board mounting was essential. The flexibility could be obtained either by rubber, fiber, or spring mountings. The degree of flexibility would depend upon the particular installation and would require some investigation.

Locating the instrument board as far away from the engine as possible is usually a very good means of eliminating vibration difficulties. Most of the present-day instrument trouble could perhaps be diminished by proper location.

(*d*) *Mounting of Instruments.* The opinions were, on the whole, very contradictory; both rigid and flexible mounting of the instruments found equal favor. However, if the instruments themselves were not flexibly mounted, then the instrument board should be.

(*e*) *Improvement in the Instruments Themselves.* It was suggested that the instruments could be improved (1) by better damping and balancing of component parts and (2) by more rugged construction of the instruments so as to be unaffected by vibrations. It was conceded that the more rugged the instruments were made, the more sluggish they would likely become.

General Impression of Replies

A survey of the replies to the questionnaire shows that comparatively little is known as to the exact cause or causes of instrument vibration. In some cases, the answers were too brief to analyze the whole properly. However, the questionnaire did accomplish its primary object. The following items stand out:

1 That instrument vibration is not limited to any type of plane, fuselage construction, engine mount, or engine or propeller make.

2 That changes in fuselage structure or engine mount are not considered essential.

3 That instrument vibration is not necessarily limited to specific engine speeds.

4 That practically all instruments are equally affected by vibration.

5 That partial elimination of vibration difficulty may be obtained by placing the instruments as far away from the engine mount as is conveniently possible.

6 That elimination of vibration difficulties may be found by proper mounting of the instrument board and instruments, and perhaps further refinements in the instruments themselves.

Suggestions for Further Research

Further research for the mounting of instruments and instrument boards perhaps should more properly be taken up by some governmental agency rather than by the aircraft manufacturer or the aircraft-instrument manufacturer. Refinements in the instruments, of course, can be more easily made by the instrument manufacturer.

Several suggestions for research have been made:

1 Records of vibrations of the instrument boards of various airplanes should be made. These records could be studied for intensities and frequencies of the vibrations affecting instruments. After the intensities and frequencies had been classified, they could be duplicated in the laboratory, and tried on various mountings of instruments and instrument boards. In this manner the comparative merits of flexible or rigid mountings of either instruments or instrument boards could be definitely and progressively studied until the difficulty had been eliminated. Flexible mounting could be obtained by use of rubber, fiber, or small steel springs combined with a small dashpot.

Steel springs have natural vibration frequency of their own, so that any spring system would have to be thoroughly tested out before the vibration of instruments could be overcome.

2 Experiments should be made with the instrument board mounted on steel springs whose tension can be adjusted. It would be by this means that the instrument board could be adapted to any condition met with an airplane.

3 Experiments could be conducted on different weights for instrument boards. It is possible that the instrument board is insufficiently loaded; a flexible mounting might then not effect much improvement unless it were too flexible to be practical. The loading of the instrument board could be varied to increase its natural period, and then combined with a flexible mounting to eliminate vibration difficulties.

4 Further refinements in instrument construction could be carried out by the instrument manufacturer. It has been suggested that an application of the principle of the Lanchester vibration damper may help those instruments which employ indicating pointers. The instrument pointer could be mounted on its pivot and driven through some simple frictional or hydraulic connection operated by a somewhat heavier pointer. The Lanchester vibration damper would not, however, take care of dynamic unbalance and therefore would practically be useless.

Hydraulic systems are not reliable since they are affected by temperature and humidity variations.

As soon as a definite program for research is successfully conducted, other improvements will naturally suggest themselves.

Grateful acknowledgment is made to all those who contributed replies and information to the committee.

Discussion

E. H. Hull.[2] Until airplane engines and propellers can be made nearly vibrationless by proper design and balance or isolated from the fuselage by elastic supports, a device such as is suggested in paragraph 6 of "General Impression of Replies"—namely, an elastic suspension of the instrument board—will be desirable.

Referring to "Suggestions for Further Research," the frequencies present in the instrument board, with their approximate relative amplitudes, can be quickly determined by Frahm-type vibration tachometers. The frequencies of response of the instrument parts such as pointers can be determined by observing them, while in vibration, through a stroboscope.

Knowing the lowest impressed frequency which causes trouble, a frequency of suspension of the instrument board can be chosen, using the expression

$$e = \frac{1}{\left(\frac{\omega}{\omega_c}\right)^2 - 1}$$

where the transmissibility e is the ratio of the amplitude of the board after suspension to the impressed amplitude, ω is the impressed frequency, and ω_c is the natural frequency of the board on its elastic supports. Any elastic material may be used in the suspension. The board itself should be made as rigid as possible to avoid flexural vibrations in itself.

Helical steel springs "have a natural frequency of their own" when the ends are held and the middle part vibrated as in valve-spring surge, but this frequency is very high and should not be troublesome here. The instrument board will show a natural frequency (the ω_c mentioned) when mounted by any elastic means, such as rubber, springs, cork, etc. It is necessary for the impressed frequency to be well above this natural frequency of the board on the mounting before any benefit can be gained from the elastic mounting.

Stops incorporating heavy damping for limiting the motion of the board would be desirable at take-off and landing. Connections, electrical and mechanical, to the instruments mounted on the board must be flexible.

When a body is supported between two springs, its natural frequency in the line of the springs is not dependent on the initial tension in the springs. Thus the mounting cannot be varied to meet requirements of different stiffness along the spring axis by varying the spring tension. The spring constant itself must be changed.

Loading the instrument board will decrease its natural frequency since $\omega_c = \sqrt{\frac{c}{M}}$, when c is stiffness and M mass.

Light or heavy boards can be made to give the same isolation providing the natural frequency of each, determined by its elastic support, is the same. If the board is made heavy, the stiffness of the supporting means may be increased in proportion, maintaining the same natural frequency on these supports, and hence the same isolation. The isolation obtained in any case depends on the natural frequency of the board on its mounting; the lower this frequency the better will be the isolation.

J. Ormondroyd.[3] The question of proper mounting for airplane instruments comes in the field of general vibration theory. In order to treat the question rationally, the source and frequency of the disturbing force must be known and the elastic and mass properties of the instrument mounting must be known. The problem of adjusting the instrument mounting to the known disturbances is one which has been solved in a tremendous number of engineering problems in other fields. The probability is overwhelming that the disturbances come from the engine rather than from any aerodynamic instability at the airfoil surfaces. Since an airplane engine operates most of its time at two more or less fixed speeds, its full speed and its cruising speed, it is possible to predict at least the frequencies of all the disturbances which can arise at the motor. These disturbances will have engine r.p.m. frequency or some multiple of that frequency. The possible sources of disturbance are:

1 Unbalance—one cycle per revolution

2 Torsional critical speed—some multiple taken in half steps of r.p.m.

3 Torque reaction—firing frequency

4 Crankcase vibration—one cycle per revolution.

There are known methods for reducing unbalance, torsional critical speed, and crankcase vibration to unimportant magnitudes. In most engines to be found in modern airplanes these steps have been taken. Torque reaction, however, is a phenomenon so inherent in the operation of the internal-combustion engine that the only way to get rid of it is to stop the engine. However, since torque reaction is inevitable, instrument mounting should be so designed that the frequencies from torque reaction at the running speeds are not in resonance with the instrument on its mounting.

Technical literature is filled with papers on the subject of spring mounting. It is to this field that the designers should turn their efforts. In line with this, probably the most important step which can be taken would be toward the accurate measurement of the frequencies and amplitudes of the disturbance actually found at the instrument boards. Any number of commercial instruments for the recording of vibrations are already in existence, and any number of special electrical devices for measuring these quantities have already been devised by various manufacturers who have had vibration troubles in their own equipment.

[2] Research Laboratory, General Electric Company, Schenectady, N. Y. Jun. A.S.M.E.

[3] Experimental Division Manager, Westinghouse Elec. & Mfg. Co., Philadelphia, Pa.

The group of manufacturers interested in airplane instruments should be warned that they must stand on their own feet in the solution of this problem. While the Government is very active in certain centers, such as the Brooklyn Navy Yard, Wright Field, and Langley Field, in the study of vibration problems, it does not have the same immediate interest in their solutions as those interested in the commercial exploitation of the parts affected.

The writer believes that the questionnaire method of starting the solution of any real technical problem is fundamentally wrong. The committee should get a man who can study the theory of vibration and work out its immediate application of the problem in hand. The questionnaire merely dodges the real issue by making what is distinctly one man's business, everybody's business, and therefore nobody's business. Surely there is somebody in the airplane industry or in the airplane instrument industry who can go deeply into the study of vibration theory and bring order out of the chaos of ideas which is shown to exist in the answers to the questionnaire.

S. J. Zand.[4] It has been the writer's experience that instruments perform very satisfactorily on some ships, but, due to the excessive vibrations of other ships, the same instruments fail. The problem therefore is to find out exactly the source of these vibrations and eliminate them as much as possible. This is similar to the solution which Mr. John Lee suggested of eliminating noise in the airplane cabin. "It would be much wiser," he said, "to remove the source of noise, rather than dampen the noise by insulating the cabin." Similarly, it would be much wiser to eliminate airplane vibrations rather than try to eliminate the vibrations of the instrument board alone.

The problem of airplane vibrations and its relation to instrument performance is much more complex than generally realized. Any elastic system or any elastic body which is suddenly subjected to an external force, or if a continuously applied force is suddenly removed, will vibrate; which means that the elastic forces of the system will no longer be in equilibrium with the loading.

The airplane is a structure which consists of many individual parts, and each part will be subject to what is called natural vibrations, which in turn will produce on the instrument board a resultant vibration of quite a complicated nature.

To solve this problem theoretically would be a task great enough for a mathematician of the highest skill. The writer does not want to say that a theoretical solution is impossible, but anybody who has had experience with differential equations will agree that the interpretation of the same for practical purposes is very difficult and very often impossible.

It is the writer's conviction that the engine is the main offending part. This is due to the difficulty of balancing any internal-combustion engine. In the case of radial engines, perfect balancing is impossible, at least at the present time.

Empirical methods in accord with the recommendations by the committee are favorably regarded, and for this purpose an apparatus faithfully recording the vibrations is the first item necessary.

There are a number of very fine vibrographs on the market, but, owing to their weight and size, none is particularly suitable for aircraft use.

The size of such an instrument should be the same as of all other aircraft instruments, and the weight should be similar to that of one of the standard aircraft instruments, so that substitution can take place without materially changing the loading of the instrument board. Such an instrument is not easy to construct as it involves a number of parts which have to be assembled in a very small case.

In order to have a reference point which will not move, a long-period pendulum is necessary. Such a pendulum ought to have considerable length, which is in direct contradiction to the statement made regarding the small size. The writer is firmly convinced, however, that by using differential, harmonic, or even gyroscopic pendulums, an apparatus recording the vibrations of an airplane can be constructed in the standard airplane instrument size, but it is, as explained, a rather difficult proposition.

The stiffness of instrument boards should be studied. Any attempt to load instrument boards to increase their natural period should be discouraged; adding weight to any existing part of the airplane is poor practice, and even if it should prove one of the solutions, it will not be acceptable to the airplane manufacturers.

Owing to such obvious reasons that need not be mentioned here, the use of dashpots as a dampening medium for instrument boards is entirely out of the question. The suggestion referring to the use of steel springs should be taken with reserve. It should be borne in mind that steel springs produce changeable magnetic disturbances which might affect the compass. Furthermore, steel springs corrode. Brass or Monel metal could be used more advantageously.

There is no difficulty in figuring the natural frequency of springs. It can be done in a few minutes by the following procedure: Denoting k, the load necessary to produce a unit extension of the spring, then the static deflection of the spring under the weight W will be $\delta = W/k$, and at once the period $2\pi\sqrt{\frac{\delta}{g}}$ and the frequency $2\pi\sqrt{\frac{g}{\delta}}$.

The k is a constant of the spring and can be either measured or else found from the diameter of the spring, diameter of the wire, and characteristics of the material used; a simple mathematical calculation and any engineering handbook gives all the necessary formulas.

The best solution to overcome excessive instrument-board vibration is to suspend the same pendulously. If the instrument board should have the same period of vibration as the r.p.m. of the engine in the case of a rigid suspension, then the same instrument board, in order to be immune to vibrations, ought to be suspended in such a way as to have a period of $1200/60 \times 1/5 = 4$ sec. (assuming the lowest flying r.p.m. to be 1200). It is at once apparent that to obtain such a low period, considering the space available for the spring suspension, is not easy.

In paragraph 4 of "Suggestions for Further Research," the use of a Lanchester damper is advocated. This is highly impractical, as the Lanchester dampener is used to dampen tortional vibrations of crankshafts, i.e., of bodies of considerable mass and revolving at high speeds. The pointer of an instrument is the lightest part and revolves very slowly. For example in a rate-of-climb indicator the pointer revolves with a maximum speed of about 1/2 r.p.m., and in 10,000 ft. altimeters, about 1/5 r.p.m. These values are maximum for commercial airplanes.

When one hears about improvements in instrument design suggested by people outside of the instrument industry, he is naturally inclined to be slightly skeptical. The majority of engineers, outside of the instrument makers, hardly realize the complexity of the problems. Aircraft instruments are compromises, and a very brief illustration will prove this statement.

The main difficulty when designing instruments for aircraft use is the fact that the power available to produce indication is very small. In an altimeter, for example, for a difference

[4] Aeronautical Engineer, Pioneer Instrument Company, Brooklyn, N. Y.

of 1000 ft. the available power is equal to about 1 in. of mercury pressure difference. For a range of 10,000 ft. there will be, due to the logarithmic form of the pressure-altitude curve, about 6 in. of mercury. The movement of the diaphragm, due to that pressure difference, is not larger than $^1/_{32}$ in. This movement, in order to be read with ease, has to be amplified tremendously, from 100 to 400 times. Thus it is seen at once that any attempt to introduce additional friction to dampen out errors due to vibration would be ill-considered. Friction must be eliminated as much as possible in order to achieve the amplification of motion aforementioned.

If one looks at a sketch of an altimeter he sees a great similarity to a vibrating reed. That the instrument makers are able to produce very reliable instruments which will stand some vibration is not a mere coincidence, but the result of very careful design and a great many calculations.

When an instrument performs satisfactorily on the majority of airplanes, but fails on some of them, it is not the fault of the instrument, but generally the failure can be traced to terrific vibration of the instrument board or parts of the structure near it.

The work of the committee is appreciated, as it will no doubt give the incentive both to the airplane motor and instrument manufacturers to study the vibration problem thoroughly. It is unfortunate that the committee could not obtain quantitative and qualitative data on vibrations. Without this information, very little can be accomplished.

Through the proper cooperation of the airplane industry with the instrument manufacturers, and possibly with the help of Government agencies, such as the Bureau of Standards, a very satisfactory solution of the problem can be obtained, and, needless to say, instrument manufacturers will be delighted to cooperate.

Authops' Closure

Many thanks are due to Mr. Hull for his valuable suggestions on practical methods for further research. It is hoped these suggestions will be acted upon by experimenters in the field.

Mr. Ormondroyd's reference to technical literature will be studied further, and it is hoped, at a later date, to issue supplementary data on this literature.

Mr. Zand's discussion is equally as valuable and will undoubtedly provide stimulus for further work in the field.

AER-53-14

Airplane Cabin Engineering

By PIERRE FREYSS,[1] NEW YORK, N. Y., and JOHN F. HARDECKER,[2] PHILADELPHIA, PA.

The intense interest in the development of the interior design of the airplane is the national consequence of the competition between the airplane, the Pullman car, the automobile, and the motor bus for the patronage of the general public. Appealing as the plane does to that class whose time is of extreme value, it must offer a degree of comfort, convenience, and luxury comparable with other means of transportation.

While essentially a problem of the decorator, interior design demands the whole-hearted cooperation of the aeronautical engineer. It must be always in mind from the inception of the structural design, so that the maximum opportunity for eye appeal is assured the decorator. Wall, ceiling and floor treatments, hardware, sanitary equipment, accessories, chairs, windows, doors, soundproofing, and fireproofing, all are within the scope of interior design. All must be blended into a harmonious whole, keeping ever in the forefront of the design the fundamental aeronautical requirements of minimum weight and maximum space utilization.

Pierre Freyss

John F. Hardecker

MODERN airplanes are no longer mere flying machines; they are a mode of transportation rapidly gaining equality with long-established contemporaries in many respects and already far exceeding them in certain phases. As a fitting climax to this rapid cycle of evolution, the proponents of air travel have become aggressively interior-conscious. Luxury evolved after literally scores of years in other means of transportation is demanded in a few short years, not as a consequence of mere pride or ambition, but as a necessity of travel competition.

Flying is rapidly ceasing to be an adventure. The ownership and utilization of a plane as a means of transportation is a matter of convenience and comfort. The development of large transport cabin planes has made it possible to travel by air with a security and comfort comparable to the automobile and motor boat. It is always a proof of stabilization when an industry so fundamentally mechanistic as aircraft reaches a point where, in addition to satisfactory functioning, there arises a distinct demand for elegance, style, and beauty.

This demand for interior styling is a natural consequence of the expansion of the prospect lists for aeronautical sales, either of planes or transportation. The youthful enthusiast who spends freely of his time about flying fields, anxiously soaking up technical details of aircraft construction and operation, ever willing to do anything to get a flight or get into aviation, is still worthy of cultivation in the general scheme of things aeronautical, but he is not the best prospect for sales. His sympathetic understanding of the many ramifications of a highly technical profession is indeed gratifying to the ego of the aeronautical specialist, but his is, primarily, an ambition to find in aviation a means of livelihood.

The real prospects are the individuals of means and large corporations. These prospects have neither the time nor inclination to master the details of the theory of flight, structural analysis, or flight operations, but they depend to a large extent on eye appeal in establishing their confidence in air transportation.

This attitude is not a consequence of indifference or laziness, but a natural derivative of the popularization of other means of transportation. Surely the utilization of a Pullman car as a means of travel does not demand an intimate understanding of railroad construction and operation, nor the ownership of a private automobile that its possessor must be an expert on gasoline engines. More and more, these competing means of transportation depend upon the luxury and comfort of their interiors for sales appeal. The more the airplane can suggest the same degree of ease and refinement in its interiors, the better able it becomes to meet travel competition.

It would therefore appear that the problem of interior design might be relatively simple at first glance if style standards are adopted which are already stabilized by competing transportation agencies. Immediately following this thought the question of weight enters the mind, and the designer is face to face with perhaps the greatest problem to be encountered in plane interiors. Practically every material or part evolved in quantity production for other industries, and therefore decidedly attractive in price and availability to the airplane manufacturer, is automatically barred on this single count—it is too heavy. This single factor alone is responsible for the fact that originality is necessary from the very inception of interior design, an originality which requires extreme ingenuity in an industry which at present is far from mass production possibilities.

Following closely on the heels of the weight inhibition is the restriction on design imposed by space limitations. Luxury and comfort are most easily accomplished and suggested by the generous utilization of space; to achieve the same effect in the decidedly restricted confines of an airplane interior calls for extreme skill and artistic legerdemain. In addition, and each a distinct problem within itself, is the need for soundproofing, fireproofing, and the providing of the many accessories to comfort so readily supplied in other transportation mediums, which in the airplane become a distinct problem in specialized interior design.

Preliminary Engineering Considerations

While this matter of interior design is essentially the problem of the decorator, he must be assured a close degree of coopera-

[1] With F. Schumacher and Co., New York, N. Y. Served in French Army from 1914 until the end of the War. Received four citations for French Croix de Guerre and Medal. Studied at Hautes Etudes Commerciales, Paris. Joined F. Schumacher and Co. in 1925.

[2] Chief Draftsman, Naval Aircraft Factory, Philadelphia, Pa., and has served this firm since 1917 in various engineering and executive capacities. Received Civil Engineering degree from Cornell University in 1917.

Contributed by the Aeronautic Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tion from the aeronautical engineer if he is to accomplish the most desirable results. No greater mistake in management can be made than to design a commercial passenger plane purely on the basis of aerodynamical and structural considerations, and on its completion, call in the decorator and defy him to make an attractive interior out of the resultant cut-up, odd-angled interior spaces.

Windows and doors should be a primary consideration in the preliminary layout of the plane design. Windows should be preferably long and narrow, in order to accentuate the apparent length of the cabin, and odd shapes should be avoided. It is also highly desirable that no construction members show through the window opening, as the general public does not have a sufficiently adequate conception of the strength inherent in tubular members of small diameter. Doors should not only be of regular shape, but they should be sufficiently large for natural entrance and exit, and should be made sufficiently thick to inspire confidence, as to the public they often suggest

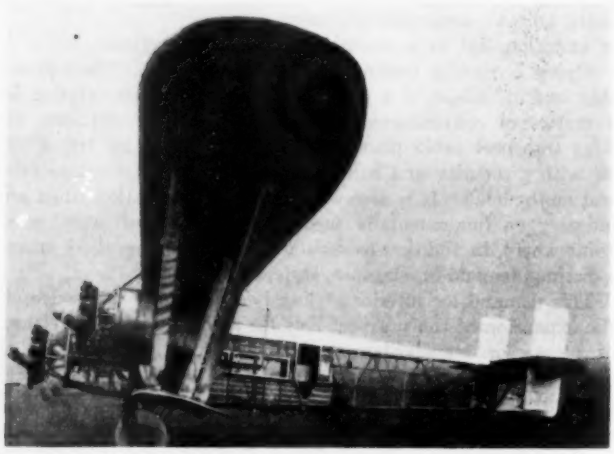

FIG. 5 BALSAM WOOL APPLIED TO CABIN FOR INSULATION

the only protection against being suddenly catapulted off into space.

In arranging for lavatory space, due regard should be given to the dimensions of available sanitary units to avoid costly special installations. Floors should be adequately supported and of such section as to give a solid feeling to the feet of the passenger walking over them, as nothing so readily suggests flimsiness to the lay mind as a floor that gives with every step. Windows that are intended to be adjustable must be readily so, and this at least is one respect in which the railroad car is not to be taken as an example of desired practice. Provisions for ventilation and heating are part of the interior design charged to the aeronautical engineer.

All controls and operating mechanisms, while desirable of concealment behind the walls of the cabin, should be so arranged in coordination with the interior finish that they may be readily reached for routine inspection and emergency repair through removable panels that suggest a routine function rather than a hurried tearing down of the plane interior that is suggestive of fear and danger to the passenger. In fact, the military practice of making a layout and mock-up of fixed equipment and useful load in the development of a plane design may well be followed by the commercial-plane designer in his planning of interior design installations.

The foregoing, while indicative of a considerable effort on the part of the aeronautical designer in achieving a satisfactory interior, must be regarded in the light of a task which, well performed, bears fruit in every single unit produced of a given plane model. This may to some extent suggest a monotony of interior design, but it must be borne in mind that once these essentials are properly established for any given model, the decorator by his skill in choosing appointments and finishes can add infinite variety to each individual plane unit. In fact, many planes purchased for private use are custom decorated.

Decorator's General Problems

Avoidance of monotony is one of the decorator's problems which he must be careful not to exceed by over-emphasizing pattern and color, lest the interior disturb the sensitiveness of people subject to air sickness. The decorator must create an interior into which the psychological factor of security enters, and build effects which indirectly assure the naturally timid with their recurrent thoughts of their long distance above the ground. He therefore has to choose tones and textures that have an appearance of substance and reliability and by handling style and line give an assurance of maximum strength. The whole interior should put the individual into an intimate atmosphere, confronting him with materials and fabrics he is accustomed to, and which conceal any unfamiliar members or construction which, to his excited nerves, may suggest fragility. The reduction of noise, the single remaining factor that suggests breakability, is now receiving serious consideration by all aircraft manufacturers, and real progress is being made.

The finished product of the decorator's art is at once a study in harmony and contrasts. It cannot be reduced to a simple engineering formula applicable in all cases. Each plane may be said to be an individual study, an attempt to apply the decorator's skill to the interpretation of the individual wishes of the owner much as the interior decorator functions in finishing the interior of a home, hotel, or club. Therefore no attempt will be made to draw detail word pictures of individually finished interiors. Even the photographs offered, with their accompanying descriptions, are not a sufficient presentation of the assembled effect, for they do not show conclusively for ready perception the wonderful crowning effect of color in creating the true beauty and luxury of the modern airplane interior. Therefore, the major materials, chiefly textiles, which are used for walls and ceilings, will be treated only in a general way, leaving for detail treatment the less obviously visible treatment of the interior, and also the many accessories and fitments which form such a significant part of the coordinated whole.

Wall and Ceiling Finishes

When choosing textiles, it is easier to find suitable decorative fabrics for walls and ceilings with harmonizing contrasts as the plane grows larger in size. These textiles are in a large proportion combination rayon weaves with modernistic designs, as modern art is the most suitable for the decoration of the airplane. The rayon weaves give the glint of silver best. Silver plays a large part in the aeronautical color scheme, as the aerial atmosphere favors its neutral and restful tone. Wool damasks,

Fig. 6 Aluminum Alloy Reclining Airplane Chair

Fig. 7 Magnesium Alloy Straight Chair

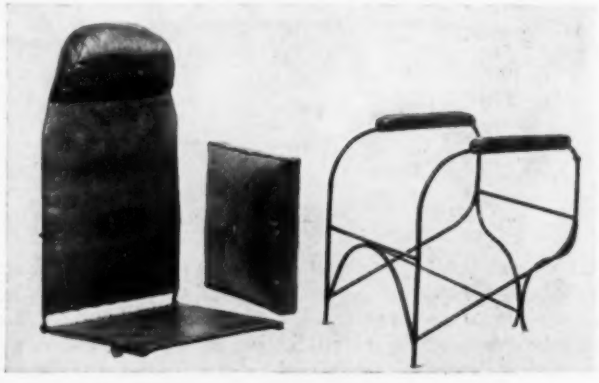

Fig. 8 Knock-Down Type of Construction Used for Airplane Chair

cotton, rayon, and rough-weave Rodier fabrics are most successfully used in the bigger transport planes for sidewall panels. In weight these fabrics vary from 7 to 12 oz. per sq. yd., the general and best weight being from 8 to 9 oz.

The usefulness of a woven fabric has been questioned by many an engineer. Some advance the opinion that it will soil and cannot be cleaned; others fear its inflammability. This latter has been overcome by a special treatment which makes it entirely fireproof, and which will be presented later. Yet fabrics have won their way because they are light in weight, strong, decorative, and do not soil more readily than other materials.

They have withstood the test, and many a large transport plane inspected after two years of service shows fabrics which have neither faded nor stained.

Fabrikoid, an imitation leather, which is a washable fabric, is of course more suitable, but up to the present this lacquered fabric has been produced only in plain colors. These colors are of the same tone as the Duco colors. So instead of being subdued as are the woven cotton and rayon fabrics, they are very decided in coloring. The decorators have tried in many ways to render Fabrikoid more decorative by air-brushing designs on it or even embroidering it with modernistic designs as was done in one cabin of the *Commodore* plane. Yet it has been impossible to obtain the highly decorative soft effects so greatly sought after for plane interiors. Therefore attention has been directed to developing new designs in light and strongly woven cotton and rayon fabrics. The woven fabric has a decided advantage in absorbing sound, a property which the lacquered Fabrikoid lacks.

FIG. 9 REED CHAIRS OF UNIVERSAL AIRPLANE CHAIR COMPANY

The best solution is to combine the use of woven fabrics and Fabrikoid. Places like sidewalls where a decorative effect has to be obtained are covered with a modernistic woven fabric, and Fabrikoid is used on the ceiling, in the lavatory, galley, and entrance. In many cases Fabrikoid is used for seat covering as it is a very strong and resistant fabric which can be washed, while the softer woven fabric is subject to replacements.

Mohair pile fabrics, or mohair velvets, find considerable favor in small planes, where they are utilized in a manner similar to the decoration of an automobile interior. Genuine leather, in upholstery finishes, is sometimes used for chairs or sidewalls in small planes. Many cabins use veneers or plywood for walls or ceiling, finished in natural-wood finishes or treated with the many decorative design finishes used in modern building interiors. In others, plymetal, with its finish surface of aluminum or duralumin, cored with light woods such as balsa, is utilized.

FLOOR COVERING

Carpets are used on the floor. The latest contribution to deaden the sound is the new rubberized carpet, with a heavy pile of wool backed by rubber. This carpet is very easy to place, as contrary to the ordinary carpet, cuts are not joined by sewing. After the carpet has been cut, the two straight edges are pushed together, and a tough web of strapping, impregnated with a special cement, is laid along the back of the joint, overlapping it for several inches on each side. When the cement has set, the joint is firm and unyielding, the resilient back and the strapping having been firmly fused, while on the face of the carpet, the thick pile meshes together and the seam is invisible. As the resilient back is waterproof, the carpet can be scrubbed on the floor. If damaged by stain or burn, the offending spot can be quickly cut out, another piece inserted, and not a trace of the joining will show.

FIREPROOFING TEXTILES

It is highly desirable that the textiles used in plane interiors be fireproofed. The processing of textiles by fireproofing formulas should leave the fabric as nearly as possible in its original color and texture. This can be done in most cases, but as chemicals are made a part of the cloth, in some cases there is a slight change in the color. This change usually consists of a slight darkening.

The fireproofing of textiles is usually done by one of two methods. The first is to impregnate or coat the fibers with materials that do not burn, and in that way exclude the air and raise the ignition temperature. The other method is to impregnate the fibers with chemicals that liberate a gas when they are heated, this gas cutting off the air supply, so that the fabric does not ignite. Of course, both these methods do not prevent the burning of a cloth, but they do eliminate the rapid burning of the fabric and therefore reduce the fire hazard.

WATERPROOFING OF TEXTILES

It is highly desirable to waterproof or showerproof the fabrics used in amphibions, flying boats, and seaplanes. This is usually done as a precaution against water damage of the fabrics. The

showerproofing of textiles also involves the impregnation of the fibers with chemicals that make them resistant to water. In looking at an unprocessed woolen or cotton fabric under the microscope, one notices a decided absorption when it is brought in contact with water. The same fibers that have been showerproofed, by the "Cravenette" process would not absorb water and if viewed under the microscope would show some beads of water clinging to the outer surface.

There are a great many methods of showerproofing cloths and their effectiveness is as varied as the processes. Most showerproofing processes consist of some surface coating of the cloth which has no permanence and is not very efficient. The "Cravenette" process of showerproofing involves the saturation of the fabrics in especially designed solutions, so that these chemicals become a definite part of the yarn, and render the fabric water-resistant as long as the cloth lasts and it is not subjected to any vigorous cleaning process. In addition to preventing the absorption of water by the fabric, this process also prevents, to a very large degree, the spotting of a cloth when water strikes it.

FIG. 11 SLEEPING ACCOMMODATIONS

CABIN INSULATION

One of the big problems to be met in passenger comfort is cabin insulation. While the major function of cabin insulation is the reduction of noise, important contributing advantages are cold insulation and fire protection. Those insulating materials which are highly inflammable should be barred. While there is a great deal of development work going on in the reduction of noise at the source, the present success in abating the noise nuisance lies in the reduction of the noises that find their way into the airplane cabin. Therefore a good airplane-cabin insulation should have three properties; reduction of sound penetration, absorption of the sound that penetrates, and lightness of weight.

The Bureau of Standards in conducting sound-insulation experiments uses a unit of measurement called a "decibel." In a scale which ranges from 0 to 108 decibels, it places the sound comparable to the rustle of leaves in a gentle breeze at 10 decibels.

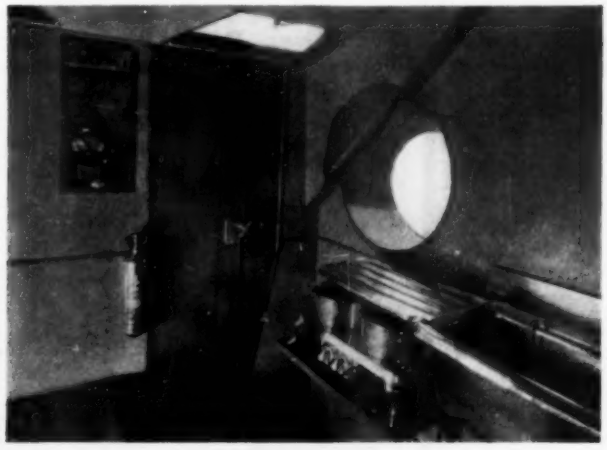

FIG. 12 KITCHEN IN KEYSTONE PATRICIAN

FIG. 13 LAVATORY FINISHED IN LIGHT GREEN FABRIKOID

an average whisper 4 ft. away at 20; conversational-speech range at 35 to 65, train noise at 65, New York subway train noise at 80, and the noise in an open cockpit plane at 90 to 100. By proper insulating methods it has been shown that a decrease in sound level of about 32 decibels can be attained. Generally speaking this is a reduction in the loudness of sound as heard in an open-cockpit plane to a level of that of a railroad coach in motion.

The most efficient insulation material commercially utilized, on the basis of weight for the same degree of sound insulation and volume of space filled, is dry zero. Dry-zero airplane blanket is a batt of ceiba fiber bound up with cheesecloth. The in-

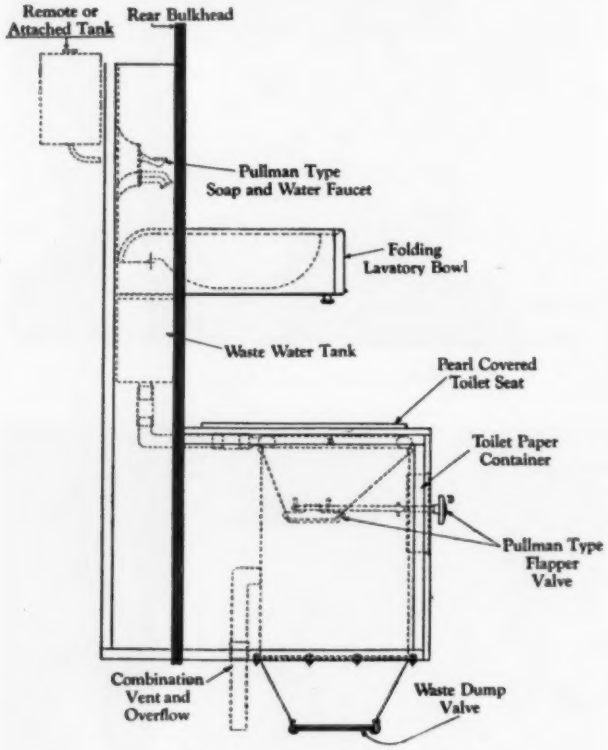

FIG. 14 IMPERIAL CABIN TOILET

tensely fine and permanently resilient tubular fibers of ceiba are "grained," that is, laid parallel and across the line of sound transmission or heat flow. Its resistance to heat flow is 25 per cent greater than that of cork, and it absorbs only 49 per cent as much moisture from humid air as cork. The material weighs about 0.2 lb. per sq. ft. in 2-in. thick layers, which is approximately $1/8$ the weight of cork. The material is highly flameproof.

Balsam wool, the next most popular and efficient insulation, is made of clean new wood fiber from Northern coniferous trees. By mechanical and chemical means the wood is broken down into individual fibers; fine, hair-like, hollow tubes. After being saturated with chemicals to render them non-inflammable and resistant to decay, and treated with an adhesive to secure a permanent bond, these fibers are felted into a fleecy mat which looks and feels like sheep's wool. In balsam-wool airplane insulation this mat is lined on one side with waterproof Kraft paper and on the opposite side with open-mesh cloth. Balsam wool weighs 0.3 lb. per sq. ft. 1 inch thick and 0.18 lb. per sq. ft. $1/2$ in. thick.

Both of these materials are easily installed, being literally tucked into place after being fitted with a simple pair of shears. In wooden fuselages they are nailed to the wooden struts, a braid being placed over the nails to protect the interior fabric. On metal tubular structures the material is wired in place, supplemented by nailing through wood fairing strips where available. It is to be noted that continuous hard materials (such as micarta, plymetal, etc.) when used for interior panels impair the sound-absorption qualities of the insulation, and that loosely woven fabrics are best for interior finish in this regard. It is possible to lower the noise level by 8 or 10 decibels by taking this simple precaution.

Other substances such as hair felt, cotton, and cork have been tested and used as insulation materials, but they are not as efficient as the foregoing. In France, seaweed is used for this purpose, being very light in weight and non-inflammable. It is kept together by fireproofed thin-woven fabric.

Inasmuch as windows are not so effective as the walls in dampening sound in a well-insulated cabin, it is necessary to use rather heavy glass with a thickness of $3/16$ or $1/4$ in. From a safety angle it is highly desirable that this be laminated glass. Briefly, laminated glass consists of two layers of glass cemented together by an inner layer of tough, flexible, colorless material, molded by heat and pressure into one clear transparent plate, which neither jars nor blows can force apart. If the glass breaks, no splinters will fly, all broken particles adhering to the flexible inner layer. Celluloid or pyralin is generally used for the inner layer. Safety glass $1/4$ in. thick weighs about 50 oz. per sq. ft., a relatively high weight, so that it is desirable to hold windows to a minimum size consistent with passenger comfort and enjoyment.

FIG. 15 LAVATORY AND WATER FLUSH TOILET WITH BUCKET CONTAINER

FURNITURE

The cabin airplane chair probably contributes more to the comfort or discomfort of the passenger in a transport plane than any other single item. Early chairs at best were rather crude affairs, very light due to their wicker construction, but otherwise not very practical. The building of seats for any purpose is one that requires considerable study of the human anatomy so that the proper comfort factors may be incorporated. A chair that may be very comfortable when tried out in an office for a few minutes may prove to be very irksome when one is forced to sit in it for any great length of time. As rattan did not adapt itself readily to a strong and permanent connection to a structural member of a hull or fuselage, attention was naturally diverted to metal tubing for the framework. There is, of course, no universal airplane chair for all uses, but fortunately several organizations have specialized in this field, so that there is a reasonable range of choice, and particular designs may be modified in detail dimensions to fit particular planes. Brief descriptions of some of the leading chairs follow.

Adapto Steel Chairs. (Grand Central Wicker Shop.) This self-reclining chair is easily made of mild carbon-steel tubing of 0.035 in. wall thickness, and lends itself readily to airplane re-

quirements. The mechanism is simple, automatic, and light. Whereas a chair frame is usually constructed in one part, this is made in three, i.e., a seat chassis, a seat, and a back. The back pivots from the chassis while the seat is connected at two friction points with the back. A chair of this type in which the restless passenger can satisfy his whims with an infinite number of positions is highly desirable. In choosing the upholstery fill, cotton has been discarded because of its weight. Down has a slight advantage in weight and comfort, but kapok is considerably cheaper and possesses water-resisting properties which are desirable as a life preserver in a flying boat. Fabrikoid is used for covering due to its strength, lightness, cheapness, and washability. Repair costs caused by tears or burns are reduced to a minimum by having each unit of the chair upholstered separately and laced. The complete weight is $7^{3}/_{4}$ lb.

Steel Arm Chair. (Grand Central Wicker Shop.) The steel tubular arm chairs required by the large transport planes such as the Ford tri-motor, merely necessitates a reconstruction of the chassis. The front and rear legs are arched a foot or so higher than on the side chair chassis, thus forming two arms which are upholstered in the same manner as the seat or back. This incorporates all the comforts of a heavy living-room chair and weighs but 13 lb. While no two planes generally call for the same chairs, it is a simple matter to change heights and widths.

Aluminum-Alloy Reclining Chair. (Aluminum Company of America.) This chair is fabricated from strong aluminum alloys using both riveting and welding as fabrication processes. Tubing of 0.036-in. and 0.040-in. wall thickness is used. The total weight of the chair is $12^{1}/_{2}$ lb. These chairs are also available in a double-chair type.

Aluminum Alloy Deck Chair. (J. G. Brill Company.) Both the adjustable and stationary chairs developed are constructed principally of heat-treated, $^{3}/_{4}$-in. aluminum-alloy tubing. To this framework is attached a one-piece leather cushion support and back. The cushion and headrest are padded and upholstered in leather. In the adjustable type there is a push-button directly under the arm at each side, the pressing of both buttons at the same time releasing the back. The stationary type weighs 13 lb. complete and the adjustable type $19^{1}/_{4}$ lb.

Magnesium Alloy Straight Chair. (Dow Chemical Company-Kelton Aurant Company.) This magnesium-alloy tubing chair is fabricated by welding, the use of a light braided fiber as filler bringing the total weight with seats and pads down to approximately 6 lb.

The custom-finished private plane offers unlimited opportunity for the decorator to exercise his skill. Built-in desks at which the business man may dictate his letters while traveling are cleverly contrived to take little space in the plane and are most useful. Complete galleys for the preparation of food on electric equipment are features of some private planes, while all others have one or more sleeping berths, somewhat similar to those in a railroad Pullman car. Combination ice boxes and table cabinets are features of others. In fact, the designers of air yachts have taken many a thought from pleasure boats or Pullman cars, and made them as practical for air as for water or rail travel.

Sanitary Equipment

The development of this very primary need in modern planes

Fig. 16 Fokker Super-Universal Plane With Engine Exhaust Pipe Arranged for Heating

may be divided into two distinct phases of development. The first installation in which all the requisites are installed as separate units as shown in the current planes of the day, and the latest, a brand new development, in which all the requirements are grouped into a single compact unit before installation. In addition to the obvious restrictions of weight and space, there is the further fact that government regulations rigidly prohibit the discharge of any waste while in flight. There were really no precedents available in other travel conveyances when this development was first inaugurated, so that the entire matter of lavatory equipment may be said to have been a pioneering undertaking.

In most of the installations made with separate individual units, it has been necessary to build a great part of the equipment as special, designed to fit the space available. Nickeline and aluminum are used to build wash stands and water tanks. Wash stands are equipped with either two faucets, one faucet, or none at all, some types being foldable when not in use, while the weight ranges from 1 to $5^{1}/_{2}$ lb. Water tanks are of various forms, flat rectangular, triangular to fit corners, quarter cylinder, and half cylinder, according to space available. Varying capacities, often of 4 to 5 quarts, and weights of $1^{3}/_{4}$ to $6^{1}/_{2}$ lb. are utilized.

Aircraft hoppers are of the chemical type, ranging from 16 to $25^{1}/_{2}$ in. in height, with diameters from 10 to 13 in. and weights from $8^{1}/_{2}$ to $19^{1}/_{2}$ lb. Some are of the folding closet type,

while others are built with slanting bottoms to fit the sloping floors found on many planes at their point of installation. The inner buckets are readily removable for cleaning.

The single-unit cabin toilet is a self-contained unit, designed from the three predominating angles of minimum weight, minimum space, and artistic design. It is patterned after the lavatory toilet-chair combination used in the recently introduced bedroom cars of the Pullman company. There are three outstanding advantages to this unit, namely, it is complete within itself, combining water and liquid-soap storage, lavatory, and water-flush toilet in a compact article that can be moved and placed in any desired location; secondly, it occupies only a part of the space now occupied by the conventional type of corner bowl and open toilet; and, thirdly, it is equipped with the Pullman-type flapper valve and water sealed against all odors.

Its pleasing appearance allows the use of the toilet room as a dressing room without the feeling of distaste that would ordinarily prevail. The modernistic design as a whole is carried into detail in the shape of the Venetian mirror, side lights, and toilet seat. The back of the chair (which forms the bottom of the lavatory) is upholstered in rich velour or leather, and the color scheme is followed in the finish of the pearl-covered toilet seat, frame, and covering of the unit. A variety of colors are provided to harmonize with the interior decoration of the planes. The panels may be of perforated metal, solid sheet in tile or painted colors, or of special sheet materials. Complete units, together with 5-gal. capacity tanks, are 14 in. by 22 in. by 63 in. in dimension and weigh about 32 lb.

FIG. 17 EXHAUST FROM THE CENTER MOTOR RUNS UNDER THE FUSELAGE WITH STOVES AND HEATING CYLINDERS

AIRCRAFT HARDWARE

The development of suitable aircraft hardware for cabin interiors is, strange to say, but a recent accomplishment. Its history has been rather peculiar. At first the airplane manufacturer was literally forced to shop at the corner hardware store and accept the weight penalty. Then individual plane manufacturers and a few specialty concerns made crude attempts at light-weight design, entirely lacking in any artistic conceptions. The advent of the decorator into the field necessitated an about face and the penalty of excess weight was again paid by utilizing automobile hardware which was pleasing in design. Only recently have the automobile-hardware manufacturers interested themselves in aircraft hardware, with the result that at last there are available small, artistic, light-weight hardware units, usually made of aluminum or aluminum alloy except where design or wear limitations preclude their use for certain component parts.

To enumerate in detail all the various types of aircraft hardware now available would be rather tiring. Therefore only a very abbreviated attempt will be made to give an indication of the various fitments which are customarily classed under this general term. Door-locking equipment ranges all the way from cylinder door locks with automatic safety-lock features, to simple latches and bolts, with external handles usually streamlined in form. Window equipment includes various forms of window regulators, window stops, and regulator handles, usually, though not always, available in light alloy materials. Aluminum-alloy hinges of all forms are readily procurable. Lighting equipment includes various sizes of dome and torchère light fixtures. Robe rails, baggage racks, ash trays, and various accessories complete the list of special light-weight hardware of artistic design developed especially for airplane interiors.

HEATING AND VENTILATING

Heating and ventilating equipment where installed, while perhaps more exterior in its visible applications, is decidedly interior in its needs and effects. While the necessity for heating is naturally influenced by the routes operated over or the territory ordinarily selected for flying operation, it is decidedly important from the viewpoint of passenger comfort, as extreme cold is reached at high altitudes even in temperate climates. It may be cited as a matter of interest that on the Western transcontinental route of the Boeing system the temperature sometimes varies from 35 deg. below zero to 135 deg. fahr., and the flying altitude from sea level to as high as 12,000 ft. when crossing the mountain ranges.

In heating, the source of heat is the exhaust from the motor.

This is carried from the various cylinders of the motor in a collector ring to the base, where a long steel pipe is brought down under and along the fuselage to carry these hot gases. Stoves or heating cylinders, usually of duralumin, are placed around this exhaust pipe, and direct fresh-heated air up into the passenger cabins through appropriate conduits and floor registers. The heating cylinders are belled out at the front to insure an adequate supply of fresh air, and various types of control valves are used to regulate the amount of heat admitted to the various parts of the cabin.

Ventilation is not such a serious problem in so fast a moving transportation medium. To a great extent it is at present merely a matter of opening and closing windows, but in addition some

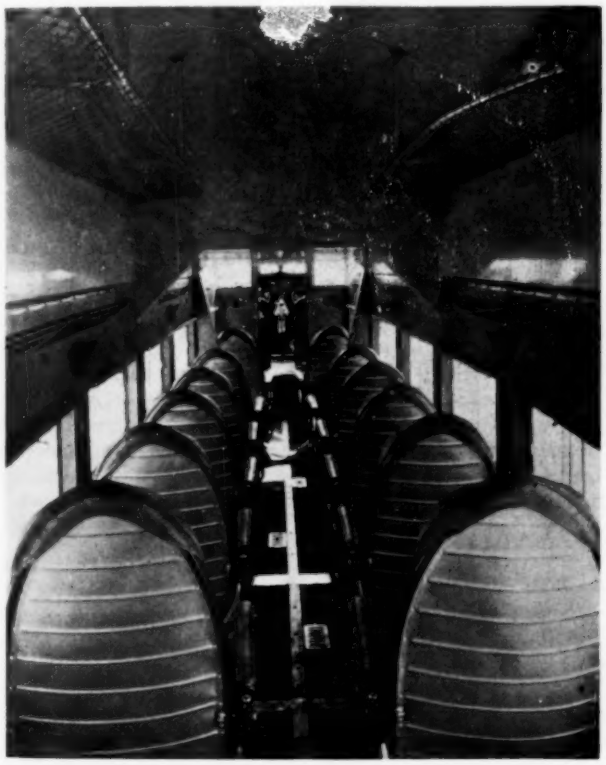

FIG. 18 FORD TRI-MOTOR PLANE '20 WITH FLOOR REGISTERS FOR HEATING

installations use an ordinary light-weight grill-type ventilator with an external flat scoop at certain desirable locations.

RÉSUMÉ

It is hoped that the foregoing will give some conception of the many problems involved under the heading of interior design. Its accomplishment is essentially a problem in coordination of many materials, many parts, and the work of many individuals. This job of coordination belongs most properly to the decorator. His is the responsibility to create in this rather limited space—and it is limited, judged by the standards of other means of transportation—an artistic appeal that makes of flying not only the last word in speed but in luxurious comfort as well. It is necessary not only to keep abreast of style trends, but many times in advance of them, so that their specialized application in aircraft materials and fitments will appear simultaneously with their more readily general application in other industries.

Air transportation is still at the stage where the first flight of an individual is significant; everything about the exterior of a plane is novel to his perceptions, the medium through which he is transported is new to him as such, and the speeds with which it is done are also generally far in excess of what he is accustomed to. Only one familiar aspect can be graciously bestowed upon him, an interior which is as luxurious and comfortable as his own home or club, and which immediately places him at his ease.

To attain this perfection in harmony of line, color, and utility in an industry which economically has not yet felt the advantages of true mass production, is a difficult task. That it has been accomplished in so fitting a manner, as shown by the accompanying illustrations, is a tribute not only to the decorators who have directly created these artistic conceptions of interior design, but also to the many specialty organizations operating primarily outside the field of aeronautics, which have had faith enough in the future of aviation to anticipate the ultimately profitable volume demand for specialized aviation products by making them available well in advance of that eventual demand.

The rapid evolution of aeronautical technical development makes it imperative that the finishing of the interior of any particular plane be accomplished in a minimum of time. There is usually very little time left after the completion of the structure of a plane for the interior design to be carried out. Therefore while this should be executed under the direction of an experienced decorator, who has a knowledge of the mechanical problems involved, the actual work is best done by the personnel of the airplane manufacturer under a specially appointed and experienced foreman. The decoration of the interior of a plane is a specialized function, best performed by those who are thoroughly familiar with plane construction and fully aware of the many intimate special problems involved.

Discussion

JOHN G. LEE.[3] After so admirable a presentation, the writer dislikes to take the opposition view. Nevertheless, he feels that any stress on cabin interior decoration is premature. He has no quarrel with special interiors for individuals who buy an airplane as if it were a yacht. They have a right to anything that makes them comfortable or suits their fancy. But for the ordinary transport plane to be used on a transport line the case is different, as also for the small plane for the private owner, where we cannot afford to make every one different.

The truth is that the airplane is not as far advanced as we like to think. The present-day airplane is about as far developed as the steamboats that immediately followed Fulton. In other words, they are clumsy and unsatisfactory in many ways. To spend much time on the decoration of a Fulton steamboat is obviously ridiculous. When as radical a device as the Autogiro can seriously be considered as a competitor of the airplane in any particular, then the art of airplane design is anything but stable. Or, more specifically, when we do not know whether to make a fuselage of shell construction with rounded sides or to build it of tubular members, then we are not ready for the interior decorator.

The writer would be glad to see all of the interior design thrown overboard. Obviously, however, we cannot do that. Airplanes compete with luxury in other forms of transportation, so we must supply at least the essentials of comfort. We may differentiate between comfort and decoration. This modern decoration is usually overemphasized. The designs are large and bold, and do not show well in a constricted space. One cannot get away from them. They are disquieting, to say the least. What decoration there is should be restful and simple.

[3] Fairchild Airplane Mfg. Corp., Farmingdale, N. Y.

The authors mentioned the use of a "mock-up," or full-size dummy structure, as a help for laying out the cabin interior. This is a most excellent idea. In the last plane which we designed at the Fairchild factory we used this method, and saved ourselves an untold amount of difficulty in the cabin design.

The subject of soundproofing is of great importance. It has always seemed, however, that we have gone at it backwards in permitting so great a source of sound as the power plant, and then trying to prevent that sound from entering the cabin. If we were to put the necessary time and money into research on a silent propeller, the result would be much better. For the propeller is really the most serious offender. The problem should be relatively easy. We know that a geared propeller is much quieter than a direct drive, and that micarta and wooden propellers are quieter than metal. That is something to start with at least.

To silence the exhaust is by no means sufficient. The human ear can record only a certain volume of sound, to put it roughly. If the volume of sound exceeds this amount, enormous reductions can be made and yet the effect will scarcely be noticed. Some time ago we were much interested in mufflers at the Fairchild plant, and finally obtained an excellent silencer. From the ground the noise of the plane was much reduced, but in the cabin there was no improvement. After flying wide open at 5000 ft., we put the plane in a dive and throttled back the motor until we obtained the same high speed and same r.p.m. as in wide-open level flight. There was no difference in noise between the two conditions. In other words, the silencer was effective, but no improvement resulted. In fact, the only comment which shed any light on the subject was the pilot's remark. "This is the noisiest engine I ever rode behind. You can hear the parts rattle around inside it."

We had silenced one of the noises, which allowed others to be heard, but did not sufficiently reduce the general noise level. If we can do something to eliminate these noises at their source, then the decorators' soundproofing will be much more appreciated.

While on the subject of comfort, the writer wishes somebody would define what "adequate comfort" is. We get as many answers as we ask people. For example, are toilets really necessary in present-day aircraft? If so, how big can an airplane be before it requires a toilet? Another point, are the reclining chairs really such an asset? The writer thinks not. They have a nasty habit of collapsing when you put your hand on the back of them in walking up the aisle. Also, when you are seated, and the pilot "gives it the gun" your seat flattens out like an operating table. To prevent this, some sort of clamp or clip is required for the passenger to operate, and most passengers are scared to tamper with any adjustments on an airplane.

It is surprising how much apparatus a human being requires to have carried around with him. The average passenger thinks that we are transporting nothing but himself. Actually we are carrying an accumulation of weights, about as follows: Passenger's baggage, 35 lb.; seat and safety belt, 15 lb.; laminated window glass, 10 lb.; upholstery, rugs, soundproofing, 15 lb.; toilet and toilet compartment, 10 lb.; total, 85 lb. Thus, for every 170-lb. passenger we have to carry 50 per cent more of unpaid weight.

As things stand now, air transport does not pay. Before it can pay we will have to at least double our pay load. That does not mean to double the size of the airplane. It means to double the pay load for the same size of equipment. Furthermore, air transport is unpunctual and unreliable. If the weather is bad, the flights are postponed, Otherwise, they are unsafe. We will have to make air transport a dependable service. When we are confronted with problems as serious as these it seems premature indeed to lay great stress on cabin interior design. Let us keep our interiors simple, and think more than twice before we add anything more for the airplane to carry around.

Airplane-Wing Trussing

By RICHARD M. MOCK,[1] WARNEMÜNDE, GERMANY

The paper compares and analyzes the existing types of wing bracing in conventional airplanes. The internal structure of airplane wings is closely linked with the external system of support, and therefore the paper covers some of the methods of internal bracing, but is mainly devoted to systems of external bracing. The efficiency of the wing trussing is a function of the size of the machine. For a low-wing design the wire-braced wing seems quite efficient, providing the span is not too great compared with the height of the plane. For a larger span, subject to high wing loadings, the high-wing monoplane is very efficient, though there are many points in favor of both the braced and the cantilever wing. For the very large plane, with a normal fuselage, the biplane bracing is advantageous. On large designs where a part of the load can be carried in the wings the monoplane is better aerodynamically.

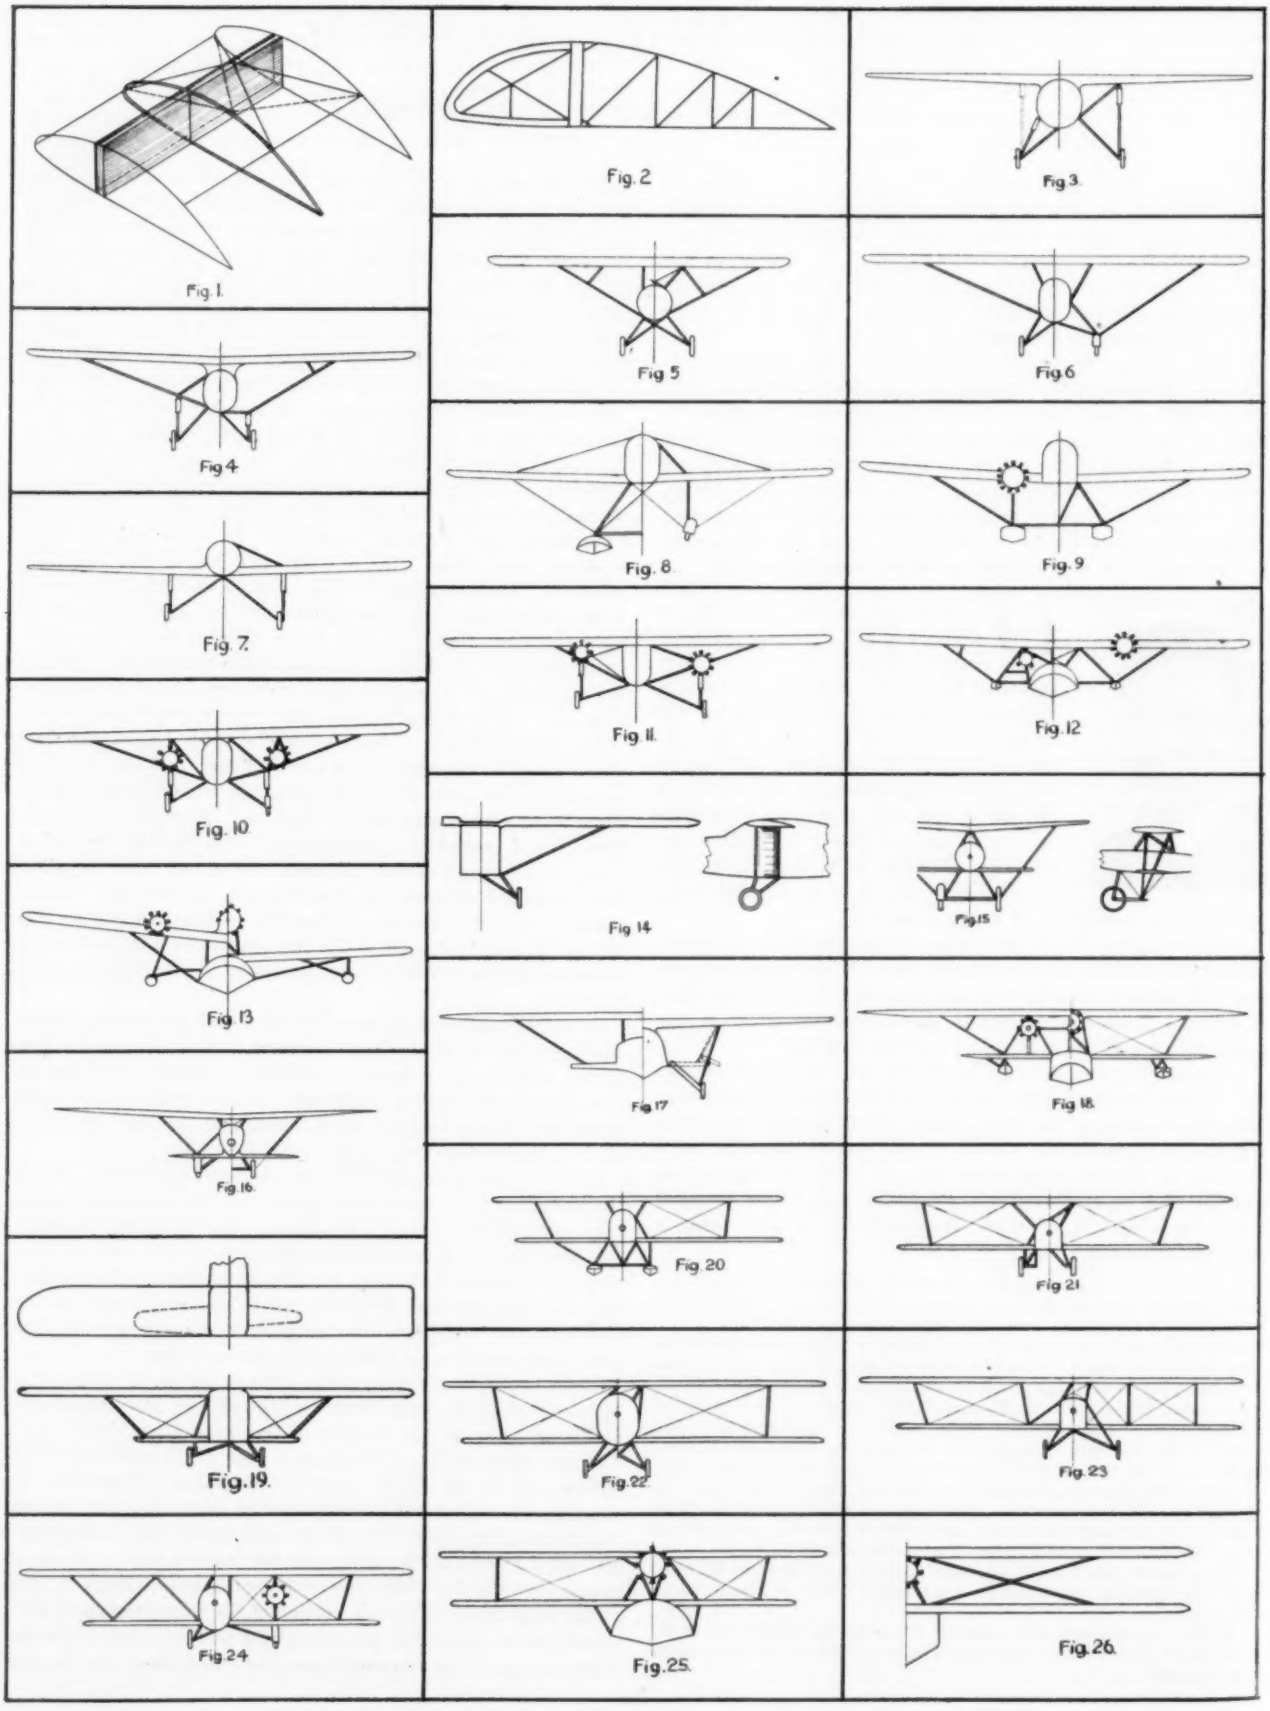
OF ALL the possible variables in airplane design, the system of bracing for the wings perhaps has been exploited the most. It seems that man's imagination has no limit in designing the trussing of members to support the lifting surfaces of the airplane. This paper will confine itself chiefly to existing types of bracing and will attempt to compare or roughly analyze them. Only the conventional airplanes, as in practical use, will be discussed; the Ente or Canard type, as well as the Autogiro, will not be included.

The internal structure of airplane wings, especially in monoplanes, is so closely linked with the external system of support that it is believed best first to cover some of the current methods of internal bracing and then to devote the remainder of the paper to some of the systems of external bracing.

Internal wing bracing may be divided into two basic schools. In one, the entire air loads on the wing are taken by a bracing inside the covering of the wings, and in which the covering is used only to give shape to the airfoil. In the second, the wing has a covering of rigid material which can be utilized to take stress and therefore to eliminate a corresponding amount of material inside the wing. In addition, there are some designs using a combination of these two.

The simplest type of internally braced wings consists of the popular two-spar design, with compression members parallel to the flight direction. These compression members are between the spars and have diagonal wires or tierods between, completing the truss. This system has been varied by having single diagonal wires in one direction and double wires in the other, depending upon the loads, or by having a complete double system with the double wires attached together on one fitting. A third is to have the wires as far apart as possible, and thus give the wing great torsional rigidity. A variation of the last is to have the wires go from the top of one spar diagonally across the bay to the bottom of the other spar. However, this is somewhat complicated and is not desirable in most wing designs. For the wires it has been proved quite efficient to employ tierods of solid cross-section and threaded terminals. In some less expensive airplanes hard piano wire is used, wrapped at the ends and soldered. Another type of internal interspar bracing used in wings of two-spar design has the entire internal wing bracing of rigid members that can take either tension and compression (such as tubes), and thus eliminate wires completely. In this type of bracing it is usual to have the system made up of similar members, arranged in a Warren truss, with none of them parallel to the flight direction. This usually eliminates the complications of compression members with airfoil shape, and yet does not complicate the method of supporting the aileron hinges should there be an aileron attached to this wing. However, it is sometimes found necessary in wings with tierod bracing because of wing, tanks, etc., to use a diagonal tube in one bay. Of all of the mentioned systems the most modern for two-spar designs seems to be that of having all ribs alike with an internal bracing of tierods spaced far apart and with compression members placed between the ribs so that it is not necessary to give them a special contour.

A basically different system of bracing a wing in torsion is that developed by the Mono-Spar Company, Ltd., of England. The system of bracing is to have a single spar in the wing with tierods from the top and bottom of the spar to tubes or ribs in the chord direction. These diagonal wires, crossing at the spar, take part of the torsional and drag loads. (See Fig. 1.)



There are many variations of the methods of internally taking the air loads on the wing when it is decided to use the covering to take some of the stress. The prime method is to have a single spar that has strength both in bending and torsion, and can thus carry all of the loads without additional members. The English braced single-spar wing has been used to a limited degree, and in Germany the single-spar incorporating a stressed covering has been used on gliders as well as on power machines.

The German single-spar system utilizes the depth of the wing to take part of the beam loads and the skin to take the torsion and drag loads as well as part of the beam loads. The most common construction of this type is that used in some German gliders and in the B.F.W. powered machines. These have a wing profile with a fairly thick leading edge utilizing a single vertical member about 30 to 35 per cent behind the leading edge and the curved rigid covering over the leading edge to act as a spar. (See Fig. 2.) This thin covering is given its shape by ribs of the usual type. The rear portion of the wing consists of ribs, usually fabric covered to give the proper profile. Sometimes the inner portion of this covering is metal to give a better base for the

attachment of the wing to the fuselage. Another method, which also has been called a single-spar type of construction, is that employed by Rohrbach, in which the central portion is used as a beam and has vertical members at the place where the usual two spars are located. The top and the bottom are closed in by sheet metal, and thus complete a box to which the leading and trailing edges are hinged.

Wings of the type used by B.F.W. are quite light and allow a very high aspect ratio. (The single spar B.F.W. M-20 has an aspect ratio of 10.) However, it must be admitted that, in their present state of design, wings of this type are not cheap to manufacture in spite of the fact that in principle there are fewer structural elements.

Somewhat similar to these are the wings with two or more internal spars in which the skin takes the drag and torsional loads, and in addition sometimes takes part of the beam loads. The simplest of this type of construction seems to be that of having the spars and usual ribs all covered with a stressed covering, thus forming the airfoil desired. Somewhat more complicated than this is to have more than two spars and a lattice-truss system between the spars, and thus give the wing its shape and also act as part of the bracing. Such wings are usually indeterminate, and are therefore sometimes quite difficult to calculate, as well as being costly to construct.

Stressed covering is normally limited only to cantilever wings, and for this reason the wing is usually tapered so that the aerodynamical lift increases toward the root and thus gives the combination of an aerodynamically efficient wing with sufficient depth at the root to take the large bending moments. However, because of the difficulty of attaching the covering, wings with stressed covering are usually quite expensive, especially if metal is used. Internally braced wings without a stressed covering are, in general, with parallel leading and trailing edges and have no taper in thickness ratio. Therefore they are somewhat cheaper, since all ribs are alike. A simple variation of the stressed covered wings is that used on some Heinkel land types of wooden construction in which there are parallel beams of the normal type supported torsionally by rigid box ribs. A plywood covering for the under side of the wing completes the structure, and the top is covered with fabric in the usual manner.

Before going to the subject of the various methods of external wing bracing, mention must be made of the tendencies in airfoil design, which it seems will materially affect the future systems of internally bracing airplane wings. There seems to be today an increasing tendency in the use of thick profiles having high-lift characteristics and allowing high wing loadings, and also to have the proper depth for sufficient spars. More and more the industry is coming to use airplanes with a short center of pressure travel, thus reducing the torsional loads on the wing. Where a constant center of pressure is not possible because of the aileron loads, when a usual aileron has been employed, it has been proposed to balance this torsional load by another aerodynamic force caused by a second external member, and thus reduce the resulting load to only a local one and a bending load on the beam. However, this has not been worked out to a practical point. In some modern designs it is usual to have inset ailerons and a constant center of pressure airfoil for the wing tip, and thus reduce the possibility of flutter in normal flight with great accelerations or in flight in which certain vertical currents or "bumps" are met.

Cantilever wings usually have a fairly thick section inboard because of the high bending moments. (See Fig. 3, left.) For this reason external bracing has sometimes been used to reduce the bending moments, and consequently to allow a shallower profile to be used. It is common in some designs to have a wing that is quite like a full-cantilever wing in all respects except that about one chord length outboard from the root a strut goes from the fuselage to the wing, thus relieving the bending moment and allowing a more shallow airfoil. (See Fig. 3, right.) Such a wing usually approaches the full-cantilever wing in aerodynamic cleanliness, and sometimes allows a lighter structure, though the aerodynamic interference of the strut and the costs of more members and more fittings sometimes overbalance the advantage of the shallower profile.

A structurally lighter development is the externally braced monoplane wing in which the strut point is some 120 to 135 per cent of the chord from the tip, thus allowing a very light type of structure, providing that the base of the external support has sufficient depth to allow a good angle between the strut and the wing and thus not cause excessive axial loads in the wing beams. Structurally, the lightest variation of this type is to have the wing taper according to the bending moments, and thus give a wing with maximum chord and thickness at the strut point and with a short chord and thin section at the fuselage, giving a low weight and increased vision without the complication of cutouts or abnormal wing tapers.

Mention should be made of the wing system of the German Rohrbach Roland and the Beardmore Inflexible, also of Rohrbach design. In these a very high aspect ratio has been incorporated, and a tension cable is used to support the single-spar wing from the fuselage, and thus have a braced wing for normal wing loadings. Because of the short center of pressure movement, this single cable puts little torsion in the wing.

The most popular type of wing bracing in America and now also finding great favor in Europe is that of the high-wing monoplane with struts from the bottom of the fuselage attached to the wings at an efficient point. (See Fig. 4.) This point varies with the depth of the fuselage, the dihedral and the pressure distribution on the tip, and the depth of the spars available. Bracing of this type has the great advantage that, without being excessively heavy, it allows a wing without taper, eliminating the costs of the dissimilar ribs, tapered spars, etc.

Of all of the possible types of wing bracing it is believed that there are more basic variations in the externally braced monoplane than in any other system. Most airplanes using this bracing are of the high-wing type as they allow the external bracing to be under tension under the most severe flight conditions. In addition, the external bracing is under the wing, allowing less aerodynamic interference than when the wing is low and the external bracing is above, with the bracing members of large dimensions because of their high compression loads. (See Fig. 7, right.) In most monoplanes of the braced high-wing type the members go from the lowest point on the fuselage to the wing. As the axial load in the wing beams is a function of the cosine of the angle between these wing struts and the wing, it is desirable to have this angle as large as possible, and yet have the strut attachment point far enough outward to relieve efficiently the bending moment caused by the air load. Outboard of this strut point the wing is designed in the same manner as a cantilever wing, and for this reason, if costs permit, it is advantageous to have the wing tapered from here to the wing tip. The design of the wing spars between the strut point and the fuselage or cabane is a function of the axial load caused by the external bracing, the air loads producing bending, the length of the bay, and the available section for spars. Thus it can be seen that, in addition to having the angle between the struts and the wing as large as possible, it is advantageous to have the length of the compression bay as short as possible. This has been carried out very nicely in the wing system of the new Boeing monoplane fighter and the French Wilbault 130 by having the cabane struts arranged in such a manner as to reduce the slenderness ratio for the inner bay of the spars. (In Fig. 5, left, is the Wilbault 130 and right,

the Boeing monoplane system.) It is also quite customary now to reduce the buckling length of the external wing bracing by having short struts between this bracing on the wing such as is shown in many of the accompanying sketches. (For example, see Fig. 3, right, the system of the Bellanca "Pacemaker.") In order to reduce the axial loads in the wing as well as the loads in the external bracing, it is advantageous to attach the external bracing struts as low as possible. This is carried out very ingeniously in the French Ateliers des Mureaux type 4 C-2, two-seater fighter (see Fig. 6), where the wings are braced directly to the landing gear. In this plane the wing-strut angle is exceptionally good, though it must be admitted that the landing-gear design is somewhat complicated and there is a great aerodynamic interference between the numerous struts supporting the landing gear to the fuselage.

In most of the American high-wing monoplanes of the cabin type in which the wings are braced externally, the landing-gear shock absorbers are attached to the wing struts, and sometimes an additional strut goes from this attachment point to the upper longerons of the fuselage. (See Fig. 4.)

This action allows the slenderness ratio of the external bracing to be somewhat reduced. In most American commercial designs the external bracing consists of steel tubes, though in many high-speed planes tension streamline tierods have been substituted and additional tierods braced above the wing take the reversed loads. Of course this means that the wing must be below the fuselage in order to have a high point of attachment for the tierods above the wing surface. In the Schneider Cup designs (the wing system of which is shown in Fig. 8, left) and the Travel Air type S racing plane (Fig. 8, right) this has been carried out quite successfully. It is the opinion of the author that this type of bracing has great possibilities as it allows a very light structure without the additional resistance of the usual struts. In both of the racing designs referred to, a very efficient angle for the under tierods was obtained by having them attached to the landing gear. However, for very rough usage, tierod bracing has the disadvantage of being somewhat flexible, and for this reason the Heinkel single-engined and multi-engined low-wing designs (for seaplane designs for heavy sea duty) have substituted tubes for the tierods and thus have eliminated the upper wires. (See Fig. 9.) In these designs the external strut bracing is afforded at a very good angle because of the wide tread of the floats. This type of bracing is also carried out on the Consolidated flying boat (Fig. 12, left) and the French three-engine Paulhan-Pillard E-5 flying boat (Fig. 12, right).

Another method of reducing the slenderness ratio of the external bracing efficiently is shown in Fig. 13, where the additional bracing also carries part of the wing-float loads. In multi-engined, externally braced monoplanes the inner bay of the wing spars and the external bracing can be relieved of great loads by utilizing the additional struts for the engine support as part of the wing bracing and thus reduce the slenderness ratio. (See Figs. 10 and 11.)

In all of the drawings mentioned only the front bay has been shown, and in most cases the airplane is shown as a land machine. However, most of these designs are adaptable for seaplane installation by attaching floats to the landing-gear fittings. However, though the objection to attaching the wing bracing to the landing gear has been somewhat overruled by the use of very good shock absorbers, care must be taken to have sufficient rigidity when including the wings in a float-bracing system.

In externally braced monoplane wings with parallel spars it is simplest to have the external bracing, as seen from above, coincide with the spar center lines and thus relieve the wings of any chord component forces such as may occur when the external bracing is carried to one point as on some folding-wing planes or on some high-wing flying boats. However, in these cases it is believed that the advantage of easily folding wings, allowed by having the struts at one point of the fuselage, or the reduced water resistance, in case of a high-wing flying boat, overbalances the additional weight caused by chord-component forces from the external diagonal wing strut. On the other hand, there is the advantage of great rigidity in having the two lower attachment points of this external bracing far apart longitudinally and thus give as great a base as possible to take the torsional drag loads in the wing. However, in such designs it is usually necessary to have diagonal bracing between the wing-support struts, which then makes the wing structure indeterminate in the chord direction, complicating the stress analysis considerably and increasing the costs accordingly.

In conventional monoplanes the external bracing is usually of streamline form. However, many manufacturers are now adapting the principle developed by Bellanca of having the external bracing with a lift or airfoil section, thus carrying some of its own weight without any great difference in resistance. Streamlining of wing-brace struts, when there are no short auxiliary members between the external bracing and the wing (such as mentioned and as illustrated in Figs. 4 and 5), means that the large section for the external bracing members must continue to the wing and thus cause a large amount of aerodynamic interference, especially if the strut is given a lift section. However, by the use of these short auxiliary struts, the large cross-section for the external bracing does not continue to the wing and allows the airfoil section to be carried to this auxiliary strut attachment point and then have a small streamline section continued to the wing. Thus induced drag is reduced. While on this subject it might be interesting to recall the wing bracing of the Bellanca CF monoplane (Fig. 14) developed in 1922 in which the external bracing supports formed the spars for a lower auxiliary wing that braced the main wing to the fuselage. Although the aerodynamic interference of this auxiliary or lower wing was very high, this was somewhat compensated by the increased lift and lateral stability of the plane. Incidentally, it is the opinion of the author that the long column members for external bracing for monoplanes for land use only can be made structurally more efficient in wood than with steel tubing. This is because of the form factor of the wood column and the possibility of better attaching the ribs for the fairing and covering the entire unit with doped fabric. However, it must be admitted that the steel-tube type of bracing with a metal fairing, though somewhat heavier, is cheaper.

Similar to the externally braced monoplane is the wing-bracing system used on the Nieuwport-Delage planes, shown in Fig. 15. In this design the landing gear is of a through-axle type with the fairing for the axle having a lift section. From the rear of this fairing goes a forked strut to the upper wing. The strut is supported laterally in the middle by a short wing from the bottom of the fuselage. Both aerodynamically and structurally, this type of design having a large upper wing and a very small lower wing is quite small, the weight of the external bracing is not excessive and is properly proportioned, and in addition it allows more lifting area. However, in the method of carrying this out in the Nieuwport-Delage machine there is a considerable number of struts below the fuselage, which it is believed causes much induced drag. Somewhat similar to this in structure, though of cleaner design, is the French Breguet sesquiplane (Fig. 16, right), in which more of the usual biplane characteristics are incorporated, with the power wing strut point braced to the landing gear by wires. The upper wing has considerably more span than the lower wing, and for this reason the interplane strut, a single streamline member, slopes outward so as to eliminate excessive overhang in the upper wing. In the French Caudron sesquiplane (Fig. 16, left) the interplane bracing consists of stream-

line N-struts attached to the lower wing above the landing-gear attachment points and then has additional struts from this landing-gear attachment point to the upper fuselage longerons. Thus the struts act as part of the landing-gear structure as well as supporting the wings.

The idea of having the lower wing of a sesquiplane assist in taking the landing and starting load was also carried into the flying boat by Dornier, who has a small stub wing at each side of his main boat hull. (Fig. 17, left.) In addition to bracing the upper wing this stub wing provides lateral stability on the water and gives sufficient planning action for starting. In the first Fokker F-XI amphibion (Fig. 17, right), the sesquiplane idea or stub-sponson idea was also incorporated, providing for the amphibion gear as well as to be used for starting. However, in this design it is understood that the upper wing supported the lower, and not the lower wing the upper, as is usual. Fig. 18 shows two methods of utilizing the lower wing of a sesquiplane in supplying a convenient support for wing floats on the flying boat, whereas quite long struts might have to be used for the side floats if the

FIG. 27 HEINKEL HE-9, HOLDER OF FIVE WORLD'S RECORDS

plane was designed only as a high-wing monoplane. The system shown on the left in Fig. 18 is similar to that used by Sikorsky. In the Buhl sesquiplanes the lower wing has such great taper that it might be said to be triangular in form. In the larger of the Buhl types (shown at the right of Fig. 19) the landing gear is supported to the wing in a method similar to that in the Caudron.

Two designs also incorporating the landing gear with the wing bracing are shown in Fig. 20. Both of these planes are Heinkel single-engine water training machines in which the landing loads are carried through parts of the wing structure. In the design shown at the left no tierods are used.

For the land types of purely braced-wing biplanes there does not seem to be as much variation in the system of trussing the wings except perhaps in the arrangement of the struts for the cabane. Figs. 21 and 22 show two of the most popular methods of carrying this out. In a biplane, it is agreed that in a multi-bay design it is possible to have some reduction in weight, though the complication and aerodynamic resistance are, of course, greater. The Martin 74 type of bracing (Fig. 21, left) eliminates the additional bracing of the two-bay design and yet incorporates much of its efficiency and at the same time provides for a landing gear of fairly wide tread. The Boeing mailplane 40-C (Fig. 23, left) is practically of two-bay design with the inner bay braced with tubes instead of wires. A variation in the usual tube- or wire-bracing biplane design is in the Parnall Elf (Fig. 24, left) in which a complete tube truss is used to provide greater rigidity and allow the wings to be folded. In multi-engined biplanes it is usual to have the outboard engines form part of the interplane bracing, and thus have a multi-bay design, utilizing the engine bracing as an integral part. This is carried out in the Boeing transport (Fig. 24, right). Fig. 25, left, shows the usual method of bracing a biplane flying boat, while Fig. 25, right, is a type of bracing used on some German seaplanes in the war.

Perhaps one of the most interesting types of wing bracing developed in recent years is that first used in the Bellanca K and later developed in the Bellanca TES. (See Fig. 26.) It is difficult to classify this type of wing in the category of either biplane or sesquiplane, as the wing bracing in no way resembles the sesquiplane as the term is generally used. In endeavoring to incorporate a large span and yet have monoplane efficiency, Mr. Bellanca has used what might be called a two-bay design, with

FIG. 28 BELLANCA TES

FIG. 29 BELLANCA K

the inner bay being a normal biplane with usual dihedral and the outer bay being a braced-wing monoplane, incorporating the advantages of the Bellanca CF and yet eliminating the aerodynamical interference by having the supporting wing stub some distance below the upper wing. In order to provide an angle as efficient as possible for the bracing wing, or auxiliary wing, the upper wing of the inner bay is given some positive dihedral, and at the same time the lower wing of the inner bay is given negative dihedral. Thus a deep box for the external wing bracing is obtained, at the same time providing for support of the landing gear.

From the foregoing it may be seen that the efficiency of the wing bracing is a function of the size of the machine. For a low-wing design the wire-braced wing seems quite efficient, both aerodynamically and structurally, providing the span is not too great when compared with the height of the plane. For a larger span, subjected to high wing loadings, the high-wing monoplane is very efficient, though there are many points in favor of both the braced and the cantilever wing. Also in airplanes of about this size and for flying boats with side floats the sesquiplane

type of bracing offers many advantages structurally, while when one considers the very large plane, with a normal fuselage, the biplane bracing is advantageous. However, on large designs where a part of the load can be carried in the wings the monoplane is distinctly better aerodynamically.

Discussion

W. E. Savage.[2] The paper discusses almost all the externally braced wing trussings used at the present time, but very little was mentioned of the internally braced wings. It is believed that "interference," which accompanies externally braced wings, should have been included in this paper, since interference must be carefully considered in developing wing-trussing design.

The paper, which is not highly technical in character, will serve as a ready reference for the different type of wing trussings used to date.

AER-53-16

Design and Development of Seaplanes for Transatlantic Service

By DR. E. RUMPLER,[1] BERLIN, GERMANY

The author takes up in succession the various problems involved in the design and construction of a multi-engined airplane capable of making a transoceanic non-stop flight of 5000 miles and carrying a pay load of 21 tons. Among the topics dealt with are: Location of engines and propellers; influence of load distribution on weight of wing structure; aerodynamical researches of the Göttingen laboratory on a model of the author's plane; hydrodynamical starting tests in tank at the Hamburg Shipbuilding Research Institute; influence of various factors on size of pay load; maximum power outputs from oversize engines at various altitudes; necessity of greatly increased airplane speeds; etc.

IN DEALING with the subject of long-distance airplanes it will only be possible, because of space limitations, to discuss a few of the problems involved. I shall confine myself, primarily, to long-distance water planes, but much of what I shall say relative to these is also applicable in a corresponding sense to land machines. I shall also try to make clear what I say by reference to practical examples.

In order to have a starting point, I shall base what I have to say on the design of a transoceanic airplane, especially so because tests carried through in the research institutes of Göttingen and Hamburg pertained to such a machine.

Location of Engines and Propellers

In the design of my transocean flying boat, the first problem that presented itself was to find the most favorable location for the engine with respect to accessibility, the lowest air resistance, and the greatest security. All three of these requirements point toward locating the engine entirely within the wing.

In the interest of safety, it is also generally understood that the power plant should be subdivided into several small units in order that equilibrium shall be affected to a minimum extent in the event of one unit's failing, and which would be of little influence relative to the continuation of the flight.

The opinion occasionally stated that several power units cannot be started simultaneously or kept at a uniform engine speed is erroneous, being disproved by the large Dornier flying boat, which has twelve engines.

By arranging the engines within the wing structure, the question as to the adoption of air cooling is decided in the negative. Therefore we must use the well-tried and reliable water-cooling system in long-distance airplanes until adequate means are found in the shape of a carefully designed system of tubes that conduct the flying wind into the interior of the wing to the cylinders of the motors.

The question as to the maximum propeller efficiency must be settled by taking into consideration the disturbing influences set up by other constructional parts. Very much depends on the ratio of the propeller diameter to the thickness of the wing. If propellers of relatively large diameter were to be employed, the question of their location either in front or to the rear of the wing would—in view of the experience we now have—not be highly important if only the propeller efficiency had to be regarded; but when propellers having a relatively small diameter in relation to the depth of the wing are to be employed, the location is more of a problem. Owing to the subdivision of the power plant the latter is frequently the case at the present time and will be increasingly so in the future. By locating the subdivided propellers at the trailing edge of the wing, the air current surrounding them as well as the fore-and-aft propeller currents, will suffer relatively the least deviation. For this reason the best reciprocal effect between the wing polar curve and propeller efficiency is to be expected.

The design of the tailless airplane that was successfully demonstrated last year at the Tempelhof airport was based on similar concepts.

As we see from this, the most favorable location of the engine clashes somewhat with that of the propeller, and therefore it may be said, in general, that the employment of special transmission mechanisms becomes unavoidable. This is a problem in itself, and it has to be solved in a manner insuring a minimum of mechanical-efficiency losses, as such losses in the transmission—as will become evident later on—cannot be countenanced in a long-distance airplane. For this reason I shall give no attention to arrangements other than those in which the engines are inside the wing, and the propellers are located above or below them.

In view of what has just been said, it would appear that the best compromise is to place the propellers behind the wings in line with the engine crankshafts and connected to the latter by means of a simple shaft. In the event that a reduction gear is employed, the shaft will of course lie in the direction of the gearwheel on the countershaft. Such an arrangement is simple and its mechanical efficiency will be the highest possible, as additional friction losses are avoided.

Also, the noise problem must be given attention. In the near future this is sure to be regarded as highly important, perhaps no less so than the arrangement of the motors and propellers. It is indeed unreasonable that passengers in a flight of about twenty hours' duration should be subjected to the incessant thundering of the engine. Doubtless many having thus been inconvenienced would desist from using an airplane on a long journey again.

The noise problem can be solved only by locating the engine a sufficient distance away from the passengers and arranging between them soundproofing material. The best possible solution that occurs to me is to locate the engines and propellers behind the passengers.

In a lecture which I delivered in 1926 at the annual meeting of the Scientific Aeronautical Society of Germany at Düsseldorf, I

[1] Rumpler Motor Company.

Presented at the National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

outlined my plan for a transatlantic service, the crossing to be effected in stages. Since then, however, the requirements of a transatlantic service as also the technical possibilities have changed somewhat.

5000-Mile Non-Stop Flight a Necessary Design Condition

In order to take full advantage of the great speed of aircraft it will be advisable to make the transatlantic flight in a single stage from a European to an American port. Another circumstance necessitating the crossing in a single stage is to be found in recent politico-economical developments. Owing to concessions which the Portuguese Government has recently granted to an air-traffic company, it will, for some time to come, be impossible to

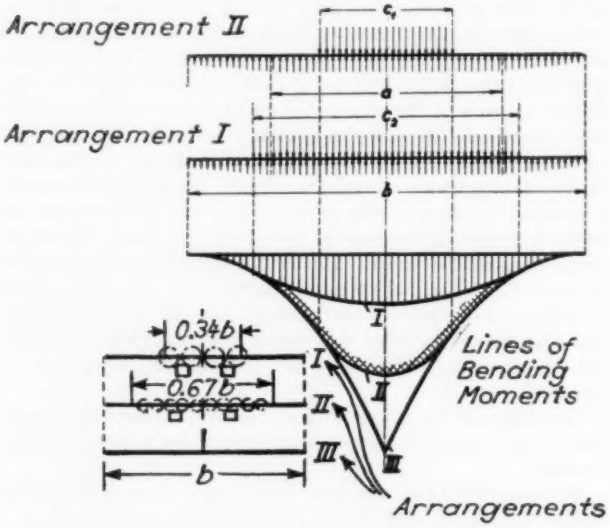

Fig. 1 Curves of Bending Moment

effect intermediate landings on the Atlantic islands under Portuguese sovereignty, namely, the Azores and Cape Verde Islands.

The shortest distance between England and Newfoundland is approximately 2360 miles. But the full advantage of air traffic will only then be attained when it becomes possible to link up directly the most important commercial places. The distance from an English port, for instance, Plymouth to New York, amounts to approximately 3350 miles, and from Hamburg to New York to about 4100 miles.

In practical air service one must always consider the possibility of contrary winds retarding flight and thereby virtually increasing the distance to be covered. Assuming that such a counter wind of, say, 26 miles per hour, is blowing during the *whole* of the crossing—which is a very unfavorable supposition to make—the hourly speed of the plane will then be less by this amount. Later on I shall demonstrate that in consideration of such possible counter winds it is desirable to choose a plane that develops a speed as high as possible. This will not only mean a shortening of the flying time, but actually also a decrease in the amount of fuel to be carried.

An airplane capable of a speed of 144 m.p.h. and heading against a wind of 26 m.p.h. will actually cover only 118 m.p.h. Taking a distance of 4100 miles and dividing it by this speed, we find the plane will have to keep in the air for 34.4 hours. In other words, the airplane has to carry sufficient fuel for a flight of this duration. In calm air this airplane would be able to cover 4950 miles with the same supply of fuel.

In consideration of these facts, I have so designed my flying boat as to enable it to make a non-stop flight of approximately 5000 miles.

Influence of Distribution on Weight of Wings

I should now like to say a few words relative to the influence of weight or load distribution on the constructional weight of wings.

Fig. 1 shows the various possibilities of distributing the weights or loads. In arrangement I the weight is distributed over 0.67 of the wing span and in arrangement II over 0.34 of the span, while in the third arrangement the total load is concentrated at a single point. It is assumed that the span and the weight in all three instances are equal.

The air forces, the sum of which of course is equal to the total weight, it is assumed, are equally distributed over the central part of the wing, while toward the wing tips it is likewise assumed that the load per unit of wing length imposed by the air forces progressively decreases in accordance with the German building regulations.

The diagram shows the curves of bending moment for the three arrangements. The curves meeting at a point represent the moment produced solely by the air forces. The same curves apply of course also to arrangement III. In a long-distance air-

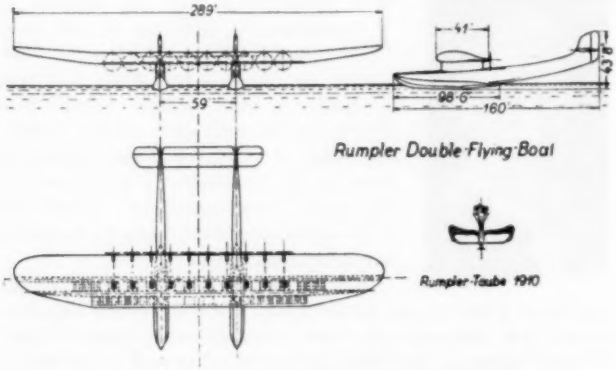

Fig. 2 Rumpler Double Transoceanic Flying Boat

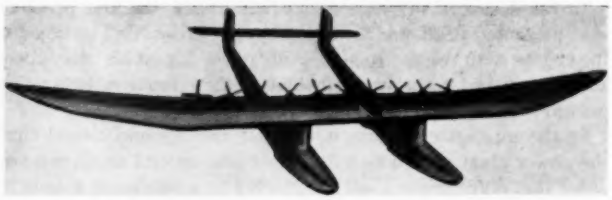

Fig. 3 Rumpler Double Transoceanic Flying Boat

plane such an arrangement will hardly be considered advisable today.

Curve I constitutes the moment of forces for arrangement I and curve II for the second arrangement, and it is seen that by just about doubling the length over which the loads are distributed an extraordinary reduction of the moments is obtained. The maximum moment for arrangement I is about four-tenths of that in arrangement II and about a quarter of that in III.

The weight of the wing, which in the first place depends on the bending forces, will in arrangement I be very noticeably smaller than in arrangement II, and much more so than in III. A rough estimate already shows that in the first plane, according to arrangement I, a saving in weight is effected of approximately 20 per cent, that is, about 11,000 lb. over that of arrangement II and of 30 per cent or 19,800 lb. over III.

This diagram conclusively demonstrates that in the case of long-distance airplanes, which are expected to carry a maximum load a maximum distance, an extensive distribution of loads similar to arrangement I should be selected as this insures the smallest constructional weight, and therefore the largest paying load.

Assuming that the other important features of my transoceanic airplane, which is shown in Figs. 2 and 3, are sufficiently well known, I shall confine myself to saying that my design with two hulls is attracting increased attention. Ten independent engines of the high-compression type, each developing normally 1000 hp., are to be employed. The most important data of the plane are given in Table 1.

TABLE 1 DATA ON RUMPLER TRANSATLANTIC SEAPLANE

Specifications

Total weight	232.000 lb.
Pay load	42.300 lb.
Fuel load	75.000 lb.
Wing area	9,850 sq. ft.
Span	289 ft.
Overall length	160 ft.
Overall height	43 ft. 3 in.
Wing chord	41 ft.
Diameter of propellers	15 ft. 9 in.
Lower edge of propellers above water	13 ft. 2 in.
Thickness of wing	8 ft. 7 in.
Inside height	7 ft. 3 in.
Ratio of chord to span	1 : 7.7
Specific fuel consumption	0.352 lb. per hp-hr.
Propeller efficiency	0.8
Flying altitude	13,100 ft.
Gliding figure	15.1
Gliding angle	3 deg. 45 min.

Constructional Figures

	Beginning of flight	End of flight
Wing load	23.6 lb. per sq. ft.	15.9 lb. per sq. ft.
Power load	23.2 lb. per hp.	15.7 lb. per hp.
Ratio of power to area	1.01 hp. per sq. ft.	1.01 hp. per sq. ft

Performances

Maximum Speed:	
Beginning of flight	183 m.p.h.
End of flight	187 m.p.h.
Average	185 m.p.h.
Average touring speed	144 m.p.h.
Radius of action	4.970 miles
Landing Speed:	
Beginning of flight	79.6 m.p.h.
End of flight	66.5 m.p.h.
Propeller speed	900 m.p.h.
Torsional vibration starts at	2160 r.p.m.
Flexional vibration starts at	290 r.p.m.

The fuel consumption I have taken at 0.352 lb. (0.16 kg.) per hp-hr. as I am hoping to be able to employ Diesel engines. Although perhaps so low a consumption has hitherto not been attained, I believe the research work carried through to develop suitable Diesel engines for aircraft will eventually lead to a complete success.

Apart from low fuel consumption, Diesel engines have the invaluable advantage over normal gasoline engines that they offer positive safety against fire and have great reliability.

The polar curve on which this calculation is based is shown in Fig. 4. It has been developed from measurements made in the research institute at Göttingen and is based on my own experience extending over many years.

Aerodynamical Researches in Model of Author's Flying Boat

Let us now turn to the aerodynamical researches which are being carried on with a model of my transoceanic plane. This investigation to find the most suitable construction for a long-distance airplane has already led to good success.

The basic requirement is to obtain as high as possible a value for

$$\left[\frac{c_a}{c_w}\,\eta\right]_{max.}$$

One of the most important auxiliary conditions is to reduce the relatively high starting and landing speed which is given by the necessarily high wing load. This is obtained by a high $c_{a\ max.}$-value. For starting, the additional requirement of a high propeller force during the starting process and especially toward its end, is to be considered.

While a large $c_{a\,max.}$-value is easily obtained by a corresponding choice of the wing section, the requirement of a maximum degree of efficiency during the start as also of a large $\left[\frac{c_a}{c_w}\,\eta\right]_{max.}$ value offers various difficulties.

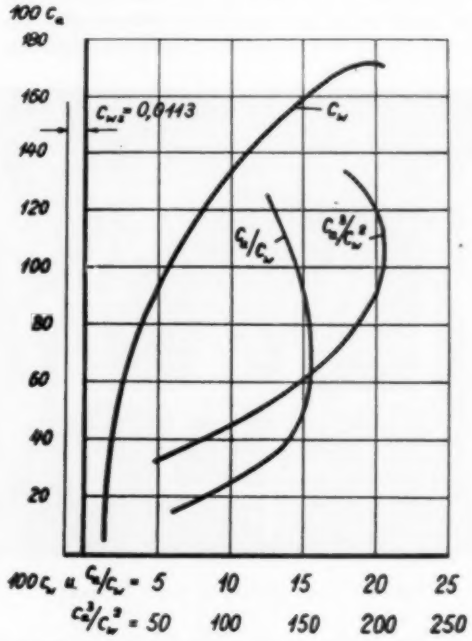

Fig. 4 Polar Curve Assumed for Performance Calculations

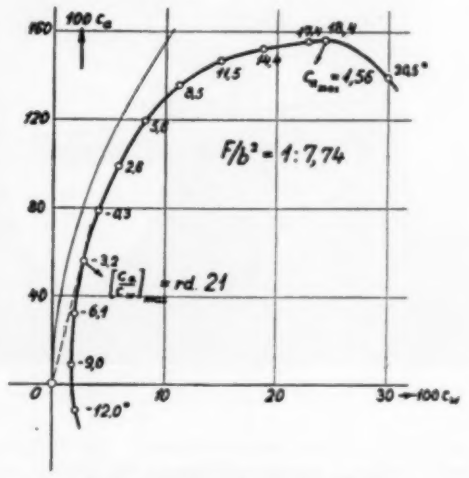

Fig. 5 Polar Curve of Wing

In order to satisfy the last requirement the body resistance and the induced and section resistances must be as small as possible, and the propeller efficiency at the economical speed as large as possible. Also the highest values of c_a/c_w and of η must be reached at the same ratio of velocity to the peripheral speed of the propeller. The requirement of large propeller push forces at starting calls for an arrangement of the propellers in which the efficiency during the low starting speeds shall be as large as pos-

sible. But, as is well known, it is very difficult to obtain an arrangement of this kind which is satisfactory at low as well as at higher speeds.

At this point I should also like to mention various matters respecting propeller efficiency. As is well known, it is not proper to state the efficiency of a propeller by itself, since when a propeller is mounted on an aircraft, each is influenced by the other. The push and torque of a propeller depend on its location on the

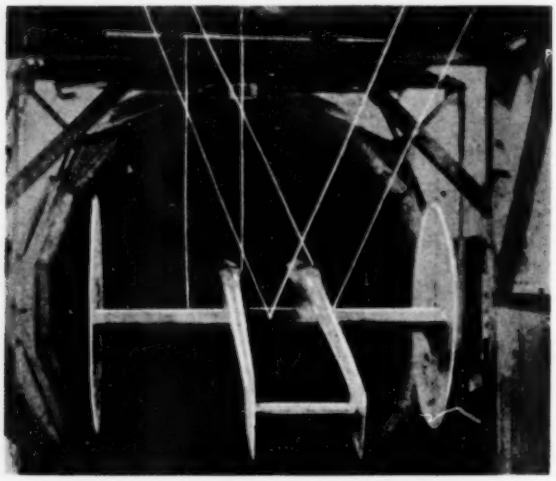

FIG. 6 PARTS MODEL IN WIND TUNNEL

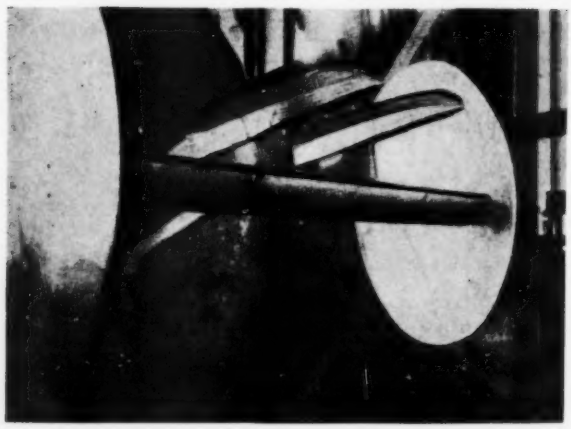

FIG. 7 PARTS MODEL IN WIND TUNNEL

aircraft, and therefore also does its efficiency. On the other hand the propeller causes a change as regards the lifting properties and resistance of a wing as compared with a wing having no propeller. By itself the degree of efficiency established from the push and torque of a propeller on an aircraft does not indicate the quality of the propeller, for the changes in respect to lifting force and resistance must also form part of the calculation. Later on I shall describe how, under the conditions obtaining in economical flight, these difficulties can be avoided. For the other matters I would refer to the interesting work of Beetz and Seiferth.

In conformance with these considerations an agreement was made with the Institute at Göttingen to carry on researches on the wing by itself, the control surfaces alone, various propellers by themselves, a part model with the propeller running, and on the complete model. As it would take too long to report on this work, which has not yet been completed, I shall limit my remarks to the results obtained with the wing and on the part model with propeller running.

Fig. 5 shows the wing polar curve, which is very satisfactory both in regard to $c_{a\ max.}$ and $[c_a/c_w]_{max.}$

Unfortunately it was not possible at Göttingen to carry through tests with a complete model wing with propellers running as the size of the wind tunnel there limits the size of the models. Even if it were possible to test a very large-scale model with propellers, the sizes of the latter and the values obtained with them would still be so small that the results could not be regarded as reliable. For this reason the tests were made with a large-scale part model and propeller. Figs. 6–8 show this model hanging in the Göttingen wind tunnel. The model consisted of the central wing section provided at each end with an elliptical disk. Inside the wing two small electric motors belonging to the Aerodynamical Research Institute of Göttingen were provided, each driving one propeller. Two hulls were fitted to the wing section. They were each provided with rudders and common stabilizer and elevator.

Fig. 9 shows polar curves of the part model which served as the basis for the propeller tests. The one indicated by open circles refers to an arrangement in which the disks sit square on the wind ends and without filleting. At $c_a = 0.8$ it begins to be irregular. The other polar, however, showing the result obtained by filleting the joints between the wing and disks is uniform in curvature, and also much more favorable in other respects. Thus clearly demonstrating the great importance of avoiding sharp corners.

In the tests with the part model about to be described the influence of alterations to the height of the propeller position, the rearward position of the propeller, the propeller inclination, and the propeller diameter is being or has been established.

Fig. 10 shows some of the results obtained in these tests on a part model built to a scale of 1:30, in which the propeller was

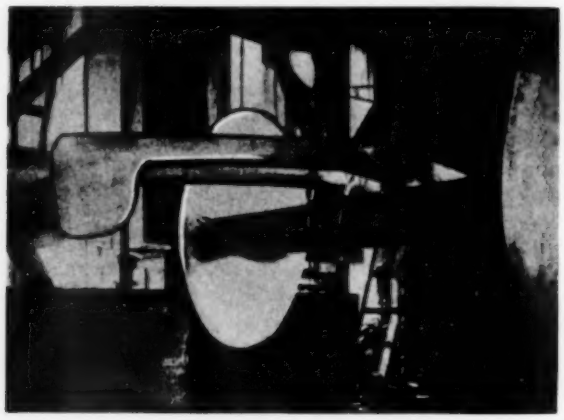

FIG. 8 PARTS MODEL IN WIND TUNNEL

located 5 mm. to the rear, the shaft was 10 mm. above rear edge of the wing, and the propeller had an angle of inclination of 1.8 deg. to the wing chord with the wing set at 8.8 deg. Similar results have been obtained with all other angles of incidence and with all other propeller sizes that were examined.

The abscissas are the ratio of forward velocity to the peripheral speed of the propeller. As ordinates are used the c_a, c_w, and c_m values of the wing area of the part model, also the k_s and k_d values in relation to the circular surface swept by the propeller, and also the η values.

The c_w values here are the resistance figures of the wing with the

propeller running, and therefore do not depict the real resistance of the part model but the reduced resistance caused by the propeller rotation. For this reason the value may be a negative one. At the intersection of the c_w curve with the axis of abscissas the resistance is equal to the propeller pull.

The polars shown in Fig. 11 cover the results of these tests with running propellers. Each polar is based on a definite progression.

By developing this further we arrive at the diagram of Fig. 12, the most important curve of which gives the $(c_a/c_w)\eta$ values for horizontal flight. The peak of this curve corresponds to the most economical flying condition with the propeller arrangement under examination and has a value of 10.2 at $\alpha = -1$ deg.

In a similar manner the values obtained with various positions of the propeller are established and in this way that position of the propeller is being determined for which the $(c_a/c_w)\eta$ curve has the greatest maximum.

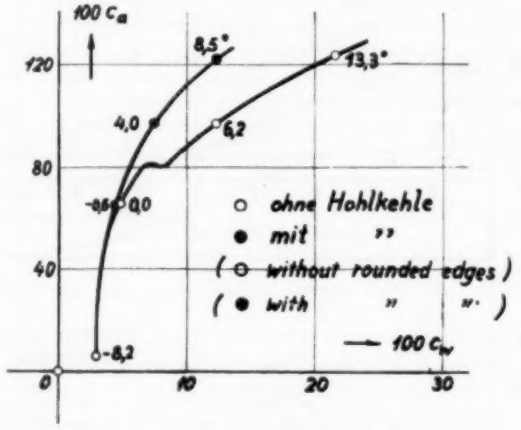

Fig. 9 Polar Curve of Parts Model

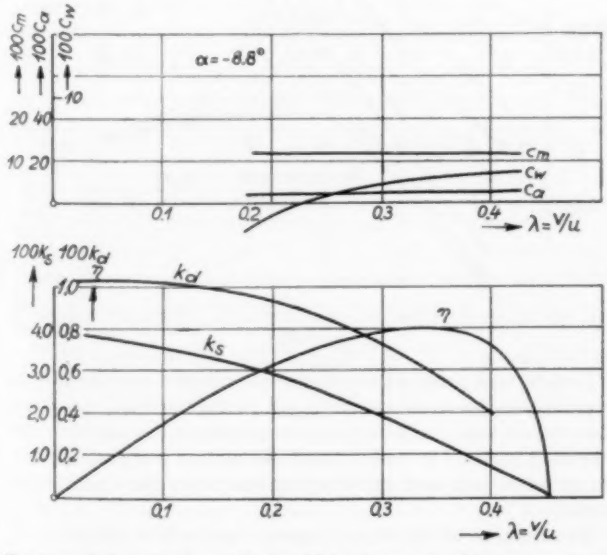

Fig. 10 Parts Model Tests With Running Propellers

These researches are not yet complete and new series of experiments employing a larger-scale model and larger propellers are in progress. The values thus obtained will be greater and the experimental results more reliable.

The results obtained thus far clearly show that it is quite possible to develop by means of systematic experiments a long-distance airplane that will fulfil the aerodynamical demands mentioned at the outset and therefore providing the best solution of the problem in hand.

Hydrodynamic Starting Tests

I shall now discuss some hydrodynamic starting tests that have been carried out by the Shipbuilding Research Institute of Hamburg on a mutually agreed schedule.

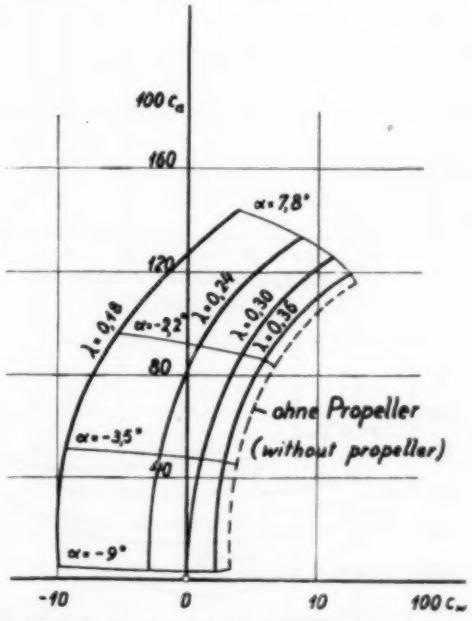

Fig. 11 Polar Curves With Running Propellers

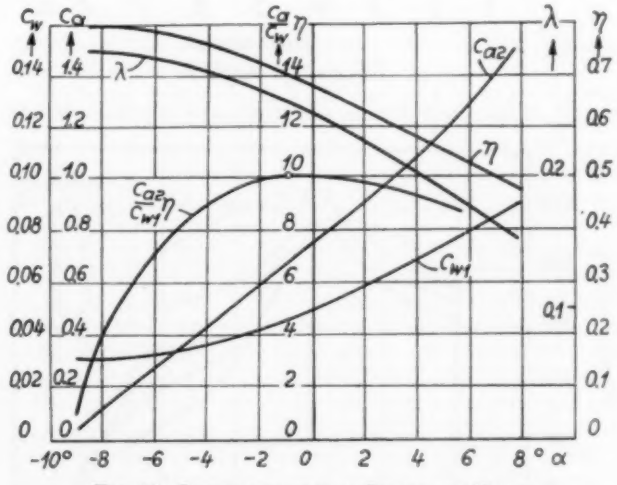

Fig. 12 Interpretation of Propeller Tests

In these tests it was assumed that the load on the boat decreases directly as the square of the speed from the moment of starting to that at which the plane lifts out of the water (Fig. 13).

It is possible to calculate the take-off speed on the basis of the aerodynamical tests, and in the present case it amounted to 130 kilometers or 81 miles per hour. It was therefore assumed that at this speed the wing carried the total weight and that the load on the hull would be zero. The load for the speeds between zero and 130 km. per hr. may then be ascertained by a parabola, the ordinate of which at 130 km. per hr. or 36.1 m. per sec. will be equal to the total load.

On recommendation of the Hamburg Institute a model scale of 1 to 25 was adopted. According to Froude's model law the loads had to be reduced in the ratio $1:25^3$ and the speeds in the ratio $1:\sqrt{25}$ or 1:5. In the present instance the model load therefore works out at $105{,}000/(2 \times 25^3) = 3.68$ kg. and the take-off speed at $36.1/5 = 7.225$ meters per second. These figures are entered on the diagram and the parabola is based on them.

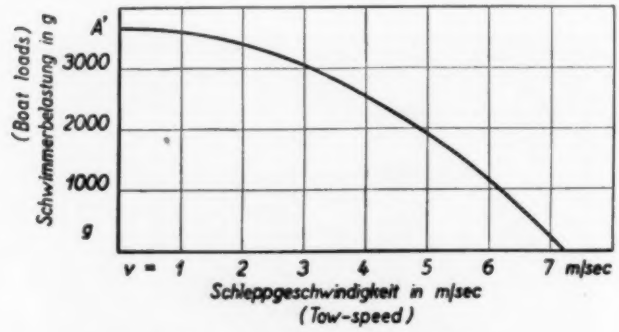

FIG. 13 LOAD CURVE OF BOATS MODEL

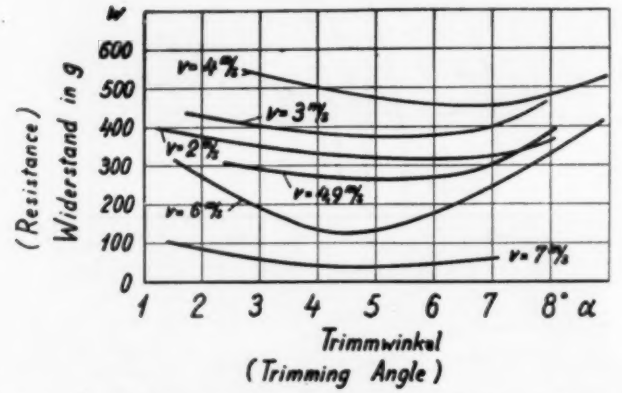

FIG. 14 RESISTANCE CURVES FOR DIFFERENT CONSTANT SPEEDS

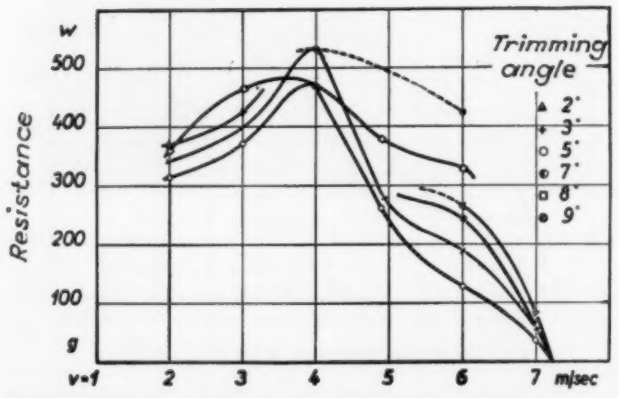

FIG. 15 RESISTANCE CURVES FOR DIFFERENT CONSTANT TRIMMING ANGLES

The experiments were carried through with the boat under a definite load and at a speed for this load corresponding to the decrease of load in the square proportion referred to and at various trimming angles.

In the tests the resistance at every speed and the various trimming angles was measured and plotted in Fig. 14. From the resulting curves the resistances belonging to the same trimming angle were then deduced. These values then were combined to form the resistance curves shown in Fig. 15, which are plotted against the speed. Each curve corresponds to a different trimming angle.

I have purposely left out of the diagram the curves for 4 and 6 deg. as otherwise the graph would not have been so clear. In this model, as can be seen from the views, it is advisable to keep the trimming angle below 8 deg. The most favorable angles are 4 and 5 deg. during the whole starting procedure. Up to $v = 5$ m. per sec., angles of 4 to 7 deg. are practically of equal value. At higher speeds 4 to 6 deg. should be maintained. In this case the second resistance rise in the Ru 93 hull graph would be avoided. The ratio of maximum resistance to flying weight only amounts to 12.5 to 13 per cent for the trimming angles $\tau = 5$ to 8 deg., which alone are practical.

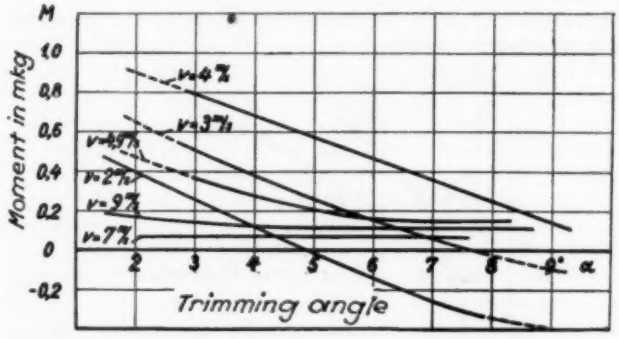

FIG. 16 MOMENT CURVES FOR DIFFERENT CONSTANT SPEEDS

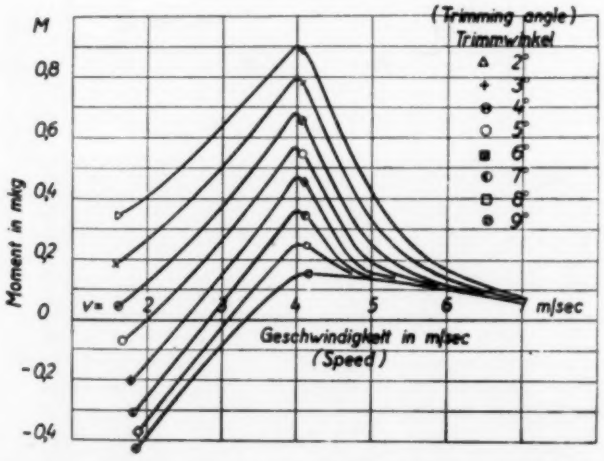

FIG. 17 MOMENT CURVES FOR DIFFERENT CONSTANT TRIMMING ANGLES

In these tank tests the moment at every speed and the various trimming angles were measured and plotted in Fig. 16. From these curves those moment values belonging to one and the same trimming angle were then deduced and plotted in Fig. 17 against the speed, so that each curve corresponds to a different trimming angle.

The moment of the water force is brought into relation with the line perpendicular to the central plane of the hull that joins the two lateral corner points of the step. Positive moment means that the machine must be pressed down so as to obtain the running angle.

As is evident from Fig. 17, the position of the hull may easily be influenced with increasing speed. The moment differences which cause the change over from 4 to 9 deg. at a speed of 6 meters per second are already so low that the accuracy of the

measuring devices employed no longer suffices to record them. From this it is manifest that the hull, after passing the critical speed, can be made to adopt every desired position by operating the elevator correspondingly. It will therefore be very easy to force the plane into a position at which the sum of the water and air resistances is at a minimum.

With the aid of these results it is now possible to formulate the actual starting process; at any instant at the start the sum of all moments must be equal to zero. The moment of the water forces is known for every trimming angle from Fig. 17. We also know the angle of pitch between wing and hull, and it is therefore possible to determine for each trimming angle the angle of incidence of the wing corresponding thereto. It is then possible to calculate the value of the air-force moments from the results of aerodynamical tests at the angle of incidence thus found and at the assumed speed. Based on the particulars given regarding the propeller, it is easy to determine the propulsive force at the speed under consideration. In this we are assuming that each motor will develop 1400 hp. during the start. As the position of the propeller is also known, it is possible to determine the moment caused by the propulsive force. Assuming that the point of application of these forces coincides with the center of gravity of the airplane, then only these three moments will arise. If it does not, however, we have to take into account the further moments arising from the weight and of the masses.

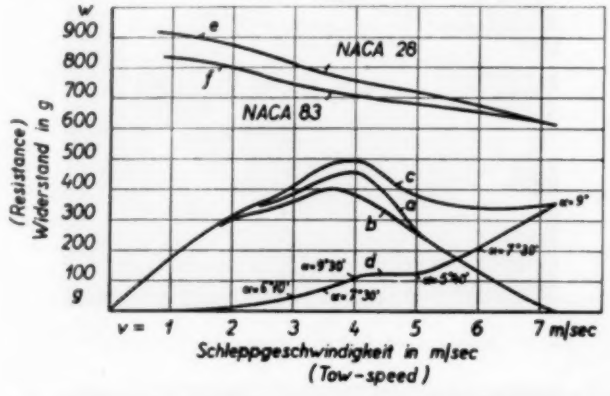

FIG. 18 BALANCE BETWEEN PROPULSIVE FORCE OF PROPELLERS AND RESISTANCE

The trimming angle of the airplane at which the sum of all these moments is zero is established experimentally. At the instant at which the airplane glides at the given speed it will automatically assume the trimming angle thus ascertained. Fig. 15 will then indicate the water resistance corresponding to this trimming angle.

If we carry through this calculation we arrive at the diagram in Fig. 18, in which curve *a* represents the water resistances. In this we are assuming that the airplane trims automatically only up to a speed of 5 meters per second. At greater speeds than this, this model would assume a very small trimming angle (slightly more than 0 deg.) if left to itself. But, as we have seen from the diagram of resistances at various trimming angles previously shown, the resistance increases very considerably with the speed and with a decrease in the trimming angle. In order to avoid an increase in the resistance it will be advisable to force the airplane into a greater trimming angle by operating correspondingly the elevator as soon as a speed beyond 5 meters per second is attained. The influence of this has been considered in constructing curve *a*.

In some airplanes in which the elevator is not effective at this speed, it may be desirable to provide a vertically operating water rudder in order to insure that the proper trimming angle is maintained. This is especially to be recommended for craft in which the control surfaces are located as high up as possible in order to prevent water and spray from touching them. In such places the stabilizer and elevator are sometimes located above the propeller airstream, so that it requires a relatively high speed for them to become effective.

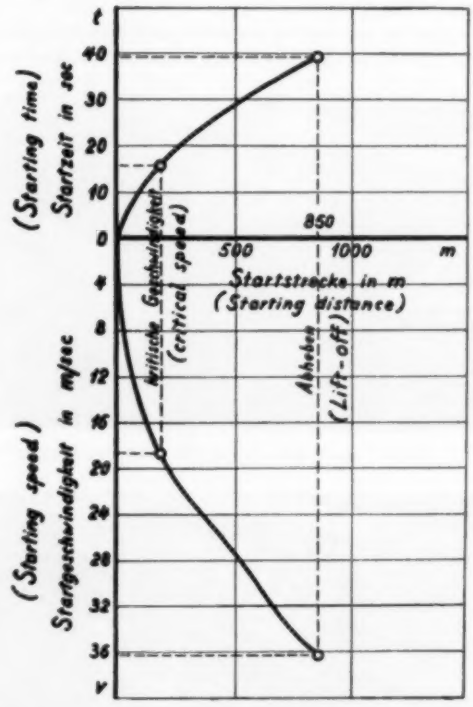

FIG. 19 STARTING DISTANCE, STARTING TIME, AND STARTING SPEED

The water rudder should be located at a point on the float where it will be submerged constantly. Also it must be arranged as far away from the step as possible so as to exert the highest possible moment with the smallest possible surface and application of power. The best position would probably be at the rear step or in front of the forward step.

The use of a water rudder, then, is of course only justified when it is possible to obtain with it a trimming angle at which the saving in air and water resistance is greater, as compared with the arrangement employing no water rudder, than the resistance of the water rudder. The latter should also be retractable into the float in flight so that it causes no additional air resistance.

The application of the values thus obtained to full-scale construction is attended with difficulties, since as yet there is no generally recognized law for such calculations that meets all requirements. However, English researches, as well the experience of the German research institutes, show that the actual maximum water resistance is considerably lower than the value obtained by converting model results in accordance with Froude's law; furthermore, compared with the model results it tends in the direction of smaller speeds.

On the basis of the experiences of the Hamburg Shipbuilding Research Institute I have arrived at a resistance curve *b* (Fig. 18) which will apply to full-scale operation, and which I call the corrected water-resistance curve.

From the trimming angles that result in a self-trimming aircraft, the angle of incidence is obtained by adding the angle of pitch to the trimming angles.

It is now possible to determine from the aerodynamical tests the resistance corresponding to the angle of incidence. This resistance is shown in curve *d*. The sum of these two resistances constitutes the total resistance during the starting period at any given moment. These total resistances are plotted against the speed and are represented by curve *c*.

The propelling force of an airscrew is a function of the speed. In the curves *e* and *f* the propelling forces of two American propellers (N.A.C.A. 28 and 83) are converted to correspond to the scale of the model and for five propellers. The former propeller has better qualities as regards starting; the latter, for economical flight.

It is quite generally acknowledged that the difference between the propelling force of the airscrews and the total resistance constitutes the power available for accelerating the airplane. This of course must at all times be positive, as otherwise the starting would be retarded. The power must also be as great as possible in order to shorten the time and the starting distance. It will be seen in Fig. 18 that the difference between the propelling force and the total resistance is quite large, and the airplane will therefore have a good acceleration when starting.

Referring to Fig. 18, I should like to point out that the angle of incidence α is indicated at various points on the air-resistance curve. It is arrived at, as already mentioned, by adding to the trimming angle the angle of pitch between the hulls and wing, which in the present instance is 2.5 deg. It will be seen that the angle of incidence constantly increases up to a certain speed and then decreases. From this it is evident that the decrease of the load on the float is directly in the square proportion of the speed, which we assumed at the outset does not hold true in the actual starting process. If the reduction of the load on the hull did proceed thus, it would mean that the airplane would

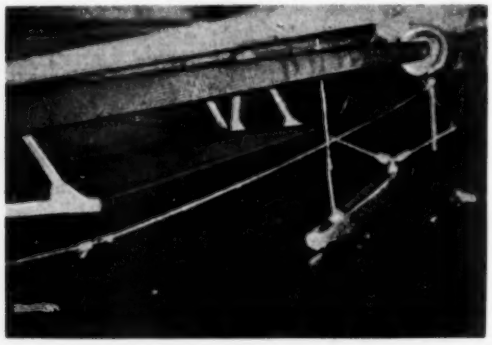

Fig. 20 Towing speed, 3.04 m. per sec.; trimming angle, 3° 12′

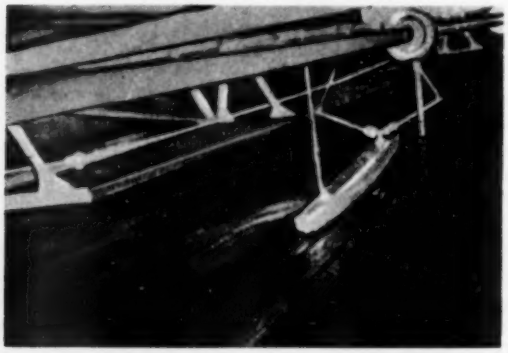

Fig. 25 Towing speed, 6.00 m. per sec ; trimming angle 6° 12′

FIGS. 20–25 TANK TESTS WITH MODEL HULL

have a constant angle of incidence from the moment of starting to the moment that the craft rises out of the water.

In the further tests which are being carried on with the object of ascertaining the counter influences set up between two hulls (when such are employed), this circumstance will be considered and the load carried will be progressively decreased to correspond with the actual aerodynamical conditions.

From Fig. 18 we find that the power available for the acceleration of the airplane is equal to the difference between the propulsive force and the total resistance, depending on the speed. Designating this force by P,

$$dt = \frac{G}{g} \times \frac{dv}{P}$$

in which G/g is the mass of the airplane, t the time, and v the velocity. From this we derive

$$t = \frac{G}{g} \int \frac{dv}{P}$$

and obtain the starting time as a function of the velocity.

If we know the speed as a function of the starting time we can determine the starting distance from

$$s = \int v dt$$

Knowing now the starting time and also the starting distance as a function of the velocity, it is possible to derive also the starting time as a function of the starting distance.

In Fig. 19 the velocity and time are plotted against the starting distance. In this case the propulsive force of the propeller N.A.C.A. 83 has been taken; this propeller is less suitable for starting than the N.A.C.A. 28, but it is given the preference since it is more efficient in flight.

It will be seen from this graph that the critical speed, that is, the speed at which the water resistance reaches its highest value, is attained after but a very small percentage of the starting distance has been traversed. The lift-off is effected after a distance of 850 meters has been covered or respectively after 38 seconds has elapsed, which are results that must be regarded as exceedingly satisfactory.

Tank Tests With Hull Ru 98

Figs. 20–25 show views of a number of tank tests carried out with the hull Ru 98. In Fig. 20 the speed is 3.04 meters (9.97 ft.) per second, which is less than the critical speed. In Fig. 21 the speed is 4.02 meters (13.18 ft.) per second. The hull already glides on the step. In Fig. 22 the hull is moving at the same speed as in Fig. 21, but at a greatly increased angle. In Fig. 23 the speed is 5 meters per second. In all these views it will be seen that the lateral wave caused by the step is very low and that the spray hardly reaches half the height of the hull. Therefore, there is no danger that the propellers, which are situated a considerable distance above the upper edge of the hulls, will be moistened by spray. This favorable condition is to be ascribed to the form of the gliding bottom at the step. The surface of the water at the rear of the hull shows a depression so that there is also no danger that the tail of the hull, which is drawn high up out of the water, will be moistened either.

Fig. 24 was taken with the hull moving at a speed of 6 meters per second and just about to take off. It is seen gliding on a very narrow strip of the front step. In Fig. 25 the speed is the same, but the trimming angle is larger.

Summarizing, I should like to say that it is quite possible, by dint of systematic research work, to determine a form of the hull or float which will insure a short start even in the case of airplanes with a high wing load. This is exceedingly important, as in this way the unknown problems necessarily arising in the design of a new plane type are considerably reduced and the prospects of success greatly enhanced.

Turning now to certain questions of general importance, neither small nor great risks may be run in the construction of a long-distance airplane. Almost all mistakes made have aggravated adverse effects. The worst faults are those having a cumulative effect which must be integrated in order to determine the total of adverse influences at work. A long-distance airplane must be a high-efficiency craft but not necessarily a high-powered craft, for there is a difference between the two. Naturally the high efficiency must be coupled with absolute safety in service.

Influence of Various Factors on Size of Pay Load

In what follows I shall discuss the influence of various factors as they affect the size of the pay load.

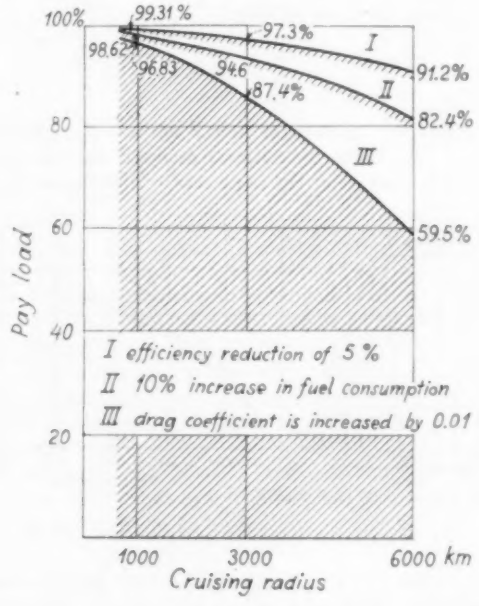

Fig. 26 Influence of Faults With Respect to the Pay Load at Various Cruising Radii

Let us compare three airplanes for flying distances of 1000, 3000, and 6000 kilometers, respectively. These distances are considered as being covered at normal touring speed, that is, in flight with the approximately most favorable gliding figure. All planes, in order to have a simple comparable basis, shall have the same paying load as the first or basic plane. Also we shall assume that the wing load, the starting speed, and also the ratio between load and starting weight in the three cases are identical, and that all three planes have the same aerodynamical qualities and the same fuel consumption per horsepower-hour.

First, let us assume that for some reason or other the propeller efficiency is reduced by 5 per cent, which will correspond to an increase of the average power output by the same percentage. This increase of power output will increase the fuel consumption and require that approximately slightly more than 5 per cent of extra fuel be carried, the weight of which has to be deducted from the paying load. The latter will, therefore be reduced in the various airplanes by

1700, 530, and 133 kg., respectively, corresponding to
8.8, 2.7, and 0.69 per cent of the pay load.

Second, let us assume that the fuel consumption will be 10 per cent greater than foreseen. In this case the 6000-, 3000-, and

1000-km. planes will respectively have to carry the following additional amounts of fuel:

3400, 1060, and 266 kg.

The pay load of 19,300 kg. (42,460 lb.) will be reduced by these weights or by

17.6, 5.4, and 1.38 per cent.

Third, unsuitable location of the engines, radiators, etc. may create an undesirable increase in the resistance. We shall assume that owing to this the coefficient of parasite resistance is increased by 0.01. We have assumed a gliding factor of 14 and a lift coefficient of $c_a = 0.6$ so that the coefficient of the total resistance has the value

$$c_w = \frac{0.6}{14} = 0.043$$

If now this value be increased to 0.053, we find that the airplane will have a gliding factor of only

$$\frac{c_a}{c_w} = 11.4$$

This requires an increase in power output of approximately 14/11.4 = 1.23 times the original amount, and the fuel consumption will increase at the same rate. This means the 6000-,

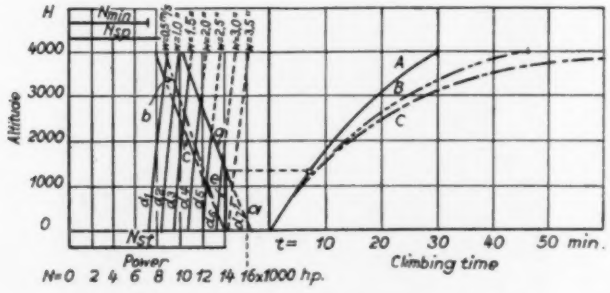

FIG. 27 POWER BALANCE AND CLIMBING TIMES

3000-, and 1000-km. planes will respectively have to carry the following additional weights of fuel:

7800, 2440, and 610 kg.

so that the pay load will be reduced by

40.5, 12.6, and 3.17 per cent, respectively.

These calculations are represented graphically in Fig. 26. The reduced values of the pay load as a consequence of various faults are plotted against the flight distances of the various airplanes.

Curve I shows the values for a reduction of the propeller efficiency of 5 per cent, curve II shows the conditions obtaining when the fuel consumption is increased by 10 per cent, and curve III those when the coefficient of parasite resistance is increased by 0.01.

These curves distinctly show that the pay load decreases when these three faults appear and also the law of this reduction. In other words, the remaining pay load will, in the event of mistakes of whatever nature, sink absolutely and relatively much quicker in the case of long-distance airplanes than in that of planes with a normal radius of action.

MAXIMUM POWER OUTPUTS FROM OVERSIZE ENGINES AT VARIOUS ALTITUDES

Fig. 27 presents a comparison of the maximum power outputs available from oversize engines at different altitudes with the power requirements of the airplanes they belong to when starting, when climbing to height of 4000 meters (13,000 ft.) at various speeds, and when flying horizontally.

These calculations are based on a long-distance airplane equipped with ten engines each developing nominally 1000 hp.

In the left-hand portion of the diagram the output of the engine is plotted against the altitude. The maximum output of the engine at an altitude of 4000 meters or 13,000 ft. is 10,000 hp., and increases at lower altitudes until it reaches 16,300 hp. at sea level. Curve *a* depicts this more distinctly.

Curve *b* shows the power output at various altitudes when a constant power reserve of (16,300 — 14,000)/16,300 = 14.1 per cent is assumed.

Curve *c* shows the power output at various altitudes when a constant and absolute power reserve of (16,300 — 14,000) = 2300 hp. is assumed.

Let us now discuss the power output of 14,000 hp. assumed for the start, which includes a considerable surplus of power.

The power requirements of the airplane for various climbing speeds ranging from 0.5 to 3.5 meters per second are shown by the curves d_1 to d_7 for varying altitudes. These curves are based on the assumption that the airplane always flies with the value of (c_a^3/c_w^2) a maximum.

Horizontal flight at an altitude of 4000 meters is demonstrated by two examples. For flight with a minimum of power this has been calculated at 7100 hp., and for economical flight the power requirement has been calculated at 8000 hp., both of which values have been entered in the diagram.

Having now established the motor power on the one hand and the power requirements on the other it is easy to compare the surplus power under various flying conditions.

When starting we have a power output of 16,300 hp. as against 14,000 hp., in which latter case, however, it will be remembered there is already included an abundant reserve of power. This is highly desirable as it will enable a quick start to be made, even in a high sea. The fact that the high power surplus is not actually required when starting or flying low is very important, as it means that the engine and gears will not be strained, and thus tends to insure great security.

The large surplus of power in reserve when starting will therefore only be required in rare instances as when the sea is running very high.

In order to determine the surplus of power available at any altitude, say, 2000 meters, with the airplane climbing, it is only necessary to compare the abscissa of curve *a*, Fig. 27, for the given altitude with the abscissa of the one of the curves d_1 to d_7 for the same altitude. We see that this difference is a positive one in the case of d_1 to d_5, and negative in the case of d_6 and d_7. This means that it is possible to climb at a speed of about 2.5 meters per second but not, however at a higher rate.

Correspondingly the same reasoning applies to curve *c*.

In order to determine the surplus of power in horizontal flight at an altitude of 4000 meters or 13,000 ft. it is only necessary to find the difference between the abscissa of the curve *a* at 4000 meters, that is, 10,000 hp., and the power requirements of the airplane in economical flight and in flight with minimum power. As shown by the diagram, 2000 hp. are available in the first case and 3000 hp. in the second, or 30 per cent.

I should like to remark here that this figure applies to the beginning of the flight. It increases very considerably in the course of the flight and reaches approximately 60 per cent toward the end.

Summarizing, I should like to point out that the surplus power shown on this diagram by the difference between the power output and the power demand of the airplane constitutes virtually a balance sheet of work. The decrease in this surplus shows that the power reserve required for horizontal flight at high altitudes differs in no great measure from that needed when climbing and starting. The assumption that a very great surplus of power

is required when starting, making for a small actual reserve of power, does not therefore hold true in airplanes that for reasons of safety are also provided with a considerable surplus of power for horizontal flight at high altitudes.

For this reason it appears to me that the auxiliary devices to aid starting, such as towing by another airplane, catapulting, starting rockets, etc., recently so much discussed would perhaps constitute a complication for airplanes of the type described having an oversize power plant. On the other hand, it is quite possible that such starting aids will be very useful for airplanes constructed from other points of view than that of long-distance flying. Everything depends on whether or not normal horizontal flight is to be performed at great altitudes with a large power reserve. If such reserves are required, as is certainly the case for a long-distance airplane, then, as shown by the diagram, it will only be necessary to draw on these reserves for a few minutes during the start and the climb.

The Problem of Speed

Before concluding I shall refer briefly to the speed problem. What I have to say in this respect will not be new to experts, but it may possibly interest the general public and aid in spreading a better understanding of the problem involved.

The distances to be traversed as well as contrary winds are entirely beyond our influence. They are given facts in the problem, and the latter ever so powerful, they must not constitute an impediment to the start and flight of a long-distance airplane.

Only the speed of the airplane is under our control, and this must be as high as possible in order to counteract effectually the influence of the opposing winds. How essential this is will be readily seen from the diagrams of Fig. 28.

The upper one of these diagrams shows the actual traveling speed in kilometers per hour of three airplanes capable respectively of speeds of 100, 200, and 300 kilometers per hour plotted against the speed of the counter wind in meters per second. As is self-evident the absolute deductions from the traveling speeds for the various forces of counter winds are the same for all three airplanes. With a counter wind of 25 meters per second blowing, 90 kilometers have to be deducted from the speed of each of the three airplanes. The 300-km. plane therefore advances at the speed of 210 km. per hour, the 200-km. plane at 110 km. per hr., and the 100-km. plane at 10 km. per hour. This is shown on a percentage basis in the middle diagram. While the 300-km. plane loses 45 per cent of its speed, the 100-km. plane loses 90 per cent.

The adverse influence of contrary winds, however, becomes more manifest still if we consider how it increases the time required to execute a flight of definite length. This is shown graphically in the lower diagram, in which the distance to be covered is taken as 6000 kilometers or 3730 miles. This is the distance, it will be remembered, which was assumed in constructing the basic plane. In the case of the 300-km. plane the traveling time increases from 20 to 28.6 hours; in that of the 200-km. plane, from 30 to 54.5 hours; and in that of the 100-km. plane, from 60 to 600 hours. The increase in time with a counter wind of 25 meters per second in the fastest airplane amounts to 8.6 hours, in the second to 24.5 hours and in the third to 540 hours. It is possible also to read from the diagram the increased flying time required for counter winds of lesser velocity.

Comparing the three diagrams we distinctly see the prolongation of the flight in the case of fast aircraft is small, whereas with slow machines of the fine-weather type it increases with extraordinary rapidity.

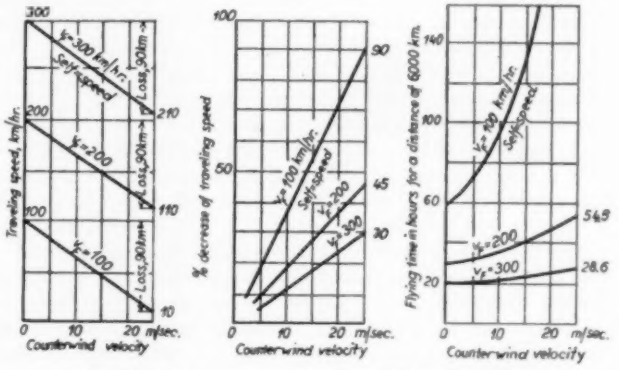

Fig. 28 Influence of Counter-Wind Velocity

Mention might also be made of the fact that airplanes with a high range of speed and good climbing qualities make it possible for their pilots easily to climb to altitudes in which the counter winds have a minimum velocity or in which they reverse their direction. That such searching for more suitable altitudes must not be left to chance but be aided by instruments goes without saying.

From this we see that the speeds of modern aircraft must still be increased very considerably, and I go so far as to assert that in case this is found not to be possible or only partially so, the future of long-distance air traffic will not be very promising.

Four years ago when I stood before the assembly of the German Scientific Aeronautical Society and delivered a lecture on transoceanic flying boats, these aircrafts were not objects of general interest. Today, however, it is quite different.

Today no one asks whether such a long-distance airplane is worth building, but how it is to be built. Its construction or development at the moment interests engineers all over the world to a very great degree. Further, the daily press in educating the general public to understand the developments taking place, and is creating for us engineers the basis on which future successes will be built.

The great problem has been recognized; it is being attacked and its solution is assured.

AER-53-17

Some Aspects of the Seaplane

With Special Respect to Its Development in Germany

By FREDERICK P. SCHUETTEL,[1] NEW YORK, N. Y.

After a brief historical résumé, the author deals, respectively, with the efficiency of the seaplane, constructional features, design of floats and boats, engine arrangement, beam load, seaworthiness, service questions, official requirements to be met, etc. Many tables, charts, and illustrations are included.

ONE of the world's greatest aircraft designers said once in a discussion in Berlin, in the fall of 1929: "Why do we talk so much about seaplanes if we are able to build multi-engined landplanes that can fly with one engine out of commission and that can thus cross the oceans with reasonable safety?" And, indeed, he had such valuable justification of his words as that given by the flights of Byrd, Kingsford-Smith, and of the Dutch India mail fliers. But his optimism went too far. In giving due credit to the pioneering spirit of the crews who succeeded in landplanes, we should not forget all those who perished in the attempt, mostly because of the insufficient floatability of their planes. We cannot use landplanes for transoceanic commercial flying, as they absolutely depend on the reliability of their engines and are merely flying fuel tanks when traveling directly from one continent to another. And as far as multi-engined landplanes are concerned, it is still a question whether they can really reach land with their speed considerably reduced by the failure of one of the engines.

We must continue along the way indicated by the American NC-boats in 1919, by Franco (Wal) in 1926, by de Pinedo (Savoia) and Beires (Wal) in 1927, and by Mermoz (Latecoere) and von Gronau (Wal) in 1930. Admittedly the range of the seaplane is not yet sufficient; but we know how the Atlantic can be subdivided, and by beginning on smaller routes we must prepare for the service, which will be a fact as soon as, for instance, the Diesel engine has been further developed. Our aim must be to produce seaplanes which will be able to compete with steamships, because they have here the best opportunity to show their superiority in speed. This competition would by no means affect the steamship companies—consider only the number of passengers aboard a *Leviathan* or *Bremen*. And developments show that it is just these companies that do take an active interest in airplane service: the ship-to-shore services of the North German Lloyd and of the French Line are well known, and some weeks ago the Lloyd Sabaudo began to connect its steamers with an express flying-boat service at Gibraltar. The fact that the commander of the DoX, Captain Christiansen, was previously master of a passenger steamer in the Hamburg-Mexico service, is also significant.

One pronounced advantage of the seaplane is the very low cost for the acquisition and maintenance of its "landing fields." So we often find seaplane services running along mountainous coasts where landplane fields are scarce, e.g., in Italy. And flights over unexplored countries have been very successfully made with seaplanes (Mittelholzer, Cobham over Africa, Pinedo over Brazil), relying on rivers and lakes as landing grounds. The natural landing areas offered by the water are normally level and large; it is not by pure chance that the heaviest airplane in the world, the DoX, is a flying boat. Besides, water areas are mostly nearer to the big cities in the world than are landing fields: e.g., New York, London, Chicago, Buenos Aires, Rio de Janeiro, Sidney; in Berlin, however, the existing "Flughafen" has the best possible location.

Political reasons are of course very important; so we have seen during the last years how Great Britain has been anxious to develop efficient seaplanes for improving the connections within the Empire. Similar reasons of a more commercial character have led to the establishment of the wide network of the Pan-American Airways.

Historical

As a part of what follows deals with German seaplanes, a few historical notes are appropriate at this point. German seaplane development was negligible before 1911. The first seaplane competition was held on Lake Constance with a representative of the single-float type. But this was abandoned in favor of the twin-float seaplane, which was the standard type during the World War, equipped with 160- to 220-hp. engines. There were flying boats used in the Mediterranean, but the German Naval Air Forces preferred the twin-float seaplane, which showed a reasonable amount of seaworthiness for that time. Incidentally, it may be stated that Dornier began his work in 1914 with the design and construction of flying boats of 142.5 ft. span and about 20,000 lb. weight. The first one made was a failure, but the second flew well, and the third passed the severe seaworthiness test of the German Navy with success.

Later came the termination of activities which was forced upon the German aircraft industry by the Treaty of Versailles, and it was not until the end of 1925 that the aircraft limitations of that pact were interpreted as applying only to military aircraft. In the meantime German designers had been compelled to sell their abilities in foreign countries to keep alive, so a certain experience and tradition was available when the time for planning efficient commercial airplanes came. During recent years there have been four establishments in Germany which have more or less specialized in seaplanes: namely, the Dornier, Rohrbach, Heinkel, and Junkers.

Efficiency of the Seaplane

As far as aerodynamic efficiency is concerned, in the smaller sizes, the seaplane is inferior to the landplane of equal weight because of the drag of its floats and bracing. The limit depends on the type of construction of course. For example, the Dornier Works succeeded in developing a two-float seaplane giving the same performance as an equivalent landplane (Figs. 1 and 2). This was done by carefully fairing the float bracing by means of "pants."

Special attention must now be given to the question of over-

[1] Aeronautical Engineer. Mr. Schuettel was born in Berlin, Germany, and was graduated from the Technische Hochschule of that city. He was formerly research engineer of the Dornier Metallbauten G.m.b.H., of Friedrichshafen.

Presented at a meeting of the Metropolitan Section of The American Society of Mechanical Engineers, New York, N. Y., Nov. 18, 1930.

loading. A seaplane cannot be overloaded to the same extent as a landplane, but this is obviously no fault from the standpoint of safety, as excessive stresses are thus avoided. All long-distance flights with landplanes have been made possible by overloading, and the machines would never have passed any official approval tests because of reduced load factors as well as because of lack of sufficient take-off and climb performance.

Table 1 gives data on maximum take-off performances as

FIG. 1 DORNIER TWO-FLOAT SEAPLANE

exact as the author could get them. The figure of merit is the familiar

$$f = \frac{W}{cP} \times \sqrt{\frac{W}{S}}$$

only with a coefficient c in order to take into consideration variations of the propeller efficiency. This coefficient was assumed to decrease from 1.0 for 1000 r.p.m. linearly to 0.93 for 2000 r.p.m. It was not necessary to introduce different factors for wooden propellers as only geared engines were equipped with them, so that the difference in efficiency was negligible. The hp. values given are maximum hp. only for this comparison, the actual power at take-off being considerably smaller.

From this table it is seen that the figure of merit for the maximum possible take-off is about 110 for normal landplanes as against 75 for normal boats and 65 for normal 2-float seaplanes without wind or special starting devices. The author has prepared from tests and reports a set of coordinated curves for normal airplane (Figs. 3 and 4). There is of course no fineness considered, no aspect ratio, no tandem efficiency, and no abnormal decrease of power with altitude due to altitude control or blower systems. Looking at these diagrams with the above figures in mind, we find the limiting performances for the different types to be as follows:

	Power reserve, per cent	Initial climb, ft. per min.	Ceiling, ft.
Landplane	7	40	1300
Flying boat	24	280	6000
Two-float plane	32	410	8500

Remember now the approval requirements for landplanes, made for the sake of safety: "Take-off within 1000 ft., initial climb 400 ft. per min. (Department of Commerce), or altitude 66 ft. within 2130 ft. from beginning of take-off, rate of climb 157.5 ft. per min. in air of specific weight 0.0686 lb. per cu. ft. (D.V.L.)." Fig. 5, derived from these data, shows clearly that American and German climb requirements are substantially the same for machines with normal engines. It is thus seen that for reasons of safety landplanes are not permitted to be as overloaded as the technical possibilities admit, and that for commercial purposes the landplane does not possess the superiority which it might be assumed to have from its distance records. The take-off requirements are even more rigid: both are roughly equivalent and correspond to a time of, say, 18 sec. (this depends largely on the wing loading). A further diagram (Fig. 6) connecting take-off time and the figure of merit shows that even the

Earhart (Fokker)	11,000	675	730	15.1	16.3	67.0	.....

[a] Special slope.

400-ft. per min. limit is not often reached. The comparative take-off times taken from the preceding curves and plotted together are rather interesting (Fig. 7). The curves show the amount of take-off time for the seaplane is longer than for an equivalent landplane.

A certain handicap to the seaplane's efficiency lies in the additional weight necessary to make boats or floats watertight and fit to withstand the stresses encountered in a seaway. Here the weight empty is about 10 to 20 per cent greater, depending of course on the type and purpose—high-sea or river service. But this handicap is counterbalanced in the case of commercial seaplanes by the larger normal gross weight they may have, and

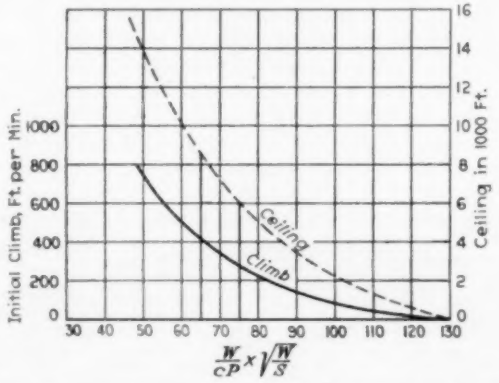

FIG. 3 CEILING AND CLIMB VERSUS FIGURE OF MERIT

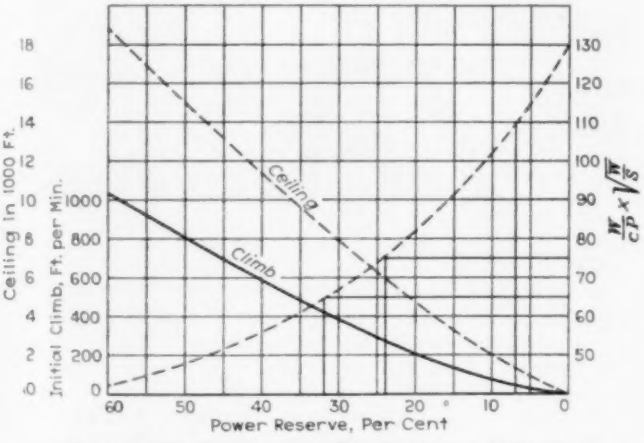

FIG. 4 CEILING AND CLIMB VERSUS POWER RESERVE

which is made possible by ample water areas with no smokestacks in the take-off direction requiring the limitation of take-off performance.

Both the natural take-off limit resulting from water resistance and friction and the increased weight of course govern the maximum ranges of seaplanes, which are of the order of 2000 to 2500 miles as compared to 5000 to 6000 miles for landplanes. But, as already said before, both types are practically equivalent for commercial service by reason of limitations which are necessary from considerations of safety.

CONSTRUCTIONAL FEATURES

Types. The different types are well known; we distinguish between seaplanes with positive and with negative stability. Twin floats, twin boats, sponson boats, and boats with low side floats (called triple floats by Richardson) belong to the group having positive stability, while single-float types and boats with wing-tip floats belong mostly to the group with negative water stability. The influence of stability on the seaworthiness will be discussed later. From the standpoint of weight the boat will in most cases be more efficient than the equivalent float plane, as the weight of the boat with stability devices and engine nacelle

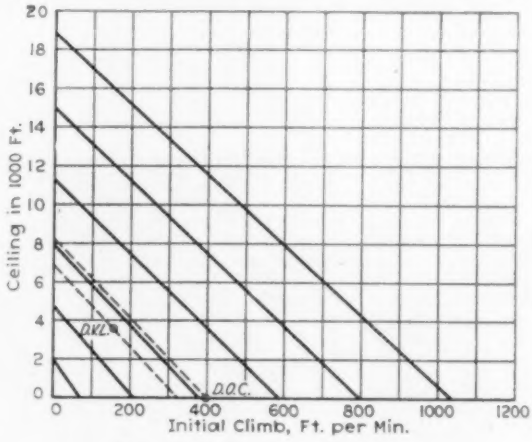

FIG. 5 RATE-OF-CLIMB CURVES

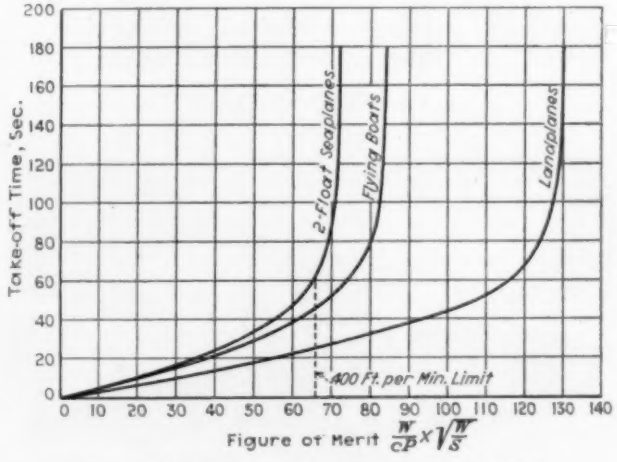

FIG. 6 TAKE-OFF TIME VERSUS FIGURE OF MERIT

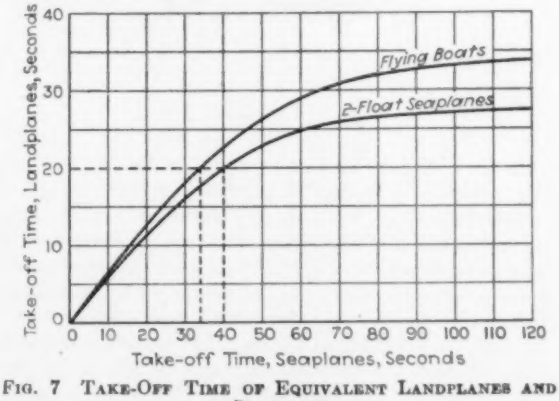

FIG. 7 TAKE-OFF TIME OF EQUIVALENT LANDPLANES AND SEAPLANES

Types. The different types are well known; we distinguish between seaplanes with positive and with negative stability. Twin floats, twin boats, sponson boats, and boats with low side floats (called triple floats by Richardson) belong to the group having positive stability, while single-float types and boats with will be less than that of the fuselage with floats and float bracing. On the other hand, there is the possibility of exchanging floats during service or of substituting a wheel undercarriage on a float plane. The combined landplane and seaplane, the amphibion, should not be overlooked here. This construction lends itself

well to beaching, but it depends on each special case whether its disadvantages shall be taken into account: namely, reduced seaworthiness—a consequence of the special necessity to save weight, increased drag, surplus weight, and the additional maintenance of the landing gear affected by sea water. The published data for the two types of craft make this clear:

	Useful load	Top speed	Initial climb	Cost
Fokker F11 (Amphibion).....	2430	112	700	33,775
Fokker F11a (Flying boat).....	2700	120	800	32,500
Reduction, per cent.....	10	6.6	12.5	4 (additional)

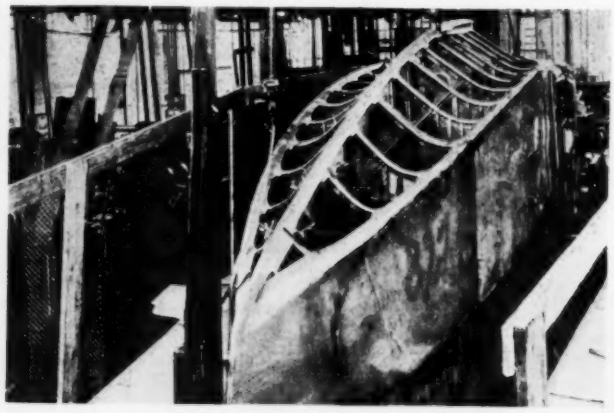

FIG. 8 ROHRBACH HULL

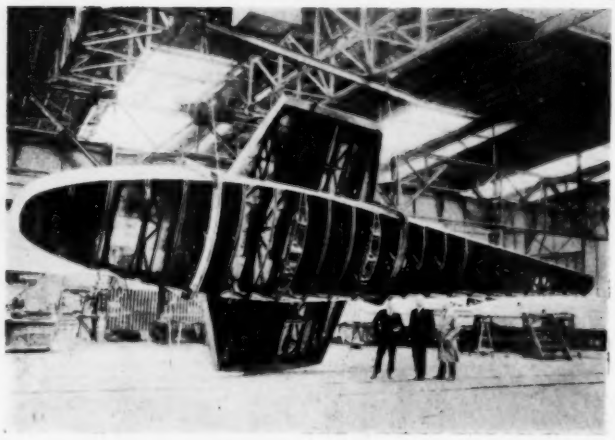

FIG. 9 HULL OF DORNIER WAL

Further, the additional landing gear will probably be so heavy for bigger ships as to make them rather inefficient, especially if one considers that they are subject to the official landplane rules.

The position of the side floats is of course connected with the question of seaworthiness, but apart from this, say, for ships for inland waters, the author would always prefer that position which provides positive stability. This means low side floats and imposes the necessity of having them nearer to the hull in order to avoid high yawing moments from a possible wave impact or from landing with an inclined wing. Thus the location of the side float has wandered from the wing tip to the hull; now it is attached to the hull in the case of sponsons. It is interesting to cite here Dr. Dornier's statement that the relative span of his sponsons decreases with increasing size of the whole boat.

Design of Floats and Boats. The design of floats and boats is a specialized kind of ship design, with much more consideration being given to lightness in weight, and strength is required to withstand landing impact at much higher speeds, whereas in building ships only the bending moments which result from the wave distribution are taken into consideration. There is, also, the twisting and bending influence of the tail forces in the case of a plane. Notwithstanding all this, we find the same constructional features: either strong transverse frames with a few longitudinals or many through-going longitudinals with some frames, resembling the Isherwood system of the shipbuilder. There are also many intermediate possibilities, and they all have been tried by different designers. Strong transverse frames are represented, e.g., by Rohrbach's hull construction (Fig. 8). Dornier employs transverse frames with fairly wide spacing inside the hull and through-going longitudinals outside (Figs. 9 and 10). Small longitudinals running through in narrow spacing are found on the "Consolidated Commodore," small transverse frames being attached to them but not to the hull covering. There is also the "Short Calcutta" with transverse rings of sheet covering (their joints being at the same time riveted to the frames) and numerous longitudinals narrowly spaced and interrupted at the frames (Fig. 11). The Blackburn boat, however, has many longitudinals running through, a number of strong frames being cut out for them and attached to the covering. The spacings of the stiffeners are rather characteristic—they are about 6 in. on British boats as against 1.5 to 2 ft. on German boats. This is to a certain extent also due to the derivation of the British metal design from wooden boats of the flexible type, and to the more complicated shape. The corresponding high number of rivets must obviously have an unfavorable influence on the production costs.

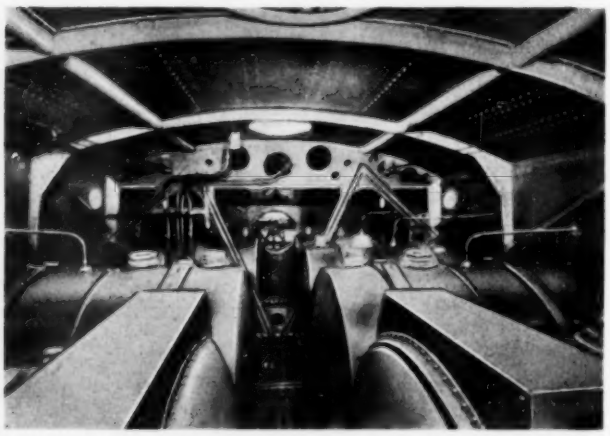

FIG. 10 FUEL ROOM OF DORNIER WAL

As for the floats, the standard type of Heinkel's is a wooden float with correspondingly flat walls, having ash frames and longitudinals and plywood covering (Fig. 12). Junkers, however, uses the reinforcing effect of his corrugated sheets also for the longitudinal stiffening of floats at the side walls (Fig. 13). An example of the use of wide spacing of stiffeners in the United States is the Edo float, which has fairly thick walls, a few longitudinals, and only the bulkheads as transverse members.

We have seen that the longitudinals may be provided at the inside or at the outside of the hull, the latter arrangement avoiding crossing difficulties. Service experiences show, however, that outside longitudinals should be avoided on the bottoms of metal ships as they complicate beaching and are likely to be damaged, thereby causing corrosion.

Engine Arrangement. The engine arrangement is normal for

float seaplanes; one has only to see that the clearance of the propeller from the water line is preferably not less than 2 ft. As the hull cannot be considered for the installation of engines so long as these are directly coupled with the propellers, all boats have separate engine nacelles either under the wing or above, the position of the screw just ahead of the wing resulting in strong interference. The position under the wing, especially in use on biplanes (with reference to their upper wing), has the advantage that the influence of the parasite drag on the efficiency of the wing is small; but the propeller slipstream counteracts the circulation, whereas in the position above the wing it increases the circulation and the lift, but shows a very bad drag with idling propellers and affects the suction side of the wing unless the nacelles are carefully designed. The question of installation is less difficult on bigger ships as the propeller clearance from the water increases with the span. It is clear that the necessity of providing separate

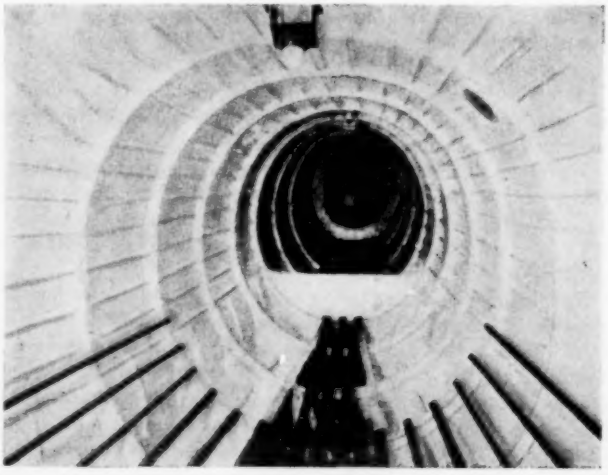

FIG. 11 INTERIOR OF SHORT CALCUTTA

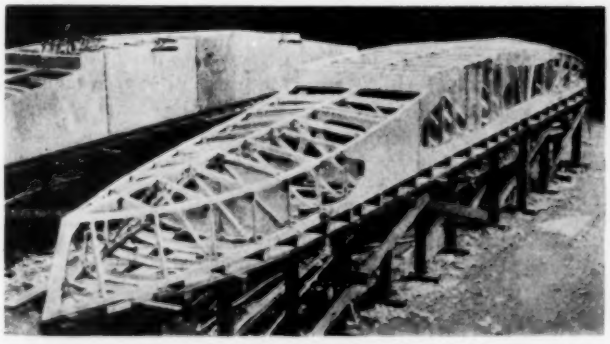

FIG. 12 HEINKEL FLOAT (WOOD)

engine nacelles has furthered the adoption of the tandem arrangement for flying boats; its advantages—small drag, no yawing moments due to engine failure—and its disadvantages—loss of efficiency for quick-running airscrews, cooling difficulties with the present air-cooled engines—are widely known. There is of course the influence of the high line of thrust on the air stability, in so far as it makes it more difficult to obtain the right balance for both cruising and gliding flight conditions.

Maneuvering on the water is more difficult and more important than on land, the importance being accentuated by the fact that seaplanes on the water are regarded as engine-driven ships subject to international navigation regulations. This point of

TABLE 2 VALUES OF BEAM LOAD W/B

[2] $W/2B^2$.

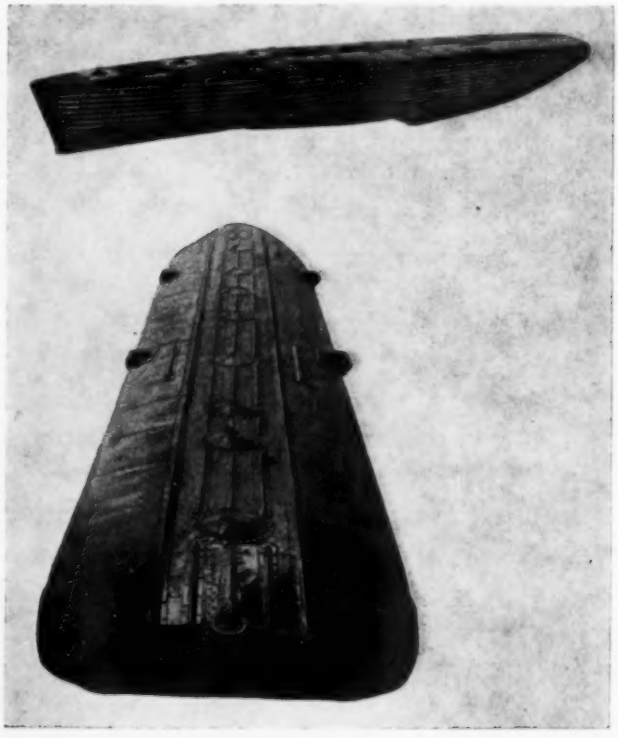

FIG. 13 JUNKERS FLOAT

view will often require the use of an enlarged rudder or ailerons, which mostly means increased control forces during flight.

Beam Load. It is interesting to investigate the beam load, or the gross weight divided by the width of the hull, for the different types and sizes of seaplanes. Values for this are given in Table 2, as well as values of weight divided by the square of the width.

These values are plotted on two diagrams (Figs. 14 and 15), and attention is called to the comparatively low values of the H-16, Calcutta, and DoR, and the high values of the Romar and Rocco. Points of two-float planes are seen on the same curve in Fig. 14. The difference between float seaplanes and boats is only seen when considering the bottom loading calculated as $W/2B^2$ for the two floats. This value of the bottom load of course varies less for normal machines than that of the beam load, but any variation of the type is much more pronounced. The plotting of points for different conditions of gross weight is justified for rough comparison as their alteration does affect but little the character of the curves, the points moving around along straight lines which radiate from zero. The second curve indicates why the take-off

of float seaplanes is normally worse than that of a boat, but it also shows that a narrow hull does obviously not affect the take-off possibility if adequately designed (compare Table 1 of take-offs). But of course the question of space for passengers and load is still more important from the economic point of view.

It is justifiable not to consider floats and sponsons when measuring the width, as these devices either do not assist very much in the take-off, or have such incidence against the hull bottom that any wave impact will probably not meet both with the same force. Thus we can assume the impact pressure to have some relation to the curve of the "bottom load." The actual values

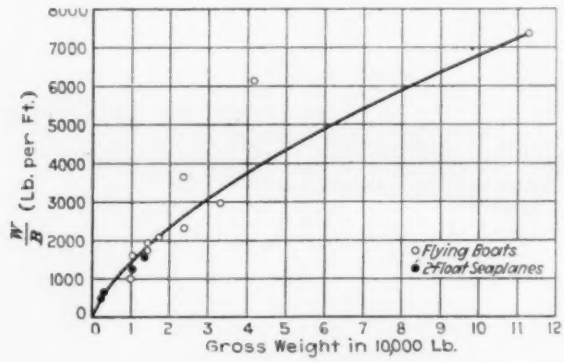

FIG. 14 BEAM LOAD VERSUS GROSS WEIGHT

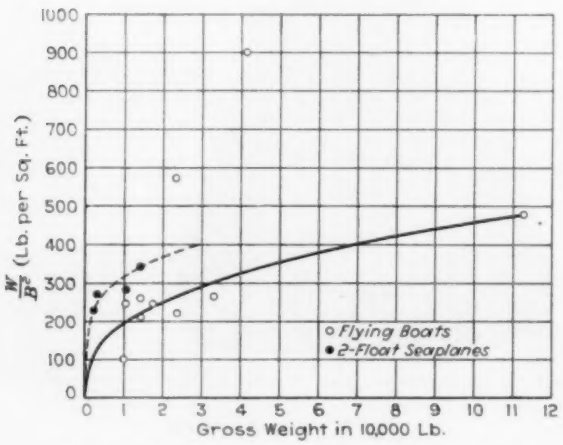

FIG. 15 BOTTOM LOAD VERSUS GROSS WEIGHT

measured by the N.A.C.A. (Reports 328 and 346) are about 10 lb. per sq. in. for the TS-1 and 14 lb. per sq. in. for the H-16, and the author imagines that bottom pressures on Rohrbach boats are not far from being as high as indicated by their proportional position on the diagram.

SEAWORTHINESS

The definition of seaworthiness deals with the maneuverability of the seaplane on the water and the combination of flight and marine performances when taking off and landing. The seaworthiness is sufficient when no injuries or damage occur to those on board the plane or to the plane itself. Going into details, seaworthiness in general comprises behavior during: (1) mooring, (2) drifting, (3) towing, (4) taxying, (5) landing, and (6) taking off.

There have been designers striving after the seaplane with "absolute" seaworthiness, but until now the seaworthiness obtained has always borne a certain relation to the weather conditions and the seaway encountered. It is hardly reasonable to require that absolute seaworthiness which we are unable to obtain, even with considerable sacrifices of useful load. It should be borne in mind that storms often cause great damage on the big liners.

From the standpoint of safety, adequate performance must be required for points (1) to (5), but it seems reasonable to except the take-off in a high seaway. Limiting thus the definition of seaworthiness does not affect the safety; the seaworthy plane is able to land in a high sea, is always maneuverable, and it rides out a storm and takes off again under better weather conditions when repairs have removed the cause of the forced landing. Even such early types as the NC-boats in 1919 and the old H-16 of the above-mentioned report experienced no serious troubles when landing normally.

When discussing seaworthiness, one should divide all seaplanes into two groups as the D.V.L. does for its strength requirements, namely, into planes for rivers and lakes, and planes for the high seas. The formation of a third group might be suggested for the coast and the Great Lakes, but presumably the short waves of the Great Lakes, e.g., are at least as dangerous as those of the ocean. As all difficulties are more or less due to the seaway, the following paragraphs will deal especially with the "high-sea" group.

Investigating details Nos. 1 to 6, we find that they are a function of different seaplane characteristics: of the flight performance as far as landing and taking-off speed and time of the take-off are concerned; and of the water stability, size, and position of the wing for the remainder.

The landing and the taking-off speed should be as low as possible, of course, as the wave impact increases with the square of the speed. But considerations of flight performances of the weight-strength ratio (especially of the wing), and of the influence of a large wing on the water stability have led in the opposite direction. The landplane has gone through the same development even without this third reason, so that it is not fair to blame the seaplane for it.

The lateral water stability of a seaplane seems to resemble that of any floating body. This is true in the case of a calm, but with wind the stability of a seaplane can only be compared to that of a sailing vessel—and this only to a certain extent as the wing area cannot be reduced like the canvas of a sailing ship. This makes clear the danger of a large wing surface, corresponding to a small wing loading. It shows also why the initial stability expressed by the metacentric height is greater for an inherently stable seaplane than for a steamship, e.g., 15 ft. for the DoX. Apart from the size of the wing the heeling wind moment depends largely on the height of the former above the water line (this is often excessive for the upper wing of biplanes), on the projected area of the hull, and on the dihedral of the wing. For example, Rohrbach accepted the tapered wing in order to balance the influence of a pronounced dihedral. Incidentally seaplanes with a high wing loading do not tend to fly away from either beach or buoy in a 40- to 50-mile "breeze."

In discussing the marine qualities of the different types, a new factor must first be considered, namely, the size—this not from reasons of stability but merely because it gives a measure of the distance from the water line to the pilot. It is quite clear that a pilot sitting high and dry in a small-float seaplane is better able to view his surroundings than one sitting low in a small boat and more or less disturbed by spray. For the bigger sizes, however, the boat is obviously better; it should always be possible to build it lighter and with less drag. The average limit for both types according to experience is at about 11,000 lb. gross weight or about 900 to 1000 hp. This is one of the reasons why the lighter two-float seaplanes attained the first three places in the severe test of the German Seaplane Competi-

tion in 1926 (Von Gronau being the winner), and that helped to develop the flying boat as the heavy patrol plane of the U. S. Navy.

Although as said before the high position of the upper wing of a biplane is rather unsatisfactory, the low position of the lower wing is still worse. The possible heeling angle of a ship with low wings is very small, and the wing tips are much exposed to the seaway. A construction cannot be considered as satisfactory when students are advised to cut off its fabric in case of distress, and in view of all this, the monoplane offers the best solution.

The most acceptable take-off and landing qualities seem to have been obtained with the central-body seaplane, i.e., with the single-float seaplane and the central boat. The better maneuvering qualities are of course associated with positive stability, that is, with the two-float system and with the central inherently stable boat. Side wind considerably endangers every seaplane with negative stability due to the increased angle of attack. One logical step has been to lower the wing-tip floats far enough to insure positive stability, as a hull that would itself give this stability would be too broad. Rohrbach, for example, did this and employed side floats instead of tip floats at the same time. But for high-sea service the low side float has not proved its

Fig. 16 Rohrbach Rocco Taking Off

superiority. The stabilizing device of outstanding merit is still the Dornier sponson, as it insures a high degree of positive stability, centralizes the buoyancy and impact forces, does away with the danger of being torn away, which is always possible for floats, and avoids the large impact of a broad, inherently stable boat by the incidence of the sponson. We have seen before that only the single-body plane combines good taking-off and maneuvering qualities, so that we understand now the success of the inherently stable sponson boat, as exemplified by the Dornier, Latecoere, and Supermarine. Planes of the "Wal" type have repeatedly been able to take off and land (of course) with considerable side wind or along a rather heavy swell, which ability is very important for all cases where wind, seaway, and swell cross each other. Take-offs of this kind are also mentioned in Report No. 328, but this same report also shows the unsuitability of the wing-tip float for this maneuver, as it was damaged by waves causing a ground loop of the whole boat.

Longitudinal water stability presents no difficulties whatever, as a certain length of the boat, e.g., is given by the position of the tail and as the length of floats is already partly determined by the required buoyancy. The necessity that the ship shall be stable with any two compartments flooded is of some importance, too, but it affects more the spacing of the bulkheads.

The shape of the bottom has a distinct influence on the seaworthiness, as it determines the wave impact, the ease of take-off, the smoothness of a landing, and the amount of spray water. It has often been stated that the flat bottom gives the shortest take-off on smooth waters, whereas keeling is more agreeable for seaway. A number of characteristic sections are shown in Fig. 17. Interesting is the application of longitudinal steps, the lowest part of the bottom being especially used for planing at high speed. The success of the flat-bottomed Wal is partly due to this longitudinal step which avoids contact of the whole bottom with the water at once and serves as a very efficient stiffener. The straight keeling of American boats compared

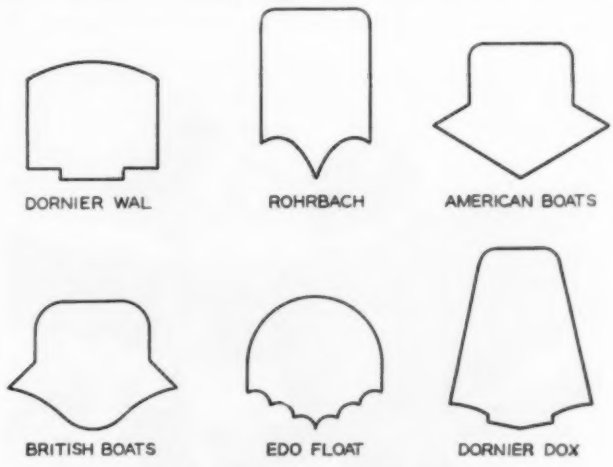

Fig. 17 Characteristic Bottom Shapes

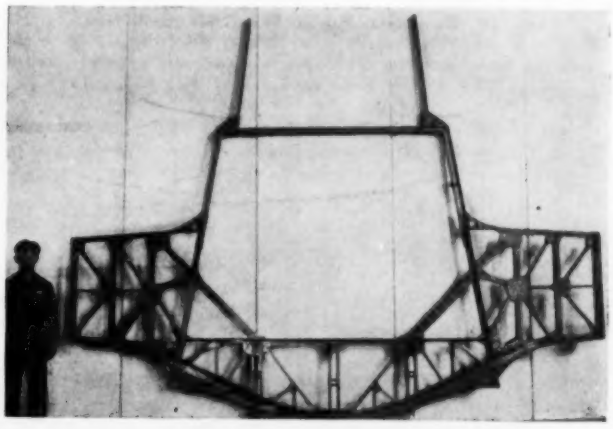

Fig. 18 Main Frame of Modern Dornier Boat

with the wave-binding Rohrbach bottom should be less efficient as regards the time of take-off and maximum tests, but no actual figures are yet known. A combination of longitudinal steps with the Rohrbach shape is represented by the Edo floats. It is interesting to note that without excessive width of the hull the draft of the Dornier DoX is 3.4 ft. fully loaded as compared with 2.7 ft. of the Supermarine Southampton, for example. Economic considerations suggest a shape of bottom lying between the flat one and the type with pronounced keeling, as illustrated by the main frame of a modern Dornier flying boat (Fig. 18).

Service Questions

Embarking. There are a number of questions for flying companies which arise from peculiarities of the seaplane. Taking up embarking first, there are these possibilities:

1 Entering the plane from the bow when it is lying on the beach or on an inclined runway with its front part. There is no question here of seaway as seaplane bases will always be

situated on sheltered water, but wind will often affect the taxying to and from such a place.

2 A pier or a rigid bridge is unsatisfactory when the tide has to be considered, as it should be so low that the wing has sufficient clearance.

3 The use of buoys is logical as in the case of yachts. However, it makes a commuting boat necessary, but this will often be available as it is also required in the case of accidents.

4 The installation of a raft either attached to an anchor or sliding up and down in guides is to be earnestly considered. It

FIG. 19 ROHRBACH ROBBE WITH BEACHING GEAR

may be accessible over a movable bridge and the seaplane will be able to go alongside under all wind conditions if the distance from the land is great enough.

5 The easiest solution is of course given by the amphibion; the floating runway of the Air Ferries in San Francisco deserves to be especially noted.

Beaching. It is the custom on European seaplane lines to leave the machines moored during the season and to take them out from the water only for repairs and overhauls. There are several methods:

a The launching cradle or slip car is well known; it needs a special shape for all non-flat bottoms, and this makes the maneuver rather difficult, say, with side winds.

b Some manufacturers supply special auxiliary wheels for their ships so that they can taxi up the beach or slope with their own power after the gear has been applied by men with rubber suits. (Fig. 19, Rohrbach, and Fig. 20, Dornier beaching gears.)

c Whereas these wheels remain at the ground base in the case of seaplanes, the amphibion incorporates them in an under carriage, thus eliminating beaching difficulties but sacrificing some pay load and speed.

d If an adequate crane is available, hoisting of the seaplane is effected easily and quickly. This method is very suitable for airplane works, where a delay of the maneuver by unsuitable wind conditions is not of the utmost importance.

e Floating docks were used in England during the war and there is one now at the central seaplane base of the German Lufthansa, but it is believed that the initial and maintenance costs are rather high.

f An elevator scaffold or slip could be provided with a second car independent of the rails, so that it might be adjusted to every position of the seaplane due to variations of the wind direction.

g A simple wooden slope lubricated with water is cheap and works perfectly with small machines having a strong keel.

The question of maintenance is rather important, too. Corrosion is still the only serious handicap for the metal seaplane, but the author feels quite sure that there will be some efficient protection developed within the next few years. As a matter of fact, metal construction is imperative for the bigger ships—the DoX would never have been built from wood.

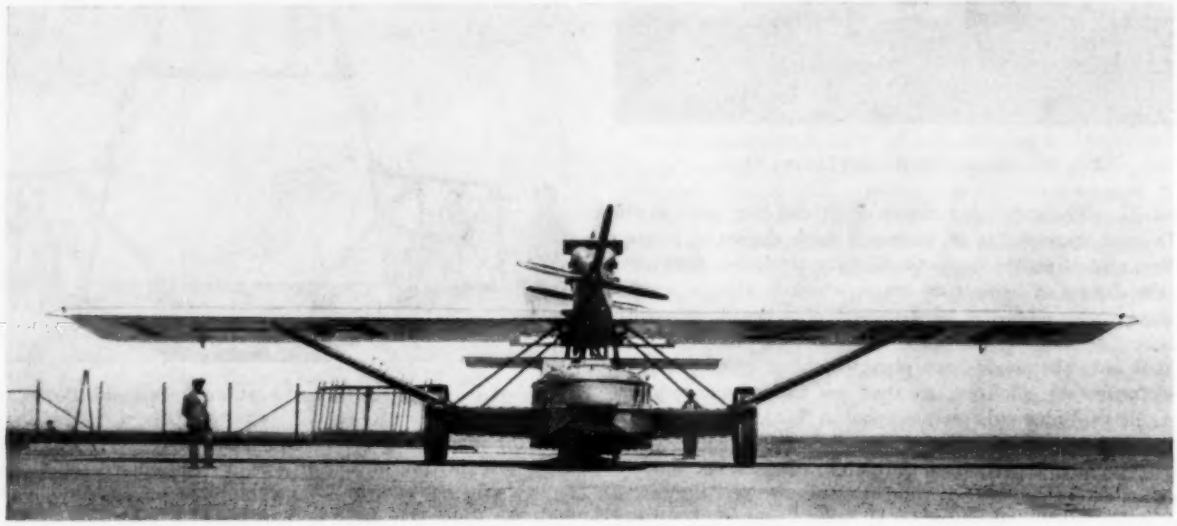

FIG. 20 DORNIER WAL WITH AUXILIARY WHEELS

REQUIREMENTS

As the requirements of the different authorities for the approval of seaplanes for service naturally differ from those for landplanes, a brief glance at them may help to give some idea of the seaplane, the development of which they follow to a certain extent. Further details are given in an article by Mock and Pappel in the *Aero Digest*, September, 1930.

First there are certain requirements for the flight performance. In its regulations now being modified, the Department of Commerce requires a take-off within 1000 ft. This is to hold for seaplanes and landplanes, but considering the higher water resistance

and friction of a seaplane when equivalent to a landplane in the air, it means a serious handicap to the former. So the Department does not actually insist on the regulation. If any requirement of this kind is made, it should limit the time of take-off, as the run is not so easily measured on the water, and this limit should reasonably not be under 45 sec. (see Fig. 7).

The D.V.L., the German Experimental Institute for Aeronautics, has no requirements at all for the take-off of seaplanes, apart from seaworthiness requirements which are now being developed. They acknowledge that the natural limit of seaplanes prevents dangerous overloading, and that the size of the natural landing places does not require limitation of take-off, and they provide for strength by requiring higher load factors for higher landing speeds.[2]

The Department of Commerce wants a certain maneuverability in the air expressed by the radius of figure 8's. The tendency toward equal treatment for landplanes and seaplanes is justified;

FIG. 21 HEINKEL HD 19 ON LAUNCHING CAR

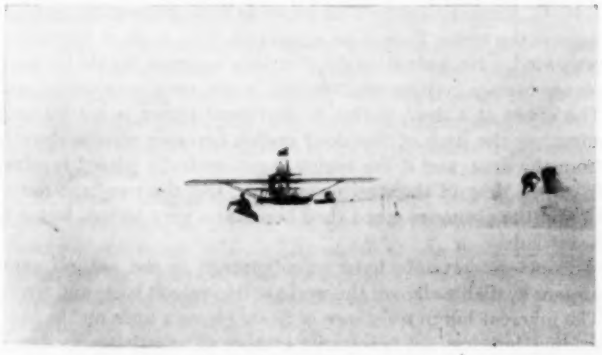

FIG. 22 DORNIER WAL OF AMUNDSEN; PREPARING TAKE-OFF FROM POLAR ICE

once in the air, a plane should be a plane. Certain minor difficulties for the seaplane arise only from special considerations for rudder and ailerons, as already mentioned, or from the influence of floats on the lateral air forces. The author believes that service experiences will also here lead to measuring the time for a circle or figure 8 instead of the radius, this time to be staggered for certain weight groups to take account of increasing inertia.

A third requirement might be new for multi-engined seaplanes: the demand that they shall fly with full load with one engine out of commission. This regulation should be seriously discussed before enforcement. When asking any boat pilot about emergency landings, he will tell you that he feels more comfortable than in other planes as a normal seaplane route is composed of a natural series of "emergency fields" and as an emergency landing of a boat on land will never endanger the lives of those on board. All planes have to face a crash when forced down over woods or mountains. The merits of the flying boat in this direction have been proved, e.g., by the recent landing of a Commodore on Cuba, by emergency landings as reported from amphibions with wheels up, by the take-off of Amundsen's Dornier Wal from the polar ice (Fig. 22), and by the take-offs and landings of a ship of the same type from land covered only with a 2-in. layer of snow when searching for Eielson (Siberia, 1930). Comparing thus the chances of a forced landing, it seems

FIG. 23 HEINKEL HE 8, LONG-RANGE SEAPLANE

to be reasonable to consider the differences by varying the requirements for multi-engined flying boats and for such landplanes.

The reason for the introduction of multi-engined airplanes was to make them more reliable and independent of engine failures. But it would be unreasonable to prevent sound development by barring with restrictions two-engined planes as well,

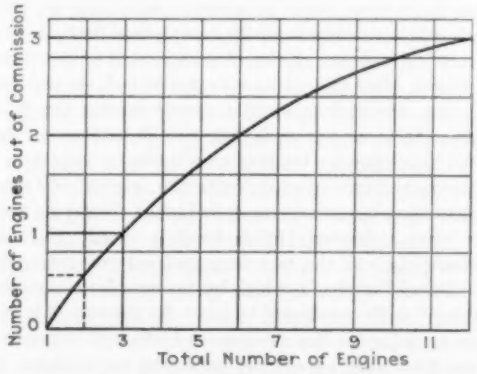

FIG. 24 NUMBER OF ENGINES OUT OF COMMISSION VERSUS TOTAL NUMBER

as one cannot forbid single-engined planes with 0 per cent reserve in the case of engine failure. The complete exclusion of the two-engined seaplane might be a consequence of the regulation that they shall fly with one engine out of commission as its weight empty is already greater than that of the two-engined landplane. Some American airplanes which are at present able to meet this requirement will not be able to do so later, for it is the fate of aircraft to gradually grow heavier and heavier. The author would suggest connecting such a requirement (if any) with a curve (Fig. 24) based on the possible failure of one-third of the engines for a three-engined and a six-engined plane, the ratio decreasing toward zero for the single-engined machine, and again decreasing for more engines as the probability of a failure of so large a number of engines at the same time is very remote. In the case of fractions the corresponding hp. and r.p.m. could be

[2] See reference to later regulations at end of paper.

determined from the propeller load curve of the motor in question.

The different requirements for strength take up much more space in the regulations, but only a few outstanding details will be mentioned here. The D.V.L. has an empirical formula for the landing load factor. It depends on the gross weight, on the 1.5th power of the landing speed, on the angle of keeling, and on the seaway, being 30 per cent higher for seaplanes which will withstand seaway No. 5 instead of No. 3. All important factors are thus combined. The Department of Commerce requires a higher load factor for floats and bracing, whereas the D.V.L. permits a lower one than for the remainder of the plane or for boats. The highest stresses are indeed in the float system, but the D.V.L. thinks that overstresses should first result in bending or deflecting that system without affecting the rest of the plane and the persons.

Generally the D.V.L. derives its requirements from the landing impact. The Department of Commerce, however, has certain requirements referring to floating which are less severe. Buoyancy and floatability are insured by special regulations for the surplus displacement and for the stability with any two compartments flooded according to the D.V.L. wording, the Department aiming at the same goal by requiring subdivision into five compartments of approximately equal size.

There have been no official requirements with respect to seaworthiness until now (they are being developed by the D.V.L.), but there are a number of flying companies with certain regulations, e.g., the German Lufthansa. The corresponding tests comprise drifting, towing on all courses from 30 to 30 deg., taxying of figure 8's, landing and taking off; all this with No. 2 seaway at least and corresponding wind. Such or similar requirements should have the same importance as those for the life-saving devices on steam ships. No private flier should be prevented from drowning if he insists upon doing so, but safety must be the first consideration for commercial flying over sea.

[The new regulations of the Department of Commerce having become known after this paper was preprinted, the author added the following concerning landing speeds during the reading of the paper: It is understood that the Department intends to extend the limitation for landing speeds also to seaplanes. Some details mentioned in connection with the take-off will contribute to the view that landplanes and seaplanes should be treated in different ways, allowing higher landing speeds for seaplanes. The author points to the fact that such an interesting development as that of Rohrbach, which by no means resulted in "dangerous ships," will be excluded by law. By the way, it is wondered how a great many of the modern and efficient American landplanes shall be able to comply with the regulations, as their wing loading indicates landing speeds of 65 to 75 m.p.h.]

Discussion

B. C. Boulton.[3] This most interesting paper covers many phases of a broad field. If one may venture a criticism it is that the author in touching on several subjects just gives enough to excite the reader's interest without satisfying it. For a paper to have the most value to practicing engineers, it should go thoroughly into the matters taken up. Owing to the wide divergence in design practice between this country and Germany and the merit of German flying boats, it is of great importance that designers in this country be acquainted with the methods and formulas used by German engineers in determining the various features of boat design. Because of Mr. Schuettel's familiarity with these, it is to be hoped that in the near future he will contribute a paper or articles giving more detailed information.

[3] Glenn L. Martin Company, Baltimore, Md.

It is a great pity that more basic test data are not available for foreign boats. This information is similar to wind-tunnel data on airfoils, and with it the relative merits of the various bottom shapes and lines shown in Fig. 17 could be determined as regards efficiency. The author's opinion that the sharp V-bottom of the Rohrbach type is more efficient than the American design is questioned.

Figs. 14 and 15, showing the beam and bottom loadings, are interesting and check with the writer's experience. However, it is believed that Captain Richardson's formula for beam in terms of weight and loaded waterline length is more reliable. The Rohrbach boats check closely with this, although they fall far above the curve given for beam loading. Fig. 15 brings out very clearly the necessity for using a much higher unit loading in designing the bottom bracing of large boats than would be satisfactory for smaller ships.

The author touches on a mooted question in discussing the spacing of bottom longitudinals and in pointing out the great difference in British or American and German practice. One at once wonders what gage of bottom plating will permit a stringer spacing of 1.5 to 2 ft. The question also arises of the effect on water resistance of the rather large external longitudinals employed by Dornier.

The suggestion made by the author under the heading of seaworthiness, that boats be divided into two classes depending on the service for which they are designed, is an excellent one. Unquestionably flying boats designed for use on the ocean must be built considerably heavier than those for river or small-lake service. It is believed important enough to consider bringing to the attention of the Department of Commerce so that a differentiation in load factors may be made.

H. C. Richardson.[4] This paper is very interesting, particularly as the writer finds close agreement with most of the matter presented. He feels strongly that long overseas flights by landplanes is only inviting disaster and is not even reasonably safe. The effect of a dead engine in decreased power is not its only effect, as the drag of the dead engine becomes serious directly from the drag, and if the engine is not centrally placed involves increased drag of the steering controls, and the resultant reduction in the optimum speed then becomes a very serious factor in headwinds.

Seaplanes certainly have an advantage in the natural aerodromes available all over the world and in inland lakes and rivers. The inherent hump resistance of floats places a limit on the overloading, but does not necessarily involve an unsatisfactory design commercially. The length of run to the take-off and the time of take-off are relatively unimportant in a harbor, and if any wind is blowing it is always blowing down the runway for a seaplane. In fact, one large landplane specifically built to show high range found that the land-gear tractive effort was a serious factor in limiting the contemplated overload.

Personally it is felt that the triple-float arrangement is superior to the sponson type and that the latter inhibits, to some degree, the employment of sharp V's which are excellent shock absorbers in eliminating the punishment involved in the use of flat bottoms or fairly flat V-bottoms; and, contrary to the generally accepted notion, the writer believes that the intermediate-angle V-bottom does not require power in excess of that required for the flatter bottom types.

For the larger sizes there is no question that the boat type will prevail due to its superior maneuverability and habitability and because twin floats of large size involve such serious wracking forces that the provision for adequate strength involves undesir-

[4] Director of Engineering, Allied Motor Industries, Inc., Chicago, Ill.

able weight. Even for the float type, the central float is superior to the twin float, and particularly with a single engine plane the central float offers protection to the propeller.

The writer is particularly interested in Mr. Schuettel's protest to the Department of Commerce ruling that a twin-engine plane must be capable of flying on one engine. This ruling makes the second power plant with all of its accessories, foundations, controls, etc., a surplus luxury which can ill afford to be carried in commercial types of planes, whereas the presence of the second engine really affords a very measurable improvement in safety in that it very importantly increases the gliding range, and it appears to the writer that the minimum specified rate of descent with one engine out of commission would be a more reasonable requirement for twin-engine airplanes.

Relative to the beam ratio, it is regretted that Mr. Schuettel does not include the length in his table, as the writer has found that, taking account of the waterline length and beam or the beam ratio, the beam required is a function of that ratio and the cube root of the weight, and that this applies to central-float, twin-float, and boat types covering planes from 1000 to 30,000 lb. and for American, German, French, and Italian designs. As to the structure the bottom framing of the Isherwood type will, in the long run, prove to be most satisfactory.

The writer is glad to see a paper of this type as he believes it is time that interest in seaplanes, particularly of the boat type, should be revived in this country.

I. M. Laddon.[5] The author's statement that, in so far as aerodynamic efficiency is concerned, in the smaller sizes the seaplane is inferior to the landplane of equal weight because of the drag of its float and bracing is not agreed with. The fact that the world's high-speed record is held by a seaplane seems to be satisfactory evidence to the contrary. In the larger sizes flying boats have been constructed which, from the standpoint of pay load and performance, exceed comparable landplanes. As a concrete example, the *Commodore*, with two series-B Hornet engines, carries practically the same passenger load that the Fokker F-32 handles, though the latter ship requires four series-B Hornet engines.

The flying boat has the inherent advantage that the hull provides the landing and take-off medium and also functions as the passenger and cargo cabin. The width of the beam necessary for satisfactory take-off assures ample space for comfortable passenger accommodation, a feature which is frequently lacking in the normal land airplane.

The writer does not agree that the maximum range of seaplanes is of the order of 2000 to 2500 miles as compared with 5000 or 6000 miles for landplanes. No one to date has overloaded a modern flying boat to the point where it is just barely able to take off under the most favorable conditions and determined just how far it will cruise. The *Commodore*, loaded to 23,000 lb. gross, would have a cruising range of approximately 4000 miles, which it is believed compares favorably with limiting conditions for the present-day landplane. This type of performance is not advocated, because it does not form the basis of a practicable every-day commercial operation. However, such a parallel should be drawn in the event that flying boats are to be judged on the basis of stunt-performing landplanes.

On the question of constructional features, with particular reference to hull design, our system has been to use a minimum amount of athwartship bracing with the idea that every pound of material used in longitudinal bracing contributes to the overall strength of the hull, whereas athwartship bracing falls in the category of local stiffening, which should be reduced to the minimum consistent with the necessary strength. The hull itself is analyzed in accordance with naval architectural methods, basing external loads on three criteria:

1 Hogging condition with the crest of the wave amidships
2 Sagging condition with the trough of the wave amidships
3 Landing condition with the load concentrated on the bottom forward of the step.

The thickness of plating, spacing of longitudinal stringers, and design of the floor-frame trusses and the keelsons are predicated on this analysis, and while the general assumptions covering external loads can be considered controversial, the structure as a whole has a uniformity of strength which assures reasonable elastic properties and minimum weight.

In general, American flying boats carry a much higher percentage of useful load than those built abroad, and in the writer's opinion the reason for this is that the Continental designers build, first, a rugged, seaworthy hull and then attach thereto sufficient wing area and engine power to permit it to fly. In other words, the average Continental flying boat is primarily a boat and secondarily a flying machine. It is contended that this method of procedure is fundamentally incorrect, i.e., the flying boat should be primarily a flying machine and secondarily a seaworthy boat. The high wing and power loading of foreign designs causes them to be sluggish flying machines, and the great length of run on take-off and high landing speed make it necessary to provide a tremendously strong and correspondingly heavy bottom. If the wing loading and power loading are kept at a reasonable figure, the flying boat will get into the air with a relatively short run in a heavy sea and not be required to take the beating which the more heavily loaded, lower-powered flying boat must undergo. A typical example of foreign flying-boat design consists of two four-engined airplanes which were purchased by an American operating concern each of which had an alleged passenger capacity of 30 persons. Our Department of Commerce would not license these aircraft to carry more than the crew and approximately three passengers. In the writer's opinion European flying-boat development has been greatly overrated as compared with the home product, largely because, with the exception of the *Commodore*, practically all American flying-boat development has been for the Navy and has not received a commensurate amount of advertising and publicity.

Reference seaworthiness, rough-water tests, and thousands of hours of satisfactory operation have proved that the low side float, i.e., one that provides positive lateral stability on the water, is at least the equal of the raised side float for heavy sea duty. Further, this float arrangement assures a degree of taxying control when on the step that is not provided with any other float arrangement.

The reference diagrams in Fig. 17 show characteristic bottom shapes. The *Commodore* bottom does not conform to any of these, but is, in general, similar to that shown for British boats, with the exception of the keel being sharp instead of rounded. Also, the *Commodore* does not utilize sponsons, which are said to be typical for both American and British boats.

The writer is in accord with the author's statement that the monoplane is the desirable type for flying boats. It is believed that the high center of thrust location of the average flying boat is an advantage in so far as stability, power on and off, is concerned, experience indicating that the flying boat is better than the average land machine in this respect.

Disagreement is taken with the author's paragraph on relative engine-wing location. In multi-engined airplanes, where flight with one motor is a performance requisite, the location of the power plants above the wing has an exceedingly detrimental effect. The drag which occurs with an idling propeller is usually

[5] Designer of the Consolidated *Commodore*, Consolidated Aircraft Corporation, Buffalo, N. Y.

of sufficient magnitude to actually prevent horizontal flight with one motor out. A recent series of tests conducted by the National Advisory Committee indicates that the engine location below the wing is preferable.

G. A. Luburg.[6] The writer finds the paper very interesting. It was, however, an article very much on the same order as one that he wrote for the A.S.M.E. last year on "Seaplane Design," in that it was very general in its statements and contained comparatively no new information of a technical nature upon which an engineering discussion could be based.

Author's Closure

Mr. Boulton is perfectly right in his criticism, in so far as it is impossible to crowd experiences on such a wide field into one paper. Besides this, the publication of data will, as long as there is competition, be subject to mutuality, and in this respect Dr. Dornier seems to have been one of the most liberal.

The remark about spacing should be understood generally. The gages on European boats are not excessive, so that the difference seems to lie in a larger allowance for elastic deformation on the unstiffened parts, combined with the use of less but stronger stiffeners. There is some initial water resistance for the Dornier type of sponsons; it disappears quickly, however, due to the rise on the step. Tank tests in this direction by Supermarine should not be generalized; Mr. Richardson is perfectly right when intimating the importance of considering the combined water work of hull bottom and sponson.

The author cannot agree with some of Mr. Laddon's statements. He feels that the development of speedy seaplanes was stimulated by the Schneider Cup, whereas no such stimulant existed for landplanes. The four-engined F-32 and the two-engined Commodore should not be mentioned so closely together as they belong in distinct, different classes, characterized by low power loading and high speed versus medium power loading and low speed. The seating capacity as such does not give a good picture if not quoted together with the corresponding range. A large cabin is of slight value to the operating company if the actual capacity must be considerably reduced for a longer run.

The maximum range for seaplanes has indeed been increased by a Latecoere plane to about 3000 miles. It should, however, be kept in mind that this type of plane was extraordinarily light in weight and that its high stress-to-weight ratio was fatal to several pilots. With the indicated gross weight the Commodore should not cruise much farther than 2500 miles. The limit of overload has been determined for many flying boats, some data being given in Table 1. It is hoped that the range of 4000 miles will follow the introduction of Diesel engines.

The author agrees with Mr. Laddon in rating the transverse stiffening as secondary. Any neglect of it, however, might lead to weakness in respect to torsional stresses. The generalization about European seaplanes is not justified, the principle that flying boats should be airplanes first and then boats is adhered to by most European designers. The four-engined boats referred to had been ordered without any reference to American requirements, which partly did not exist at the time of their construction. It should have been mentioned that their failure was mostly due to an engine type which, in geared condition, had been said to be satisfactory for the tandem arrangement, but which did not prove to be so, according to the author's information.

The author regrets that he did not know Mr. Luberg's paper at the time. The duplication of some statements may give the satisfaction of knowing that seaplanes are working just the same on the other side of the ocean as in this country. It is believed that the data concerning maximum tests and comparing landplane and seaplane take-offs are valuable enough to have justified a paper for them.

---

Sheet-Metal Airplane Construction

By PROF. DR. ING. HERBERT WAGNER,[1] DANZIG-LANGFUHR, PRUSSIA

ONE of the first successful attempts to manufacture all-metal planes in Germany was made by the airplane branch of the Zeppelin Works at Lindau, later known as the "Dornier-Metallbauten." This firm had the advantage of the experience of the Zeppelin Works in the use of the light-weight metal duralumin. Entirely new principles of construction were applied in Professor Junkers' "Iron-Monoplane" (Eiseneindecker) built in 1915. Up to that year the covering of airplane wings served essentially the sole purpose of giving them a certain shape and of providing a surface for maintaining the supporting air pressure. The distribution of the stresses was assigned to a special supporting structure which also included the external wiring and struts. Junkers made the external fairing of the wings of metal and, at the same time, combined it with the internal supporting structure so as to form a strong integral supporting body.

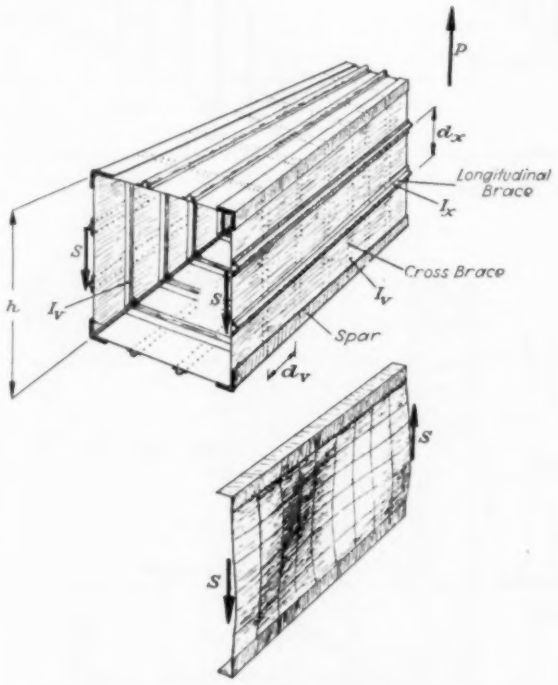

FIG. 1 BOX FUSELAGE
(The lower part of the picture shows the side wall buckled due to shear S.)

Thus the increase of weight of the fairing as compared with a cloth covering was at least partially saved, in the internal structure.

These principles prepared the way for the development of all-metal planes in Germany, and in the course of years various forms and types of such supporting fairings have been developed.

Inasmuch as the use of sheet-metal fairing for support is the outstanding constructional characteristic of such structures, it is the object of this paper to discuss the possibilities of building such sheet-metal walls.

Fig. 1 shows a hollow fuselage consisting of spars and sheet-metal walls. These walls are stiffened by means of braces, made of rolled shapes and riveted to the walls. For convenience the transversely arranged braces will be called "cross braces" and those running in a longitudinal direction "longitudinal braces." Such a fuselage will be subjected to bending stresses by forces exerted by air pressure on the tail plane or by the tail skid in the course of landing. The side wall will therefore be subjected to the shear S, and the top and bottom walls, together with the spars, serve as tension and compression members.

Consider first the strength of such a sheet-metal wall subjected to a shearing stress. With the shear S increasing, the sheet-metal wall finally breaks and buckles diagonally. This, like any other collapse or buckling, happens suddenly with the load increasing only slightly.

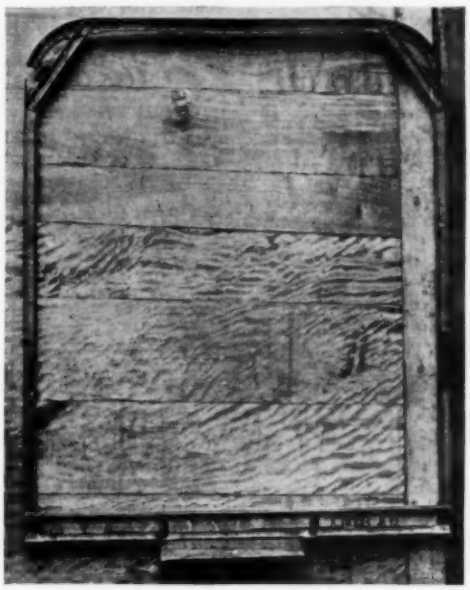

FIG. 2 FUSELAGE FRAME OF A ROHRBACH LAND PLANE
(The bottom beam is fitted with a web securely braced against shear.

In cooperation with Dr. Schmieden[2] the author has made calculations of this problem of strength, the results of which give the basis for the following considerations.

When the walls buckle out the braces are bent, the load S depending on the bending strength of these braces. The numerical value of S may be calculated as follows:

$$S = \frac{33E}{h}\sqrt[4]{\left(\frac{I_v}{d_v}\right)^3 \frac{I_x}{d_x}}$$

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] "Das Ausknicken versteifter Bleche unter Schubbeanspruchung," by C. Schmieden, in the *Zeitschrift für Flugtechnik und Motorluftschiffahrt*, vol. 21 (1930), no. 3. A supplementary treatise by Dr. Schmieden and the author will soon be published in the same magazine.

In this formula E is the modulus of elasticity of the material; h is the height of the fuselage or beam, I_v is the cross-sectional moment of inertia of a longitudinal brace, and d_z is the distance between these braces. At a given external load S and for a certain height h of the beam, the moments of inertia of the bracing, therefore, have to be chosen so that

$$\left(\frac{I_v}{d_v}\right)^3 \frac{I_z}{d_z} \geqq \left(\frac{Sh}{33E}\right)^4$$

Assume an external shear S of 10,000 kg. (22,000 lb.), and using the above formula, the problem is to determine which type of construction may be used to best advantage with different beam heights.

First, if this beam is to be constructed without bracing, how small must this height h be? Such a beam may be represented by the floor-beam of a Rohrbach land plane, as shown in Fig. 2. The value of the shearing stress τ at which such an unbraced sheet collapses and buckles diagonally has been determined by theoretical calculations as well as by experiments. This value (see Fig. 3) depends on the ratio of the distance d between the bracing members to the thickness s of the metal sheet. For all values of d/s higher than about 50, τ can be calculated from the following formula given by Southwell-Skan:

$$\tau = \frac{5E}{(d/s)^2}$$

For $d/s = 50$ the buckling stress of duralumin is about equal to the yield point (approximately 1500 kg. per sq. cm. = 21,330 lb. per sq. in. shearing stress) and consequently its increase is not worth considering even with smaller distances between the bracing members. To get a light structure, i.e., to subject the sheet to the highest practically obtainable stress, the distance between the bracing members must not be made greater than 50 times the thickness of the sheet.

If, now, the beam with a shear load of 10,000 kg. (22,000 lb.) has a total height of 22 cm. (8.66 in.) and a height of about 15 cm. (5.9 in.) between the spars, then a desired shearing stress of 1500 kg. per sq. cm. (21,330 lb. per sq. in.) will call for a thickness of about 3 mm. (0.118 in.) so that the sheet is sufficiently braced to resist buckling. For such beams, and of course for beams of smaller height as well, special bracing can be eliminated.

Considering, however, a beam with a height of 33 cm. (approx. 13 in.) with the same shearing stress of 1500 kg. per sq. cm. (21,330 lb. per sq. in.), the sheet need only be 2 mm. (0.079 in.) thick, while the distance between the bracing members must not exceed 110 mm. (3.95 in.) to give the sheet sufficient resistance. As the spars are already too far apart in this case, bracing must

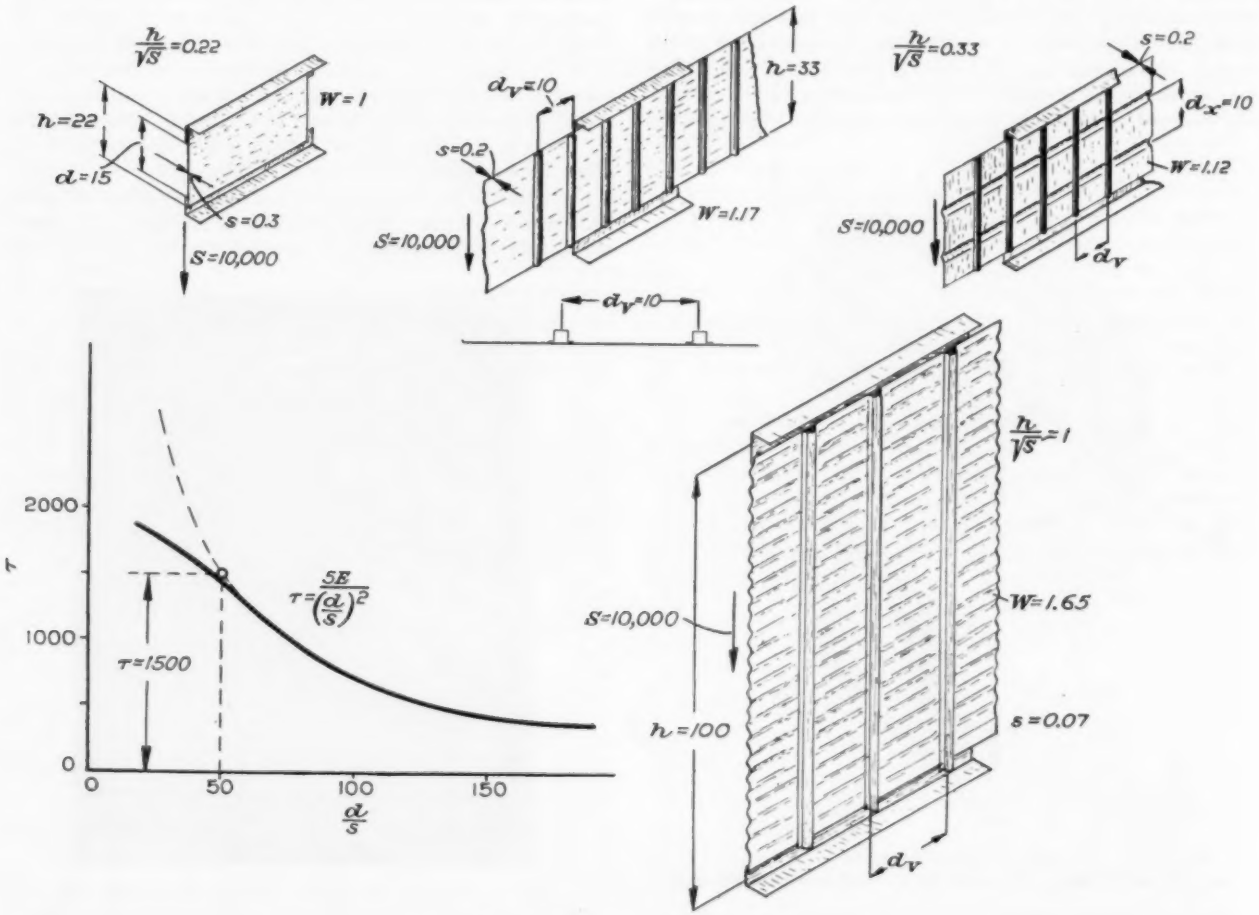

FIG. 3 DETAILS OF SIDE WALL

(In the lower left-hand corner the shearing stress τ is given, under which plane sheets with a wall thickness s buckle, if the distance between the bracing members is d. The other illustrations show the most favorable forms of design of sheet-metal walls securely braced against shear, dependent on the value of $h/\sqrt{S}$. W indicates the ratio of the weight of the sheet wall (exclusive of the spars) to the weight of a sheet secure against shear (exclusive of the weight of the bracing), so that the figures after the decimal point give approximately the comparative weight of the bracing. The weight of the sheet only is, at a given shear load, approximately the same for all heights of the beam.)

be provided. If, for example, cross-braces are chosen, the moment of inertia of these braces has to be determined from the formula previously given, in which the resistance to bending of the sheet proper, namely, the value $s^3/12$, must be inserted for I_z/d_z.

$$\left(\frac{I_v}{d_v}\right)^3 \frac{s^3}{12} = \left(\frac{Sh}{33E}\right)^4$$

If such cross-braces are chosen as are customarily used for airplanes, it will be found that they can be very light, their weight amounting to about 17 per cent of the weight of the metal sheet. Bracing the sheet also in a horizontal direction, most easily and simply accomplished by corrugations or by the use of corrugated sheet metal, would result in an additional reduction of the weight of these profiles. By these means the moment of inertia in horizontal direction is materially increased so that now the stiffness of the cross-braces may be decreased. Then the weight of the cross-braces amounts to only about 12 per cent of the weight of the metal sheet.

At the given shear load of 10,000 kg. (22,000 lb.) the thickness s of the wall is decreasing more and more with increasing height of the beam. If no special longitudinal braces are provided the moment of inertia I_v of the cross-braces would, according to the equation, have to increase disproportionately fast in order to provide sufficient resistance to buckling. For beams of such a height only corrugated sheet is used. Then the weight of the

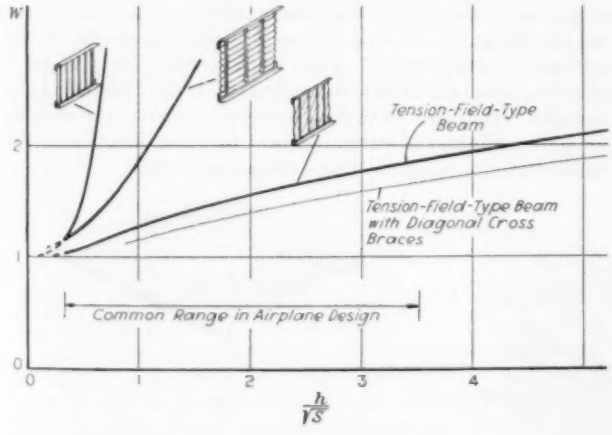

FIG. 4 RELATION BETWEEN W AND $h/\sqrt{S}$

(The ratio W of the weight of the sheet wall, without spars, to the weight of a sheet secure against shear, exclusive of the weight of the bracing, is plotted against the factor $h/\sqrt{S}$ for various designs of sheet-metal beams (plane sheet metal securely braced against shear by cross-braces; corrugated sheet with longitudinal corrugations and braced by cross-braces; tension-field-type beams with vertical cross-braces; tension-field-type beams with cross braces arranged at an angle of 120 deg. to the spars). In this sheet, which is secure against shear, the allowable shearing stress τ is equal to 1500 kg. per sq. cm. (21,300 lb. per sq. in.). See also Fig. 3.)

cross-braces rises only slowly with increasing height of the beam, amounting to about 65 per cent of the weight of the metal sheet for a beam 100 cm. (39.37 in.) high, which should be 0.7 mm. (0.0276 in.) thick.[3]

These examples show how the design of beams with various heights may be determined when they are subjected to a shear of 10,000 kg. (22,000 lb.). These most favorable types of design also hold true for any other values of shear as long as the value $h/\sqrt{S}$ is the same as in these examples. This can easily be understood from the law of similarity[4] as applied to the science of the strength of materials.

In Fig. 4 W, the ratio of the weight of the sheet wall, exclusive of spars, to the weight of the sheet secure against shear, exclusive of bracing, is shown to rise with increasing value of $h/\sqrt{S}$.

The values of $h/\sqrt{S}$, which are common in airplane design, vary between about 0.3 and 4 cm. kg.$^{-1/2}$. For the side wall of a fuselage having a height of 200 cm. (78.74 in.) and which has to resist a shear of 3600 kg. (7920 lb.) the value of $h/\sqrt{S}$ will be 3.3. As, for such high values of $h/\sqrt{S}$, the added weight of the bracing would be quite considerable, the construction is modified by making some of the cross-braces especially stiff (see Fig. 5).[5] Such strong frames are also often necessarily employed for other

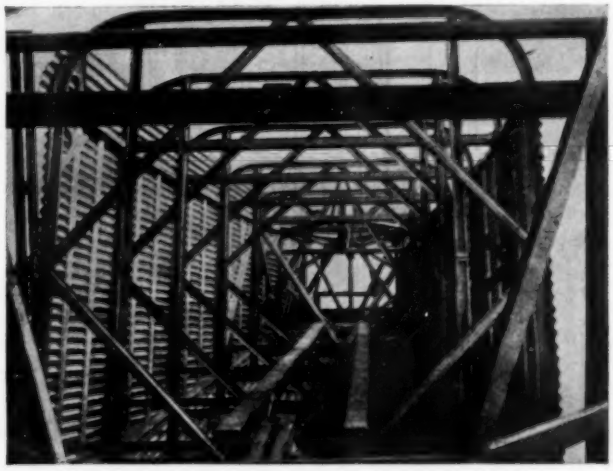

FIG. 5 INTERIOR OF THE FUSELAGE OF A JUNKERS AIRPLANE, SHOWING THE STRONG FRAMES, BETWEEN WHICH THE CORRUGATED SHEET IS STIFFENED BY BRACES

purposes, as, for instance, in the passenger cabin for taking up the loads.

The strength of such a construction can likewise easily be determined. (See Fig. 6.) According to well-known principles a shearing stress in a vertical direction is always accompanied by an exactly equal shearing stress in a horizontal direction. The sheet-metal wall between two strong frames, therefore, has to be considered as a beam with the height d, which has to transfer the horizontal shear $\left(S\frac{d}{h}\right)$ from the bottom spar to the top spar; and the corrugated sheet with its bracing must be dimensioned accordingly.

Thus far the resistance of braced sheet-metal walls to shearing forces has been considered. There follows now a discussion of the resistance to compression forces in the direction of the spars.

Consider, for instance (Fig. 7), the top of a square fuselage subjected to the stress set up by an elevator reaction, which produces compression stresses in the upper sheet-metal wall and the upper spars. If the upper sheet-metal wall were not sufficiently braced it would buckle as indicated in Fig. 7. The pressure X, at which this occurs, may be comparatively easily calculated as follows:

[3] The weight of the sheet wall is, of course, also dependent on the kind of corrugations. In the case under consideration, corrugations having a depth of 15 mm. (0.59 in.) have been assumed. For the same reason the curve for corrugated sheet in Fig. 4 is true only for certain dimensions customarily used for airplane design. The curve of the value W for tension members, however, is only slightly dependent on the cross-sectional form of the cross-braces.

[4] For details see Professor Wagner's treatise, "Einige Bemerkungen über Knickstäbe und Biegungsträger," in the *Zeitschrift für Flugtechnik und Motorluftschiffahrt*, vol. 19 (1928), no. 11.

[5] The illustrations of the Junkers designs have been taken from Langsdorff's book "Fortschritte der Luftfahrt," by courtesy of H. Bechhold, Frankfurt am Main.

$$X = \frac{20E}{h}\sqrt{\frac{I_v}{d_v}\frac{I_z}{d_z}} + \frac{10G}{h}\frac{T_v}{d_v}$$

From this equation the relations of the weight of the material and the height and pressure, i.e., $h/\sqrt{X}$ may be derived; these relations being quite similar to those assumed when the effect of shear was studied. A brief discussion of the equation will suffice. The first half of the equation contains the moments

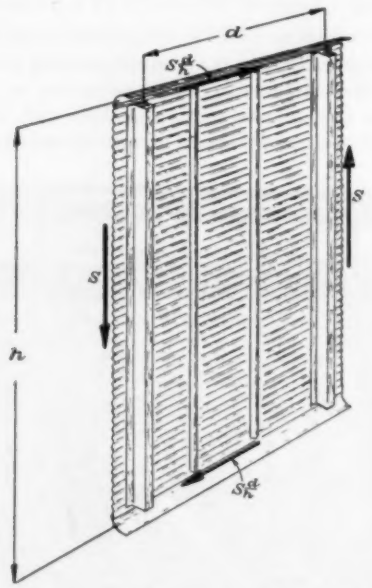

FIG. 6 THE DIRECTION OF FORCES IN THE SHEET-METAL BEAM OF FIG. 5

of inertia of both bracing members, both factors being of the same power. In the second half of the equation GT_v is the resistance of a cross-brace to torsion. This half of the equation may be neglected if the cross-braces have so-called "open sections" (see Fig. 7), which have little or no strength in torsion. Cross-braces, however, built up of closed (tube-shaped) profiles or which together with the corrugated sheet form a channel-like cross-section, as shown in Fig. 7, have considerable resistance to torsional stress. A numerical evaluation makes it apparent that the compression strength of the wall is thereby approximately doubled. At all events, closed profiles are to be preferred for corrugated sheet-metal structures.

An examination of the equation furthermore shows that even when using comparatively heavy cross-braces and coarsely corrugated sheet the compression strain in the corrugated sheet metal lies, in most cases, well below the yield point (about 2600 kg. per sq. cm. = 36,972 lb. per sq. in. for duralumin), which means that the material may not be used to its full advantage. These difficulties can be evaded by curving the surfaces as in Fig. 8. Although numerical data on this type are not available it is certain that the resistance to compression forces is considerably increased.

So far sheet-metal walls which are braced against forces of shear and compression have been discussed. The following discussion covers another type of design developed years ago by the author when he was with the Rohrbach Metallflugzeugbau and described in 1929.[6] The present discussion is limited to the most essential points.

Fig. 9 illustrates a sheet-metal wall, consisting of upper flange, lower flange, a thin sheeting, and cross-braces subjected to a shear S. At a very small load the thin sheet will buckle diagonally.

It has been shown that the sheet may be prevented from buckling by arranging cross-braces very close to each other. What will happen if the distance between the bracing members is so large that the sheet may buckle almost unhindered?

After the first buckling the load may be considerably increased, for example, a hundred or thousand times, without collapsing the beam or rendering the surface excessively uneven. The wrinkles in the surface may attain a depth of perhaps 3 mm. (0.118 in.) and a width of perhaps 100 mm. (3.94 in.), thus representing only very slight corrugations.

Fig. 10*a* shows a square sheet of very thin metal, which is assumed to be as thin as paper. This may be wrinkled (Fig. 10*b*) without applying much force, thereby somewhat diminishing the edge-to-edge distance a. Tensile stresses acting at the upper and lower ends of the sheet in the direction of the wrinkles (Fig. 10c) will not change the direction of these wrinkles, though their depth will be somewhat reduced by the lateral contraction. There is no force acting in the sheet perpendicularly to the direction of the wrinkles. The direction of the greatest elongation of the sheet is, for such conditions of stress, identical with the direction of the tensile strain, thus representing a single-axial strain.

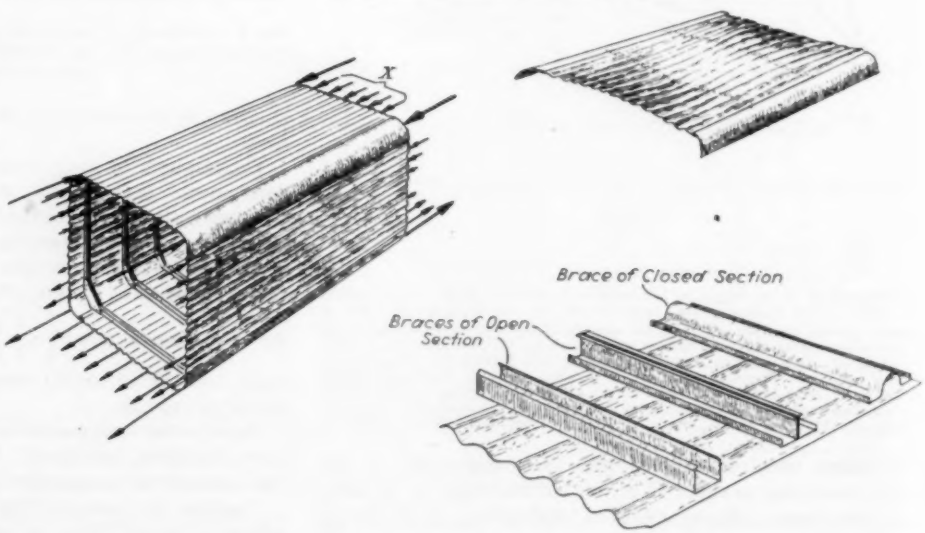

FIG. 7 FUSELAGE UNDER A STRAIN OF FLEXURE
(The upper right-hand corner illustrates the buckling of the upper sheet-metal wall due to the shear S. The lower right-hand corner shows braces of open and closed sections.)

Attention is called to a phenomenon of disturbance caused by the fact that the edges are not free, but are riveted to braces. It will be noted from Fig. 11 that the edges themselves cannot

(The upper surface is curved, which increases the resistive strength against forces of compression. The braces can be clearly distinguished.)

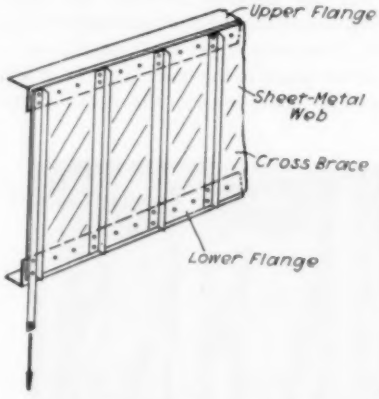

FIG. 9 TENSION-FIELD-TYPE BEAM

not change the direction of the greatest elongation of the sheet or the direction of the wrinkles, which remains 45 deg. This means that the diagonals are not running from I to II (see Fig. 12*d*), but at an angle of 45 deg., their direction being, in the case of rigid rods, independent of the distance between the rods.

Fig. 13 et seq. illustrate a few experiments with "tension-field-type" beams made several years ago at the Rohrbach Works.[7] Fig. 13*a* shows a sheet-metal beam supported at the right end and carrying a load of shot-bags by means of levers. Upper flange, lower flange, and the thin sheet-metal wall can easily be recognized. The position of the cross-braces on the back of the beam is recognizable from the riveting. All dimensions of the experimental model are to scale.

The tension wrinkles are distinctly visible and appear rather uniformly over the whole sheet. The shear in the beam increasing to the right, because of the load on the different rods, the wrinkles in the right part of the sheet are more strongly formed than those in the left one. The difference, however, obviously is not great. The load shown on this picture is far beyond that at which the first buckling of the sheet occurred. This initial buckling could be caused by slightly pressing one of the levers by hand, i.e., by a shear of very few pounds. The

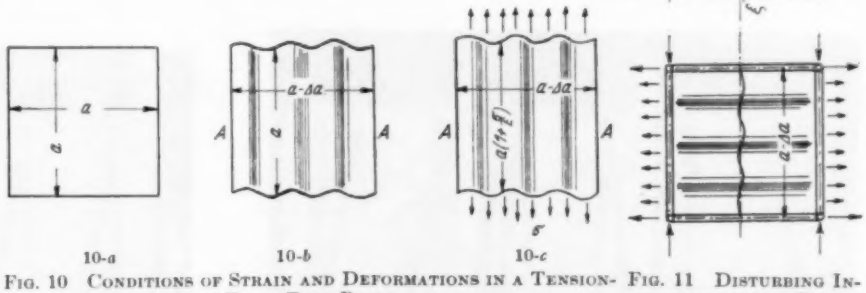

FIG. 10 CONDITIONS OF STRAIN AND DEFORMATIONS IN A TENSION-FIELD-TYPE BEAM

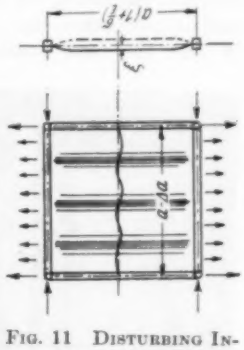

FIG. 11 DISTURBING INFLUENCE OF THE EDGES

wrinkle. It can, however, easily be shown that this disturbance is of no importance to further considerations.

A simple but important practical example may be illustrated by Fig. 12. Fig. 12*a* shows a frame formed by four rods which are to be pin-jointed to each other and are assumed to be perfectly rigid. A thin sheet is to take up the shear. Because of this shear S, shearing stresses τ will become effective within the sheet metal. The direction of the main stresses is at an angle of 45 deg. to the direction of these shearing stresses. The main stress σ_1 sets up a tensile strain, its direction being identical with the direction of the greatest elongation of the sheet metal. The other main stress σ_2 causes a compression strain. If the sheet is very thin it will soon buckle under the effect of the compression strain and wrinkle in the direction of the tensile strain, σ_1 (Fig. 12*b*). With further increase of the shear S the tensile strain σ_1 will rise rapidly until, at very high loads, it will take up nearly all the shear. Thereby the field has buckled uniformly. Such a field is called a "tension field."

The value of the tensile strain σ_1 can easily be calculated as follows:

$$\sigma_1 = \frac{2S}{as} = 2\tau$$

The equation shows that the tensile strain is twice as great as would be the shearing strain, if the sheet would withstand shear.

Adding (see Fig. 12*c*) another equally rigid rod to the four rods and pin-jointing the new one to the rods O and U naturally would

wrinkles shown in this illustration do not represent permanent deformations. They disappeared entirely after the load had been

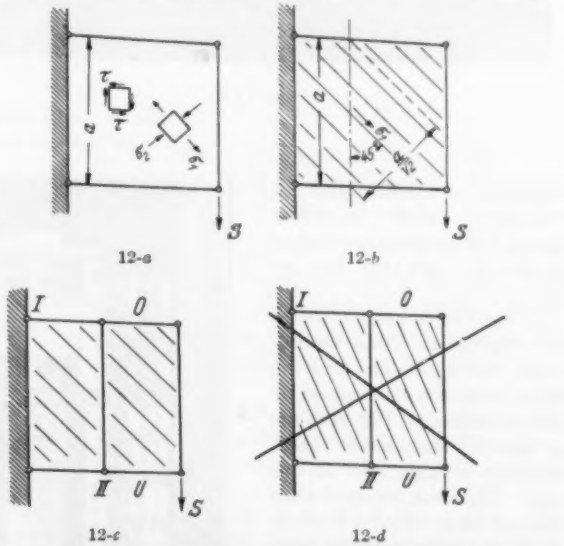

FIG. 12 THIN SHEET WITH RIGID RODS AT THE EDGES AND LOADED BY A SHEAR S

[7] On the occasion of a lecture delivered in Danzig, Dr. Rohrbach permitted the author to publish the pictures of these tests.

removed. Permanent deformations appear only when the tensile strain in the sheet has nearly reached the yield point. This is hardly influenced by the local transverse strains which are caused by the formation of the wrinkles.

Fig. 13*b* shows the beam from the back, under an appreciably higher load. The tension field, indicated by the wrinkles, stands out very distinctly. The angle between the spars and the direction of the wrinkles, which, as stated, is 45 deg. in the case of perfectly rigid rods, is in this case somewhat smaller on account of the flexibility of the cross-braces. It is about 40 to 42 deg., which is in accordance with the calculation.

At the load applied in Fig. 13*b* the yield point of the sheet has already been somewhat exceeded. It is of great importance to the simplicity of calculation that the conditions of the stress in the sheet and the braces are not essentially changed even when the yield point in the web has been exceeded. On the contrary, the assumption of negligibly small transverse strength of the sheet now proves to be even more true than before.

In Fig. 13*c* the beam is shown after the break of the vertical rods, the allowable load on which was being determined by this experiment. Fig. 14 shows a similar sheet-metal beam carrying a single load on one end. The break occurred when the web tore. Such a tension-field-type beam may be compared with a framework having cross-braces placed in the same direction and diagonals at the same angle of 40 deg. as that of the tensile strains in the web of the beam (see Fig. 15). If, for the diagonals in a framework, straps are used of such a width that two adjacent ones just touch each other, and provided that they are of the same thickness as the sheet of the beam, these straps will be stressed to the same extent as the sheet.

In a tension-field-type beam the spar of each field between two cross-braces (see Fig. 16) is bent toward the sheet metal by the tensile strains in the web acting at the spars. The cross-braces which support both spars against these forces are subjected to compression loads which tend to cause buckling. Any of these stresses can be calculated very easily. The results of such calculations are, in accordance with the results of the tests, the following:

If the distance between the cross-braces is chosen within reasonable limits, such as being equal to about $1/6$ to $1/3$ of the height of the beam (i.e., the length of the cross-braces), the bending moments in the spar caused by the pull of the sheet have practically no effect upon the strength of the spars. On the contrary, the resistance of the spars to breaking strain is very high because of the comparatively close arrangement of the cross-braces which support the spars.

Furthermore, the deflection of the spars between two cross-braces on account of this pull of the sheet is so small that the spars may be assumed to be rigid. If great deflections of the spars were to occur the tensile strains in the web would become unequal and the direc-

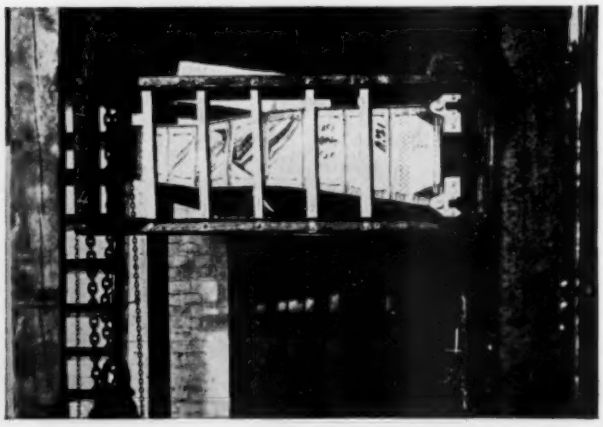

FIG. 14 A TENSION FIELD UNDER LOAD
(The break occurs when the web tears.)

tions of the wrinkles and tensile stresses respectively would no longer be parallel. In accordance with the calculation, such things, however, do not happen. Yet should this happen to a certain degree, due to the weakness of the spars, this problem could be checked comparatively easily by calculation, at least as far as this is of practical importance.

This unexpectedly high stiffness and resistance of the spars to bending forces is an essential fact. Thus, for instance, as the author subsequently heard, a Mr. Rode, in referring to deliberations of American engineers, called attention, in the Austrian magazine, *Der Eisenbau*, in 1917, to the observation that a web, after buckling, could still transmit forces by resisting tension. But, as Mr. Rode fears the insufficient transverse strength of the

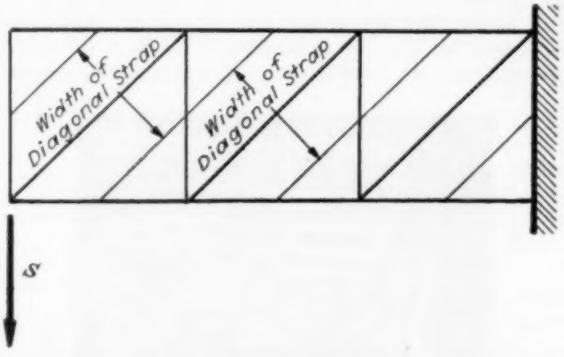

FIG. 15 COMPARING A TENSION-FIELD-TYPE BEAM WITH A FRAMEWORK BEAM

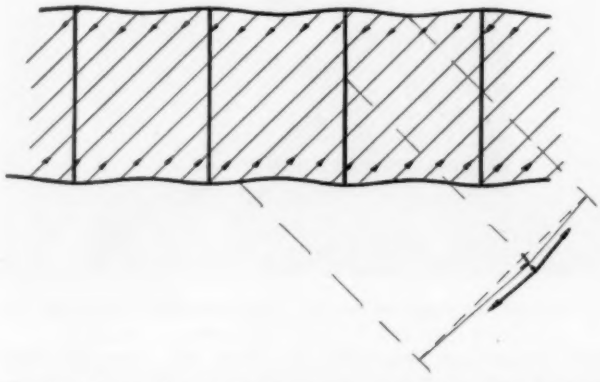

FIG. 16 SPARS AND CROSS-BRACES OF A TENSION-FIELD-TYPE BEAM UNDER STRAIN
(The strained sheet complicates buckling of the cross-braces.)

spars, he consequently does not conclude that such a design can actually be carried out to advantage.

It has been shown that the cross-braces are under compression strains. (See Fig. 16.) They must, therefore, be stiffened to prevent buckling. However, this stiffness can be comparatively small since the strained sheet metal holds them in place. For when a cross-brace buckles and moves out of the plane of the sheet metal it must also move the sheet to which it is riveted. Thereby the tension lines of the sheet suffer a displacement at the cross-brace with the result that the reaction of the stress lines against the cross-brace exert a force which is opposed to the buckling force. This essentially increases the resistance of the cross-braces to buckling stresses. This resistance has been calculated by the author. Depending on the distance between the cross-braces, it is about 4 to 7 times as great as Euler's buckling load for unsupported columns.

The cross-braces may also be arranged at an angle to the spars (see Fig. 17), in which case, under certain conditions, the member may be built lighter. Arranging the cross-braces at an angle of 120 deg. to the spars will have the least weight. The total weight of the web plus the cross-braces is thereby decreased by 15 per cent as compared with a sheet-metal wall having cross-braces arranged perpendicularly to the spars. However, this advantage can be used to the full only when the external shear S_1 acts essentially in one direction only. For this beam with diagonal cross-braces is considerably less resistant to the shear S_2 in the opposite direction. The shear S_2 in the direction shown must not exceed a value equal to about $^1/_3$ of the shear S_1.

In Fig. 4 a curve has been plotted which represents the weight required for such tension members. It will be noticed that

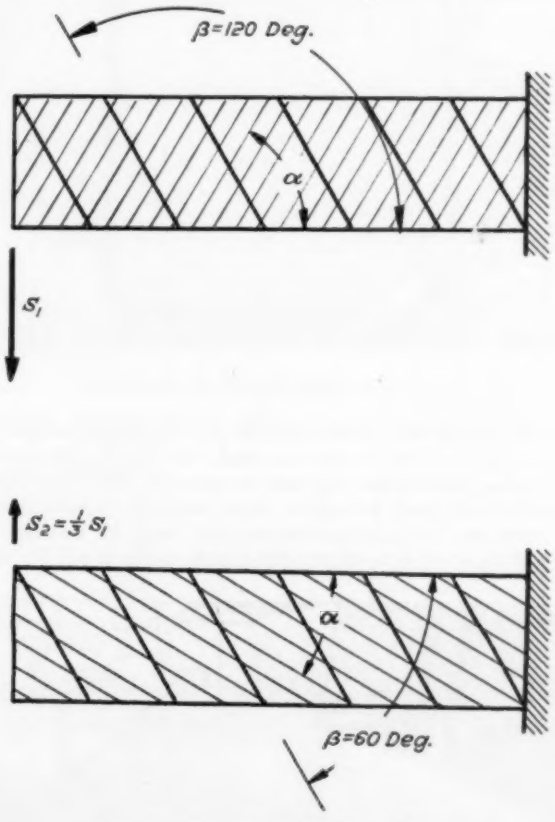

FIG. 17 EFFECT OF REVERSING LOAD
(The direction of the wrinkles [tensile strains] is changed if the external load S is reversed. The direction of the wrinkles approximately bisects the angle between the spars and the cross-braces, $\alpha = {}^1/_2\beta$.)

beams of great height and comparatively small shear, i.e., with high values of $h/\sqrt{S}$, are essentially lighter, for example, than corrugated sheet metal amply stiffened against buckling. Since these high values of $h/\sqrt{S}$ are frequently encountered in airplane design these tension-field-type beams are particularly suitable for airplane design.

Fig. 18 shows a frame of a Rohrbach seaplane, whose bottom beam has been designed as a tension-field-type beam. Figs. 19 and 20 show the hull, the walls of which represent tension-field-type beams.

The weight requirements for sheet-metal beams (Fig. 21), which must resist, in particular, longitudinal forces in addition to the shearing forces, will now be discussed.

In a fuselage made up of sheet-metal walls which are braced to resist buckling not only the spars but also the corrugated sheet-metal sides resist longitudinal forces. It should be observed

that as the spars used at the edges of the fuselage are directly restrained against buckling in both directions, they can resist a much higher compression stress than can the sheet-metal wall which is held against buckling only by comparatively easily bending beams, namely the cross-braces. Naturally the permissible compression strain depends on the weaker member of the structure. Thus, on the one hand, the force in the spars of this type of construction decreases because the sheet metal takes up part of this force, and on the other hand, the cross-section of the spars has to be made comparatively large for this smaller force, if the sheet is to be prevented from buckling out and sustaining greater and permanent deformations before the calculated breaking load is reached.

FIG. 18 FRAME OF A ROHRBACH SEAPLANE

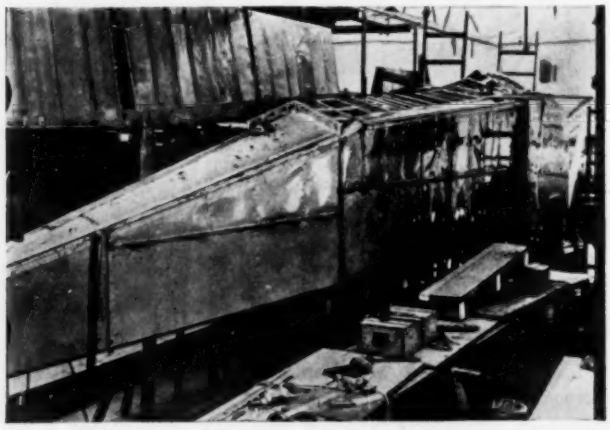

FIG. 19 HULL OF A ROHRBACH SEAPLANE
(The surface walls are designed as tension-field-type beams.)

In the tension-field-type beam the sheet metal buckles under a very small compression load and therefore does not resist compression loads to any appreciable extent. But as this buckling of the thin sheet metal takes place without appreciable strain and no permanent deformations remain after removing the load, the spars may be loaded as highly as warranted by the fact that they are supported by the adjacent walls of the fuselage. Though they must resist all of the longitudinal force in the tension-field-type beam they may, nevertheless, under certain conditions, be lighter than the spars of the sheet-metal beam which is securely braced against shear and compression.

Consider now the stresses in a wing of the Junkers type such as is shown in Fig. 22. The corrugated sheet metal, the corrugations of which are in the direction of flight, is fastened to strong spars that resist the bending moment. The torsional moment appearing during a vertical dive puts the corrugated sheet under a shear load. The sheet, therefore, has to be braced between the spars by longitudinal braces. These braces, running parallel to the spars, can be noticed in Fig. 22. How do these longitudinal braces behave under compression forces when the wing is bent?

The longitudinal braces are held by the corrugated sheet metal against buckling out of the plane of the sheet wall and, the cross-sectional area of the longitudinal braces and consequently their compression load being very small, the corrugated sheet metal is such an effective support that the permissible compression strain in the longitudinal braces is hardly lower than that in the spars. This can easily be proved with the help of the equation previously given for the compression forces in such sheet-metal walls.

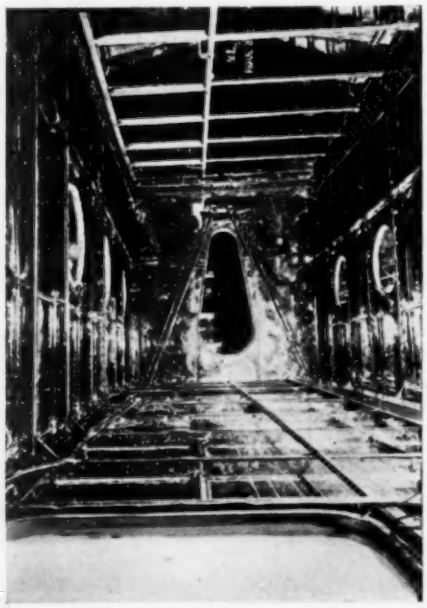

FIG. 20 INTERIOR OF THE HULL OF A ROHRBACH "ROMAR"

We have thus arrived at a result quite similar to that obtained for the tension-field-type beam, i.e., the sheet-metal wall serves only to resist the shearing forces. The spars resist nearly all the longitudinal forces, but, on the other hand, may be loaded as highly as conforms to their being well supported in two planes.

Fig. 23 shows a Junkers wing which has the spars spaced so closely that the corrugated sheet need no longer be stiffened by special cross-braces.

It has been shown that sheet-metal beams may either be fitted with sheet metal which is securely braced against shear or be designed as tension-field-type beams. A warning should be issued against the middle course. If a web is made with corrugations, as shown in Fig. 24, and if the distance between these corrugations is made larger than would conform to the optimum strength of the plain, smooth part of the sheet between the corrugations against shear, then this part of the sheet will buckle

and exert tensile forces on the corrugations. This stretches out the corrugations, and ugly bumps or protrusions will remain in the sheet when the load is removed. Even in the case where special diagonal bracing is used to resist the shearing forces, the distance between the corrugations must be chosen cautiously.

Thus far the structural weights of different sheet metal constructions have been compared with each other. There remains the comparison between the weight of these constructions and that of fabric-covered structures. This comparison will give different results, depending on the size of the airplane. Since the external forces exerted by the air on the plane and, consequently, the shearing stresses in the sheet-metal beams are rising at least with the square of the lineal dimension, the thickness of the sheet required for taking up the shear increases at least in direct proportion (linear) to the size of the plane.

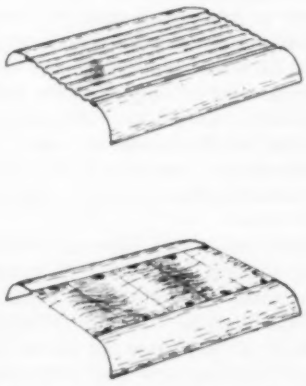

FIG. 21 SHEET-METAL BEAMS AND TENSION-FIELD-TYPE BEAMS SECURELY BRACED AGAINST SHEAR AND COMPRESSION AND UNDER A LOAD OF COMPRESSION FORCES ACTING IN DIRECTION OF THE SPARS

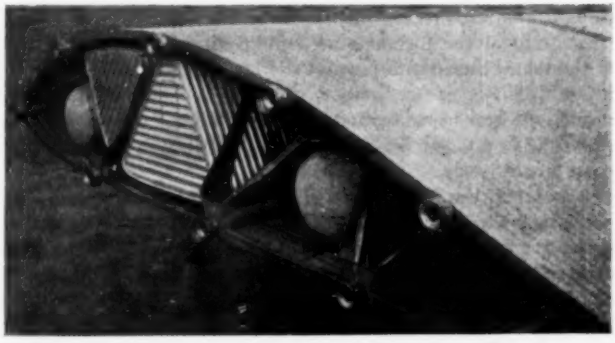

FIG. 22 INTERIOR OF THE WING OF THE "BREMEN" (JUNKERS W 33)
(Note the longitudinal bracing running parallel to the spars.)

For small airplanes the required thickness of the sheet is so small that the sheets must be made thicker than this calculation would demand in order to make them secure against accidental local stresses. Moreover, sheets less than 0.3 mm. (0.0118 in.) thick are difficult to manufacture in sufficiently large sizes and such a sheet-metal construction will, under these conditions, of course, be heavier than a small fabric-covered plane. It should be added that for small and medium-size airplanes, corrugated sheet metal appears to be preferable to smooth sheet metal because it has a higher resistance to local stress and because very thin plane sheets are easily deformed in riveting.

However, for larger airplanes the strength in shear is the deciding factor as far as the thickness of the sheet metal is concerned. Such fully utilized sheet beams are, at all events, lighter than a framework, if they are, for example, built as tension-field-type beams. For heavily loaded, very large planes, therefore, the metal-covered type may be the most favorable solution in so far as weight is concerned. However, those parts of the wings, even of large planes, which are under little strain, particularly in the neighborhood of the trailing edge, may be covered with fabric, as it has been done, for example, on the huge Dornier seaplanes "Superwal" and "DoX."

Fabric-covered airplanes have been compared in this paper with metal-covered ones only with regard to their respective weights. The other advantages and disadvantages are so well known that only brief mention is necessary.

Metal-covered planes require a greater amount of work in the design room and the shop and are a little more difficult to repair. The construction of the wings of very small planes is particularly difficult.

Metal-covered wings have a greater air resistance than those

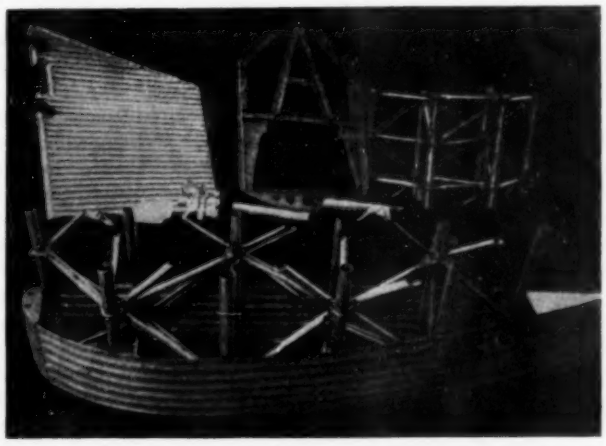

FIG. 23 JUNKERS WING
(The spars are arranged so closely that the corrugated sheet is secure against shear even without special bracing.)

covered with fabric. This holds true not only for corrugated-sheet-metal but also for smooth-sheet-metal covering, as this deforms under the strain of the air pressure and because the frictional resistance is increased on account of the rivets and especially bracing placed on the outside. The advantages of metal-covered airplanes are their durability and lower fire hazard. Very large all-metal airplanes are lighter than fabric-covered ones. The use of wood for pontoons as compared with the use of metal has the disadvantage of water-logging and thereby increasing the gross weight.

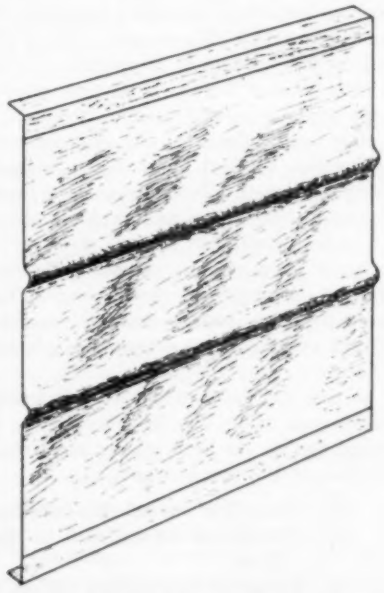

FIG. 24 SHEET-METAL BEAM WITH LONGITUDINAL CORRUGATION
(If the distance between the corrugations in a plane sheet is too great the sheet will buckle between the corrugations and exert tensile stress on the corrugations in a manner similar to the tension field. These are thereby stretched out.)

An attempt has been made in this short paper to survey the most important problems of strength encountered in the design of metal-covered airplanes. The discussion has been restricted to plane sheet-walls, because the problems of strength of curved sheet-walls have not yet been settled entirely.

Discussion

COL. V. E. CLARK.[3] The paper is most interesting and valuable at this time because of the rapidly increasing use of duralumin and "Alclad" monocoque construction in this country.

It is believed that there is at present more need for experimental data on the sheer strength of thin plate girders and reinforced shells than on any other phase of airplane structure. In a way the use of the term "sheer" is an unfortunate habit among engineers as it tends to obscure the fact that shear in the web of a beam is a combination of diagonal tensile and compressive forces acting at right-angles to each other. A thin web without vertical stiffeners is buckled in compression at a comparatively small stress.

In the case of a girder employing vertical stiffeners refitted to a thin web, the compressive stresses must be confined largely to the stiffeners and the chords, since the web is effective only for tensile stresses. There is no sharp division between the case where the web will support the compressive component and where it will not. The allowable compressive stress in the web is gradually reduced as the d/s ratio is increased. (d = minimum spacing of reinforcing members.) The addition of vertical stiffeners to a thin web not only provides additional compression-resisting cross-sectional area, but also undoubtedly increases the ability of the web to support diagonal compression.

Credit is due Dr. Wagner for inviting attention to the fact that the shear strength of thin webs is a function, not only of the spacing of stiffeners, but of their compressive strength as well.

There is an important difference between the plate girder and the side wall of a stiffened monocoque shell of curved cross-section. The shear strength of the former is reduced by the bending inward of the chord members, while the continuity of the latter avoids this marginal effect. The flat-sided fuselage with square corners is comparable to the plate girder, but is of little interest because of its poor aerodynamic qualities, awkward appearance, and tendency toward "drum-head" vibration.

It is very difficult to obtain experimental results applicable to fuselage or float construction without testing a complete monocoque shell. Tests demand the provision of a plate girder simulating continuity and avoiding the usual marginal effect.

The Southwell-Skan formula given by the author is applicable to beam webs without vertical stiffeners where the web must support diagonal compressive loads. The fact needs emphasizing that it is not applicable to panels bounded on all sides by stiff margins or to continuous skin stiffened by frames and stringers.

Testing and development work in metal monocoque construction is well under way in this country, but the application to design has so far been wholly empirical. A few of the complexities of the problem are:

(1) Strength of curved skin in compression due to bending
(2) Strength of curved skin in diagonal tension due to shear
(3) Design of longitudinal stiffeners to withstand inward component of tension in skin
(4) Strength of main bulkheads
(5) Loads on and strength of curved frames.

The writer would like to put a few questions regarding details and uses of the formula presented by the author that do not seem clear.

In the formula giving the shear force S required to buckle walls, I_z and d_v are not explained. Is the assumption correct that I_z is the moment of inertia of the section of the longitudinal reinforcements, d_z the distance between them, and I_v the moment of inertia of the transverse reinforcements, and d_v the distance between them? If this is true, how would the value of I_z/d_z be calculated in the tail portion of a monocoque fuselage where there are no longitudinal reinforcements and the skin is corrugated? Could each corrugation be treated as a reinforcement and d_z be the pitch of the corrugations? It is interesting to note that, should this formula be applied to smooth shell structures, the maximum shear load is governed entirely by the properties and location of the reinforcements and is independent of the skin thickness. It would have been interesting had the author explained how this formula could be applied to the tail section of a monocoque fuselage when a smooth skin and a large number of equal size longitudinal reinforcements are used.

The article does not state whether the constants in the formulas are calculated for the metric or English system of measurement.

The subject of allowable shear stress in a thin reinforced sheet is very interesting at the present time. It is regretted that Dr. Wagner did not present the actual test data or explain the deviation of the Southwell-Skan formula. Using the English system of units in this formula, it is found that for values of $d/s = 50$, where d = diameter of tube and s = wall thickness, it gives values comparable with those we use. For values in tubes with d/s less than 50, it gives values proportionally higher than those now recommended in this country. For values in thin web beams and monocoque shells with cross-bracing, where $d/s = 100$ to 350, it gives values far below those based upon our test data. It is believed that in reinforced smooth skin structures d/s is seldom less than 100.

A study of the formulas used for computing the properties of the reinforcements to prevent the buckling of the web is very interesting. It is understood that I_z/d_z = the moment of inertia of a transverse section of a longitudinally corrugated web of width d_z divided by the width or the height, as in a wing spar.

Apparently the deeper the corrugations, the greater will be the shear load capacity of the web. It is regretted that the author did not give this optimum depth for the best strength-weight ratio—the depth governed by the sheet thickness and d_z. It would be interesting to know if the same formula may be used for the so-called "wandering web" used sometimes in wing spar webs where the corrugations are large in proportion to the sheet thickness and lie normal to the plane of horizontal shear. If it is applicable, then d_v must be the pitch of the corrugations and I_v the moment of inertia of a cross-section of a complete corrugation, about its neutral axis.

The author's formula giving the allowable compressive load presents a very interesting question—whether the sectional properties and spacing of the longitudinal and transverse reinforcements have an equal effect in calculating the allowable compressive load. It appears that the material in the longitudinal reinforcements, if any, has a dual purpose—that of preventing the skin from buckling and that of carrying some of the compressive load directly while the transverse reinforcements simply prevent the skin and longitudinals from buckling and do not carry any of the compressive load which is acting normal to the transverse members. The same formula contains another very interesting factor—that of the effect of the torsional strength of a transverse reinforcement. Is it correct to calculate T_v as the torsional moment that the section of the transverse member will carry at the ultimate or yield point and G as the torsional modulus of elasticity? It is not clear in the paper how this strength affects the allowable compressive load normal to the reinforcement. It is noted that the author did not compare the diaphragm or bulkhead type of transverse reinforcement with the ring type. In the design of a bulkhead

[3] Buffalo, N. Y. Mem. A.S.M.E.

is I_s calculated for a section from the center to the outer fiber at a point in question?

In applying this formula to a monocoque fuselage covered with corrugated sheet and not employing any longitudinal reinforcements, is it correct to calculate I_x as the moment of inertia of a cross-section through one corrugation of the skin and d_x as pitch of corrugation? Again, it is interesting to note that in applying this formula to a smooth-skin monocoque structure the thickness of the skin does not enter into the calculations for the maximum compressive load when I_s and I_x apply to the transverse and longitudinal reinforcements, respectively.

The writer agrees with Dr. Wagner that the radius of curvature has an important influence on the allowable compressive stress in the region of small radii.

It has been our experience that the effect of the radius of curvature on the allowable compressive stress in a smooth metal monocoque shell cannot be plotted as a linear function. From test data available it appears that the effect of an increase in the radius of curvature is practically negligible when the radius of curvature is greater than 1300 times the skin thickness, while the reduction of the radius of curvature from $300t$ to $200t$ increases the allowable compressive stress about 9 per cent, where t = sheet thickness, and for smaller radii the rate of increase is greater.

It has been found that failure in compression in metal monocoque structures results in an inward buckling of the skin and reinforcements. This is apparently due to the eccentric loading of the reinforcements.

The author has made detailed refererce to square-section bodies where four main longerons are used to carry the principal stresses. It would have been interesting had he treated a round or elliptical section with a number of longitudinal reinforcements all having the same section. In such structures there are regions of the skin that lie between the regions supporting maximum shear and those supporting maximum compression that are subjected to both shearing and compressive forces. It is believed that in these regions a careful study should be made to select the proper amount of skin or shell reinforcement.

It is interesting to note that the author gives an angle of 120 deg. between the longitudinal and transverse reinforcements as the best angle to take shear in one direction. Since in the opposite direction we require in the case of wing spars about one-half the main strength and this angle reduces the strength to one-third, this rule might not be applicable to wing-spar design.

The author's reference to "tension field type" beams apparently applies to all reinforced thin sheets where d/s is large and the sheet wrinkles under a light shear load which is actually carried by tension lines. The author states that beams built as the "tension field type" are "lighter than a framework." This might open a discussion for those who are fostering the truss type of construction for very deep units. It is assumed that the author means "truss" when he uses the word "framework."

It would have been interesting had the author given a general idea regarding the amount of reduction in performance when corrugated covering is used on fuselages. The increase in drag may be partly due to the angle existing between the line of air flow and the axis of the corrugation.

Closure by J. Otto Scherer[9]

Colonel Clark's discussion of the paper brings up a number of interesting points. The writer is sorry that he cannot answer the questions as to the derivation of the formulas, etc., but believes such should be answered by Dr. Wagner himself.

Dr. Wagner, it appears, has rather slighted two important forms of all-metal construction, forms which are steadily increasing in popularity in this country, while making a case for the "tension field" beam, with which he has had extensive experience and which has given very good results.

With regard to the increased drag caused by the wrinkles appearing in the "tension fields" of Dr. Wagner's beams, it might be pointed out that about two years ago the D.V.L. published the results of rather extensive full-scale tests conducted to determine the effect of skin smoothness on drag.

These tests showed that an absolutely smooth surface gave a considerably lower drag. However, as soon as this surface was marred, if even only to the extent necessitated by countersunk rivet heads, the drag increased to a "normal" figure, which varied but little for all the usual types of covering.

By "usual types of covering" are meant a fabric covering, as normally applied and finished, a plywood covering with its ever-present small unevennesses, a smooth metal skin with either countersunk or round-head rivets, and the corrugated Dural skin. The "tension field" construction would probably present surfaces about the same as a normal plywood wing covering.

With regard to the corrugated-skin construction, it may be of interest to mention that the Junkers Works use two depths of corrugation, depending on whether the structural stresses carried by the skin are relatively high or low. On such parts as the fuselage and the portions of the wing near the fuselage, the corrugations have a depth equal to $^1/_3$ the pitch, while on the outer parts of the wing, etc., the depth of the corrugations is only $^1/_6$ pitch.

The metal monocoque fuselage employing a corrugated skin is usually strong enough to carry all the flying loads, even though no longitudinals are incorporated. Experience, however, has shown that it is desirable to run a rather stiff longitudinal along the bottom center of fuselages of oval section or along the lower corners of those of rectangular section. Such longitudinals are of considerable value in protecting the fuselage against damage incident to accidental mishandling on the ground.

In conclusion may one take the liberty to remark that, though designers in this country are, on the whole, inclined toward types of all-metal construction in which the skin is designed to carry the compression as well as the tension components of the shear stresses, Dr. Wagner's type of construction is well worth consideration and well applicable to good advantage on a number of types built in the United States today.

The "tension field" construction could nicely be applied to almost all jobs which make use of a rectangular welded steel-tube fuselage with fabric covering. The fabric, with its dope, weighs just about as much as a thin Dural sheet, but does not contribute anything to the strength of the structure. The Dural sheet, on the other hand, can safely be included in the structure, making possible a reduction in the weight of the trussing without any sacrifice of strength.

APM-53-1

The Stresses in Rotating Disks

By THOS. H. FROST,[1] CAMBRIDGE, MASS., and K. F. WHITCOMB,[2] WORCESTER, MASS.

This paper comprises the results of a photoelastic investigation, sponsored by The Norton Company, of the stresses in rotating disks. The classical theory of Chree with a few additions is presented, and the results of the experimental determinations are compared with the theory as well as actual breakages of vitrified wheels.

THE object of the investigations described in the present article has been to determine, by photoelastic experimentation, the stress distribution in rotating disks of constant external but varying internal diameter, and to compare the results obtained with the existing classical theory and actual practice.

The practical consideration which suggested the work was the modern demand for higher grinding-wheel speed as an effective means of increasing production. Since engineers are not agreed on relative speeds, with equal safety, as wheel dimensions are varied, it was felt that a more complete understanding of stresses and their causes would be of great value in the design of wheels as well as in the specification of higher, but safe, operating speeds.

Theory of Stresses in Rotating Disks

In order to obtain some idea as to what streases exist in a rotating disk, the solution on rotating isotropic disks by Chree[3] is given in the Appendix. This solution, based on the theory of elasticity, is most generally accepted as being the correct one. A few additions to Chree's paper, such as diagrams showing the stress forces and the strains, have been made.

The theoretical stress equations, as derived by Chree, giving the relationships between stress, speed, mass, and dimensions are as follows:

$$\widehat{rr} = \frac{\omega^2\rho}{8}(3+\eta)\left\{a^2 + a'^2 - r^2 - \frac{a^2a'^2}{r^2}\right\} \quad \ldots\ldots [22]$$

$$\widehat{\varphi\varphi} = \widehat{rr} + \frac{\omega^2\rho}{4}\left\{(1-\eta)r^2 + (3+\eta)\frac{a^2a'^2}{r^2}\right\} \quad \ldots\ldots [23]$$

Where:

$\widehat{rr}$ = radial stress at any point distant r feet from the center of the disk, in pounds per square foot

$\widehat{\varphi\varphi}$ = tangential stress at any point distant r feet from the center of the disk, in pounds per square foot

ω = angular velocity of disk in radians per second

ρ = mass per unit volume of disk

η = Poisson's ratio, assumed equal to 0.27 here

a = radius of disk in feet

a' = radius of central hole of disk in feet.

These equations were used in obtaining the theoretical values of stress presented later in this paper.

The Photoelastic Method

Photoelasticity has been explained in detail in various journals, hence it is felt that a very brief résumé will suffice to make clear the method of experimentation used in the present investigation.

It is well known from the theory of elasticity that at any point in a stressed body there exist three orthogonal planes across which the traction is purely normal. These normal tractions are known as the principal stresses, and when they can be determined both in magnitude and direction, the elastic state is completely defined. When one of these stresses is zero, we have a two-dimensional stress problem, and it is in such cases that the photoelastic method is used to determine the direction and magnitude of the principal stresses. A model of the structure which it is wished to examine is made of some transparent material, usually some form of celluloid, and placed in a beam of polarized light. When the model is stressed it becomes temporarily double-refracting, and upon analysis of the light the image of the model is seen to be highly colored. These colors are a measure of the difference of the two principal stresses at any point, and this difference can be measured with a high degree of accuracy by introducing a compensating device in such a way that the color effect can be destroyed. The directions of the principal stresses can be also determined by a simple manipulation of the plane of polarization of the light.

The Apparatus Used

The set-up of the apparatus as used for the determination of the stresses in rotating disks was necessarily different from that conventionally used for the examination of statically loaded specimens. A photograph of the arrangement as used in these experiments is shown in Fig. 1.

In order to secure an intermittent source of light which would give a stroboscopic effect, two electrodes connected to a high-tension transformer set were employed. These electrodes are contained in the box 2 and are connected in series with a bakelite disk 1 stripped with copper. Two copper-wire brushes properly placed made contact at a certain time during each revolution of the shaft with the ends of the copper strip on the Bakelite disk, thus completing the circuit to the electrodes and forcing a spark inside the box at the same position of the disk during each revolution of the shaft. By controlling the input to the high-tension transformer the synchronization of spark and disk could be easily controlled.

The light from the box 2 was polarized by the Nicol prism 3 and passed through the rotating celluloid disk 4 in a parallel beam. The compensating device for measuring the magnitudes of the principal stresses is shown at 5, and the analyzing Nicol prism at 6. A potential of 70,000 volts was found to be sufficient to allow easy optical observations.

The design of the disk used, as well as the device employed for fitting it to the shaft, is shown in Fig. 2. The original celluloid disk had an external diameter of 20 in. and an internal diameter of 6 in., two drive-pin holes $^1/_2$ in. $\times$ $^5/_8$ in. being placed 180 deg. apart. As the experiment progressed the internal

Contributed by the Applied Mechanics Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

diameter of the disk was changed successively to 9 in. and 11.29 in., this last diameter being the largest that could be used with the holding device as originally designed.

The holding device itself was of simple construction, consisting of a duralumin disk $^3/_8$ in. thick with two shoulders on one side. The larger of these shoulders received the celluloid disk which was to be examined, and this shoulder was made $^1/_{64}$ in. thicker than the sheet celluloid used for the models to insure against any friction across the surface of the disk. The smaller

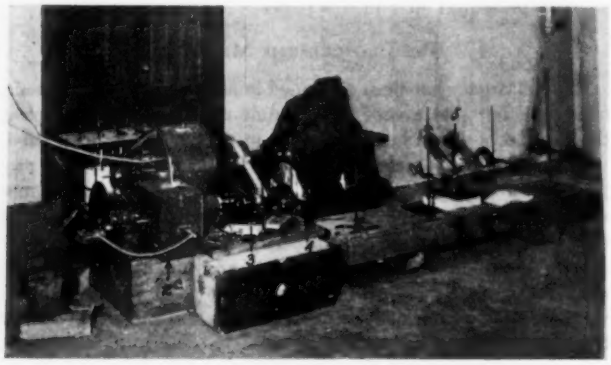

FIG. 1 PHOTOELASTIC SET-UP

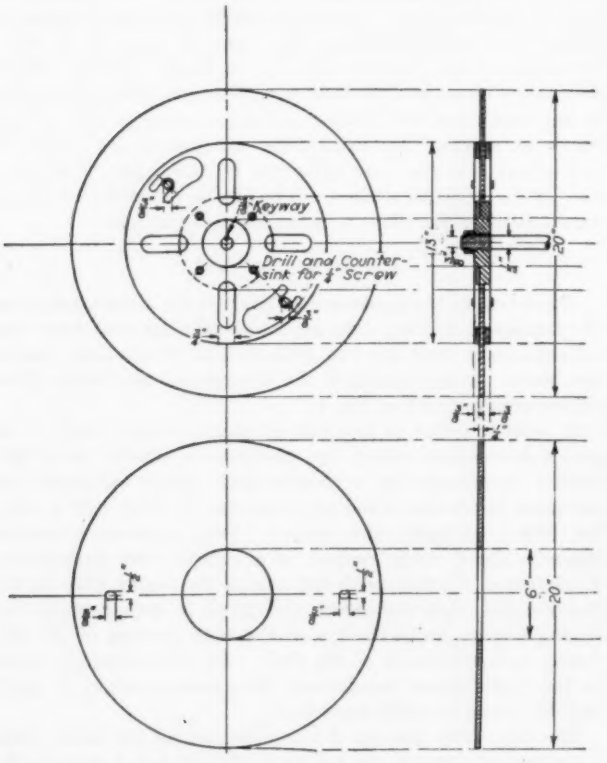

FIG. 2 DESIGN OF DISK AND OF DEVICE EMPLOYED FOR FITTING IT TO THE SHAFT

shoulder received a duralumin disk which served as a guard on the outside of the rotating model. The duralumin disks and the model were secured together by the drive pins mentioned above. These pins had a shoulder $^1/_2$ in. in diameter between the two metal disks to prevent the celluloid from being squeezed by the holding device in assembling.

In order to observe the stresses in that part of the model covered by the holding device, four slots were cut through the duralumin disks at 90 deg. apart and at 45 deg. from the drive pins.

Fig. 3 shows the model and holding device demounted. The spacer disk in the foreground is one of those used as a bushing between the disks having inside diameters greater than 6 in. and the shoulder of the holding device which received the 6-in. disk directly. It can be seen from the photographs that the

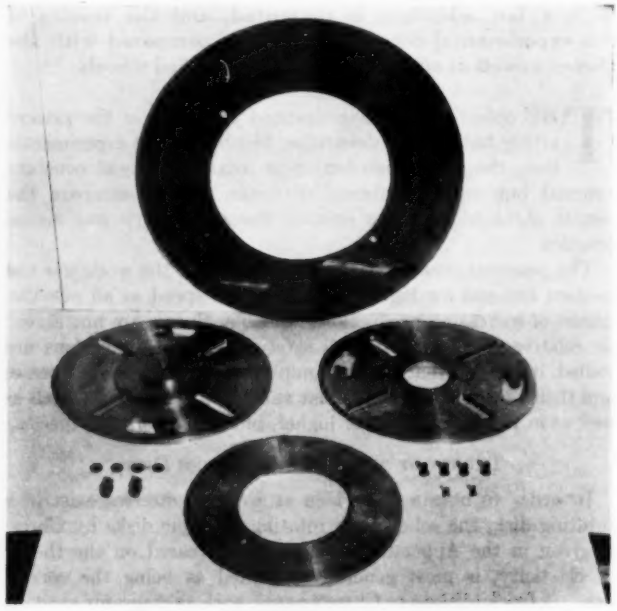

FIG. 3 ROTATING DEVICE DEMOUNTED

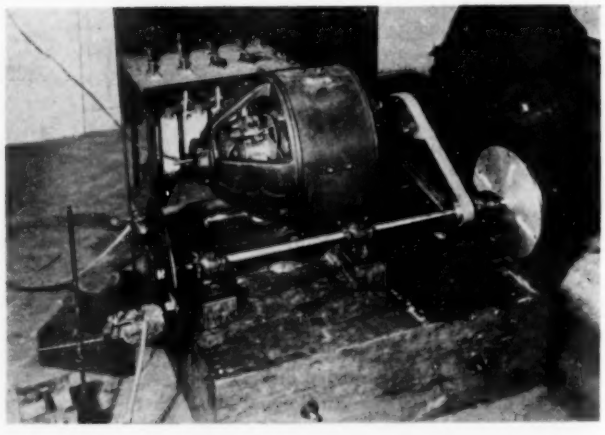

FIG. 4 METHOD OF ROTATING DISK AND SYNCHRONIZING DEVICE

drive-pin holes in the duralumin disks have been placed with open space on all possible sides in order to permit direct photoelastic observation of the stresses around the pins when the disk was in motion.

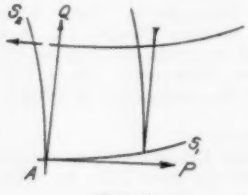

FIG. 5

Fig. 4 illustrates the apparatus used for rotating the disks. The model to be examined and the synchronizing apparatus are shown on opposite ends of a 1-in. shaft supported by three ball bearings.

A 10-hp. d.c. motor furnished the motive power, and by introducing resistances in the armature and field circuits, any desired speed could be obtained.

Experimentation

The apparatus being arranged as shown in Fig. 1, the model was rotated to the desired speed, all measurements of r.p.m. being taken on a Hassler tachometer, which was frequently checked during the runs. The operator placed himself in such a position that he could observe the model directly through the analyzing Nicol, and at the same time manipulate the compensator. The high tension being applied to the electrodes and synchronized by an assistant, the image as seen through the apparatus appeared still and continuous, so that the observations of stress magnitude could be made at leisure. By moving the photoelastic equipment bodily outward, any desired radius could be completely explored.

The measurement of stress magnitude at any point on a radius gives the difference of the principal stresses unless it be at the inside or outside periphery, both of which are of course free. The separation of these values of difference of principal stress into the two existing stresses is usually accomplished by means of Filon's equations.[4] In the case of the rotating disk, however, it became necessary to consider the body forces which are not taken care of in the above-mentioned equations, and also to use the equation of equilibrium given in polar coordinates. An adaptation of the Filon method to care for such cases is given below.

Adaptation of Filon's Method

In order to obtain the principal stresses, Filon developed a method based upon equations given by A. Mesnager for the space rates of change of the principal stresses, taken along the lines of principal stress. In this problem, due to the symmetry of the figure the directions of the principal stresses are along radii and along concentric circles. Filon's method proceeds as follows:

If we denote by S_1, S_2 arcs taken along the lines of principal stress corresponding to stresses P, Q, respectively (Fig. 5), dS_2 being obtained from dS_1, by a counterclockwise rotation of 90 deg., and if ρ_1, ρ_2 are the radii of curvature of the two lines of principal stress, being measured positive when the tangents to the curves rotate counterclockwise as the arcs S_1, increase, we have the equations

$$\frac{\partial P}{\partial S_1} + \frac{P - Q}{\rho_2} = 0$$

$$\frac{\partial Q}{\partial S_2} + \frac{P - Q}{\rho_1} = 0$$

These expressions are nothing more than the equations of equilibrium at one corner of a curved elementary rectangle. If we integrate them and proceed along the corresponding line of principal stress, we obtain

$$P = P_0 - \int_0^A (P - Q)dS_1/\rho_2$$

$$Q = Q_0 - \int_0^B (P - Q)dS_2/\rho_1$$

We see that the integrands of these equations contain the differences of the two principal stresses which we obtain by photoelasticity.

In our particular problem the equation of equilibrium of an element taken from the disk takes on a somewhat different form. Let us consider this equation of equilibrium [2] in the Appendix, namely,

[4] *Engineering*, October 19, 1923.

$$\frac{d\widehat{rr}}{dr} + \frac{d\widehat{rz}}{dz} + \frac{\widehat{rr} - \widehat{\varphi\varphi}}{r} + \omega^2\rho r = 0 \ldots\ldots\ldots [2]$$

Chree has found as shown in the Appendix that, with thin disks, the shear stress $\widehat{rz} = 0$. Therefore Equation [2] takes the following form:

$$\frac{d\widehat{rr}}{dr} + \frac{\widehat{rr} - \widehat{\varphi\varphi}}{r} + \omega^2\rho r = 0 \ldots\ldots\ldots\ldots [2a]$$

Equation [3], the second equation of equilibrium given in the Appendix, becomes zero since Chree found that $\widehat{rz}$ and $\widehat{zz}$ were equal to zero.

Integrating Equation [2a] gives

$$\widehat{rr} = \int \frac{(\widehat{\varphi\varphi} - \widehat{rr}) - \omega^2\rho r^2}{r}\, dr + K$$

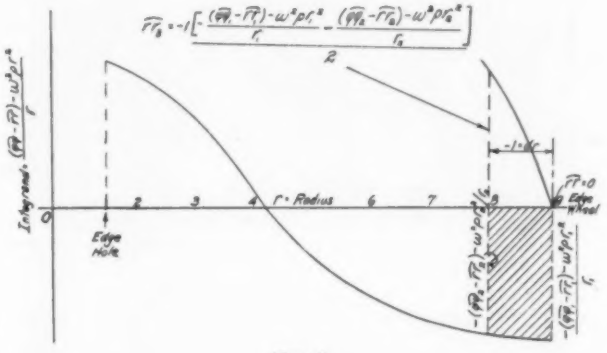

Fig. 6

where K is a constant of integration of such a value that at the free surface a value of $\widehat{rr} = 0$ is obtained.

It will be seen from this equation that it contains a term $(\widehat{\varphi\varphi} - \widehat{rr})$ in the integrand which is the difference between the tangential and the radial stresses at any point that is being considered. But this corresponds to what we obtain by photoelasticity.

Thus if we substitute these values of $(\widehat{\varphi\varphi} - \widehat{rr})$ in this equation for given values of r and also obtain $\omega^2\rho r^2$ for the same values of r and finally take the area under the $\frac{(\widehat{\varphi\varphi} - \widehat{rr}) - \omega^2\rho r^2}{r}$ — r curve by multiplying

$$\frac{(\widehat{\varphi\varphi}_1 - \widehat{rr}_1) - \omega^2\rho r_1^2}{r_1} + \frac{(\widehat{\varphi\varphi}_2 - \widehat{rr}_2) - \omega^2\rho r_2^2}{r_2}/2$$

by dr, which will be taken as unity, we shall obtain the radial stress at the point considered—see Fig. 6.

By adding the values obtained above by integration to the photoelastic value obtained for the particular point considered we obtain the tangential stress for the point considered. This method was followed in determining the tangential- and radial-stress-distribution curves from the photoelastic values obtained in tests of disks with different-sized holes, as is shown under Results.

In a general problem we should not have a straight line along which to integrate as we have in this case with the radial stresses. In such cases this adaptation of Filon's method would be inapplicable.

Results

In Fig. 7 are shown the results of two runs at 3400 and 3700

r.p.m. for a disk having an internal diameter of 6 in. The values plotted are those obtained by photoelastic analysis, viz., the difference between the tangential and radial stress at any point. The separation of these values into the separate values of the principal stresses has been accomplished by the adaptation of Filon's method explained above.

In Fig. 8 the experimental results given in the preceding figure are shown after the separate values of the radial and tangential stresses have been determined by the aid of the adaptation of Filon's method. Also the theoretical values for the same conditions have been calculated and are shown plotted in the same figure.

It is interesting to note that the difference between theory and experiment at the slower speed is approximately 20 per cent at the inside edge of the disk. This is the maximum variation found in the series of experiments when considering the edges of the holes. At the higher speed the theoretical and experimental curves lie much closer together. The agreement between theory and experiment for the radial stresses is very good, but the magnitude of these stresses is small as compared to the tangential ones.

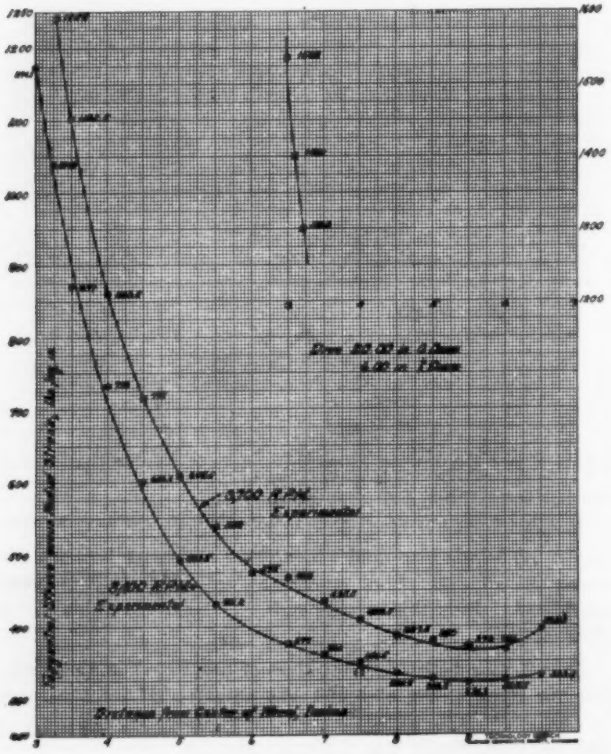

FIG. 7

In Fig. 9 the experimental results of runs at approximately the same speeds on disks having inside diameters of 9 and 11.29 in. are given. The separate values of the radial and tangential stresses are given in Figs. 10 and 11, respectively. In the case of the disk of 9 in. inside diameter the agreement between theory and experiment is very close for the tangential stresses; the experimental values, however, are somewhat lower than the theoretical ones. In the case of the disk of larger inside diameter it is interesting to note that for the first time the experimental values at the inside edge of the disk are higher than the calculated ones.

Brief runs were made on a disk having very small internal diameters. In Fig. 12 the difference between the radial and tangential stresses as experimentally determined is shown in comparison with the theory. The agreement between theory and experiment is so close that only the theoretical separate values are shown graphically. The curves of difference of stresses are radically different in shape from those taken on disks of large internal diameter. The downward slope of these curves from the outer periphery to the center of the radius, as well as the very abrupt increase in stress as the inner edge of the disk is approached, is very clearly reflected in the separate

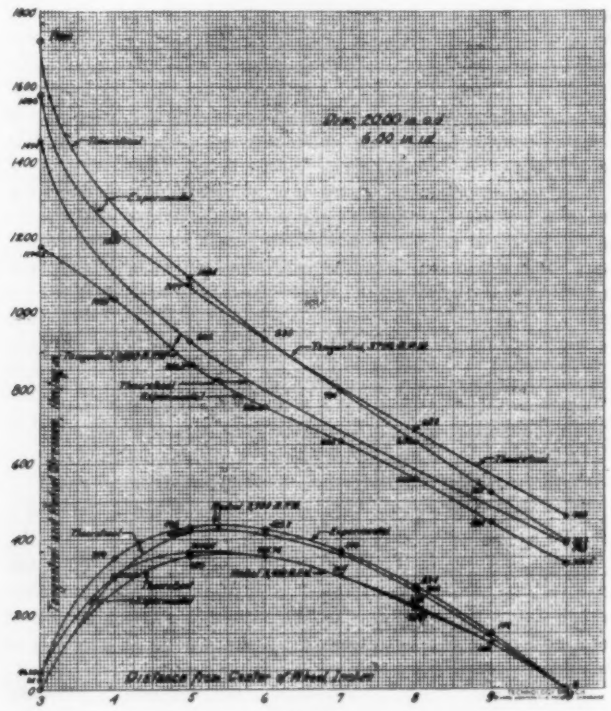

FIG. 8

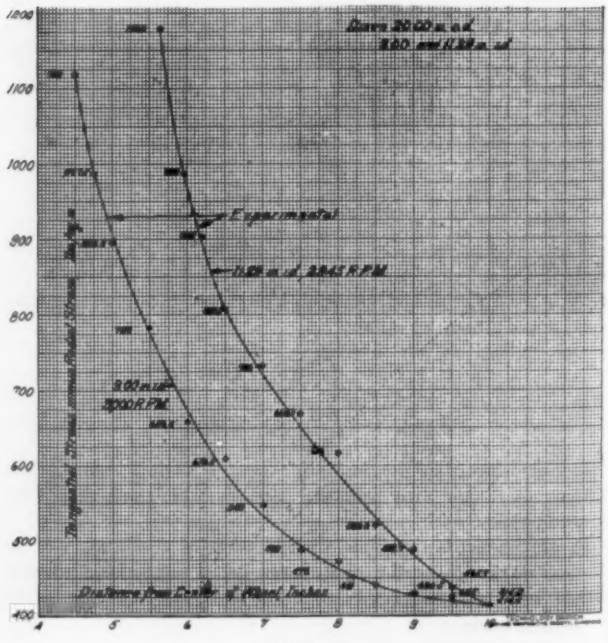

FIG. 9

theoretical curves for the tangential and radial stresses. At the middle of the radius the difference in stress is very small, but the actual values of the radial stresses are larger than those found in the disks having larger internal diameters. It is also of interest that at certain points the absolute values of the radial stresses are very close to those of the tangential stresses.

In Fig. 13 the results of the tests on a disk having an internal diameter of 0.25 in. are shown. These curves are very similar in shape to those of the preceding figure. However, the maximum radial stresses in this case are higher than those in Fig. 12, and approach more closely the values of the tangential stresses. The maximum stress in the disk as determined experimentally is considerably lower than in the case of the disk of 1.09 in. internal diameter.

In order to determine the effect of varying speeds on the maximum tangential stresses, runs were made on the disks having internal diameters of 6, 9, and 11.29 in., the results being shown graphically in Fig. 14. The curves show very clearly the effect of hole size at given speeds. It is also interesting to see that the stress at the edge of the hole varies approximately as the square of the rotational speed.

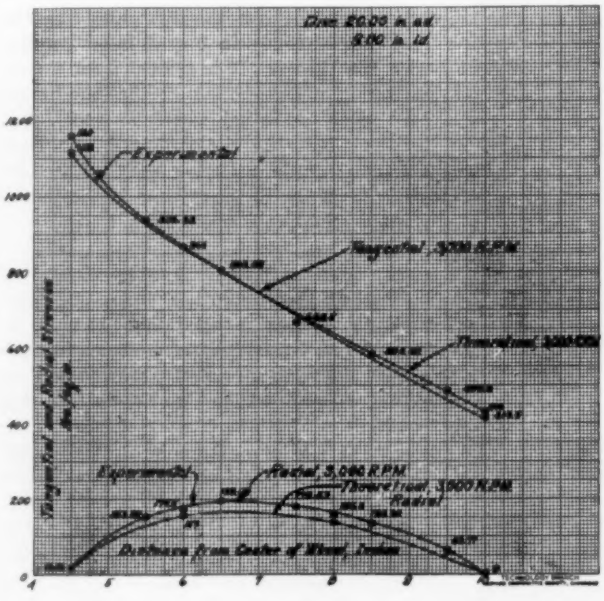

Fig. 10

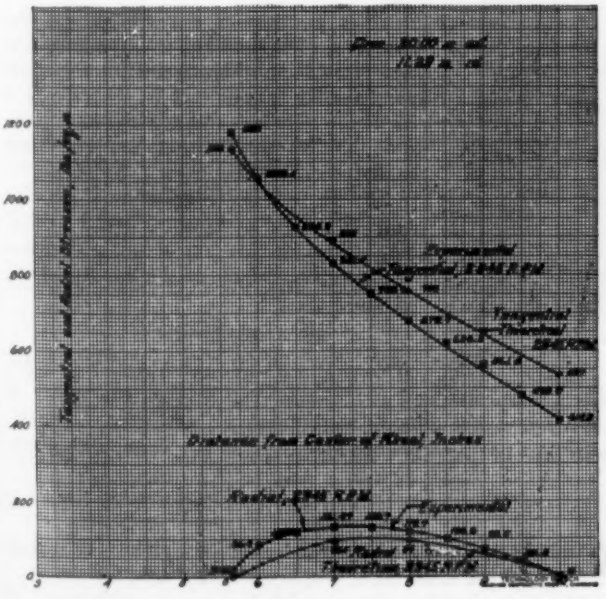

Fig. 11

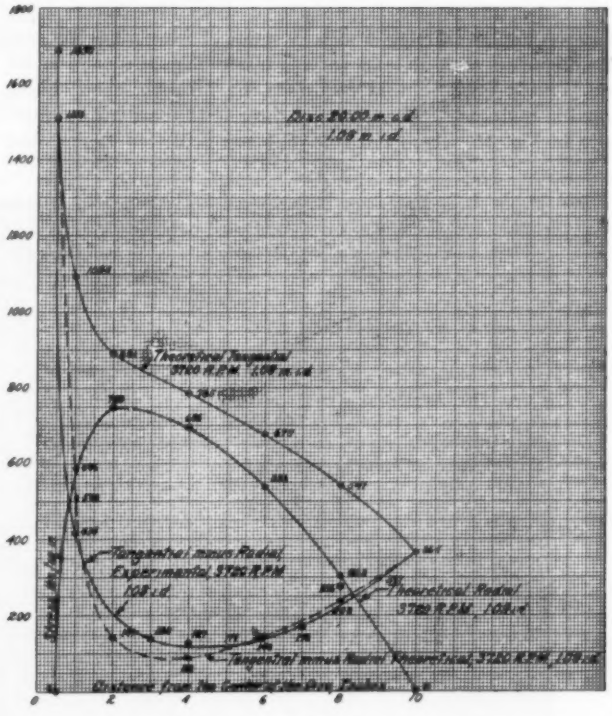

Fig. 12

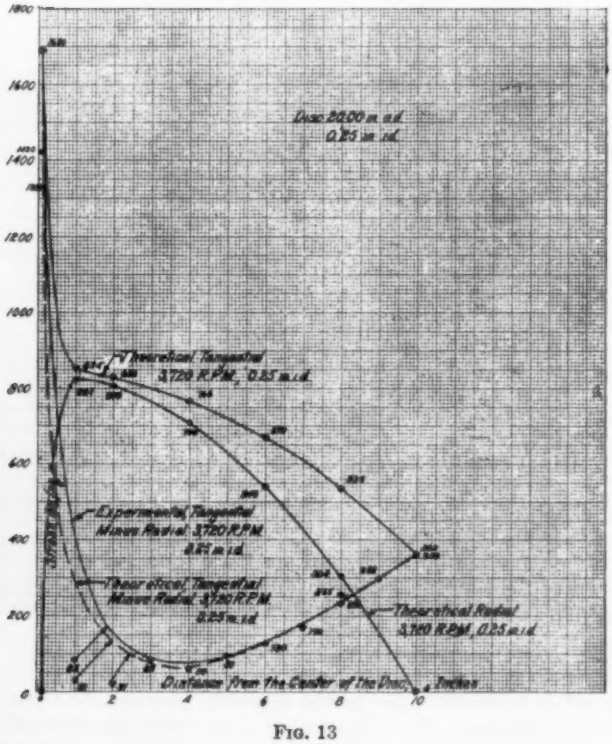

Fig. 13

Fig. 11

In order to compare the results of these experiments with those on actual grinding wheels, a series of wheels having outside diameters of 20 in. and varying inside diameters were made and rotated until rupture occurred, the breaking speed being noted in each case. The results of these tests are shown graphically in Fig. 15, where the hole diameter is plotted against the

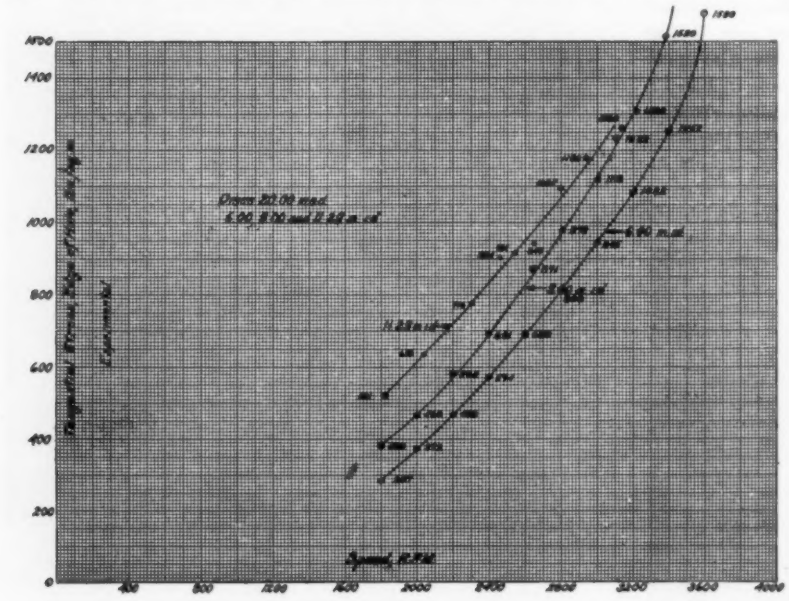

FIG. 14

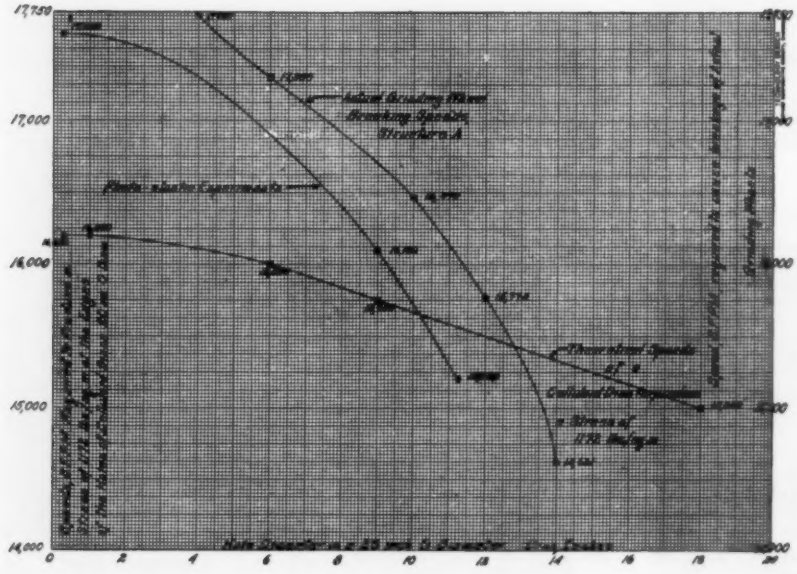

FIG. 15

speed in surface feet per minute necessary to cause the actual wheel to rupture. Since the structure of the wheels was identical, it was assumed that the breaking stress would be very nearly the same in all cases. The celluloid disks used for the photoelastic experiments were then rotated successively until the maximum tangential stress at the edge of the hole rose to an arbitrarily chosen value of 1172 lb. per sq. in. The curve of speed necessary to produce this magnitude of stress plotted against hole diameter is shown also in Fig. 15. It can be seen that the two curves are very nearly parallel, which indicates that the photoelastic experiments approximate very closely the elastic behavior of the actual wheels used for this comparison. The curve which results from theoretical calculations is also shown in the same figure, and it will be noticed that it crosses both of the experimental curves. The discrepancy, however, is not so great as would appear at first glance since the scale of ordinates is unusually large.

It was felt of course that the structure of the actual wheels would greatly influence the shape of the curve obtained in Fig. 15. The first structure employed was designated as "Structure A." A second structure of wheel, designated as "Structure B," was then chosen, and the experiments outlined above were repeated with this new material, the results being shown in Fig. 16 in comparison with the theory. It is evident from a consideration of Figs. 15 and 16 that the breaking speeds for actual wheels are controlled between limits by the structure employed, and that for the materials used in these investigations one of these limits is the theory and the other is the photoelastic analysis.

Summary of Results

Photoelastic experiments on rotating disks having a common external diameter of 20 in. and varying internal diameters have, in comparison with the theory of Chree as well as actual wheel breakages, given the following results:

a The maximum stress in a rotating disk is a tangential tension at the edge of the central hole.

b This maximum stress is proportional to the square of the rotational speed, within the limits of experimental error.

c Increasing the diameter of the central hole results in an increase in the maximum stress.

d The discrepancy between theory and experiment when considering the edges of the holes of rotating disks ranges from zero to approximately 20 per cent in the case of a disk with a 6-in. hole rotating at 3400 r.p.m., where the photoelastic results are lower than the theoretical results.

e By controlling the structure of grinding wheels the curve of breaking speed against hole size can be varied to accord with either the photoelastic results or the theoretical calculations.

Conclusion

Taking all data into consideration it is felt that a reasonable and usable agreement between the theory of elasticity, actual grinding wheel breakage, and photoelastic experiments has been pointed out.

Appendix

CHREE'S solution, with several additions, giving the derivation of the stress equations in a rotating disk, follows.

The term "disk" is here restricted to mean a thin plate, of

which a section parallel to the faces is bounded by two concentric circles. The disk is assumed to be of uniform density ρ and of an isotropic material, for which m is the bulk modulus and n the modulus of rigidity—see Thomson and Tait's "Natural Philosophy," Part II.

Take the axis of the disk for the axis of Z with the origin 0 in the central plane or plane bisecting the thickness of the disk, and let the disk rotate with a uniform angular velocity ω.

The internal-stress equations of equilibrium for an element of this disk are derived as follows:

Fig. 17 shows the distribution of the stress forces on an element enclosed between two cylindrical surfaces of radius r and $r + dr$, two planes through the axis at angles φ and $\varphi + d\varphi$, and two transverse planes distance dz from each other in general. This element has been removed from the interior of the rotating disk.

We may suppose the disk at rest, acted on by a centrifugal force $\omega^2\rho r$ per unit of volume $= R$. The other body forces in the φ and z directions are equal to zero.

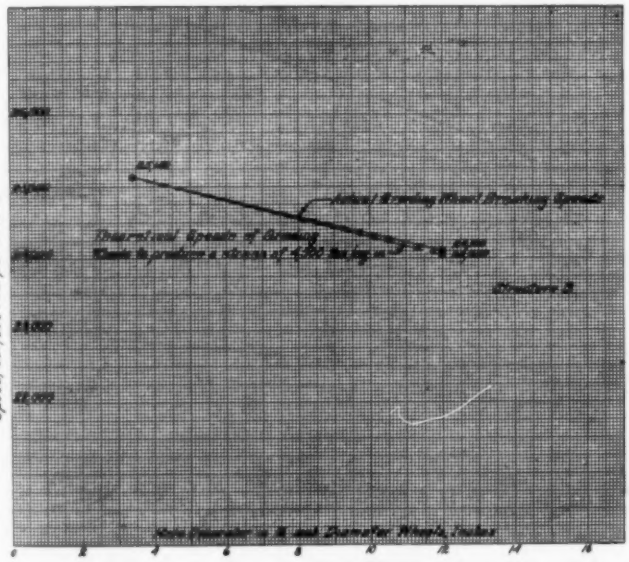

FIG. 16

The moment equations about the axes through the middle point of the element give the usual result

$$\widehat{r\varphi} = \widehat{\varphi r}, \qquad \widehat{rz} = \widehat{zr}, \qquad \text{and} \qquad \widehat{z\varphi} = \widehat{\varphi z}$$

Resolving along r, we find for $\widehat{rr}$:

$$\left(\widehat{rr} + \frac{\partial \widehat{rr}}{\partial r}\,dr\right)\cdot(r + dr)\,d\varphi dz + \omega^2\rho r \times rd\varphi drdz - \widehat{rr}rd\varphi dz$$

Disregarding infinitesimals of the second degree, we obtain:

$$\widehat{rr}drd\varphi dz + \frac{\partial \widehat{rr}}{\partial r}\,dr \times rd\varphi dz + \omega^2\rho r^2 d\varphi drdz$$

For the stresses $\widehat{\varphi\varphi}$, which act inward at an angle of $\frac{1}{2}d\varphi$ to the middle radius, we have:

$$-\left(\widehat{\varphi\varphi} + \widehat{\varphi\varphi} + \frac{\partial \widehat{\varphi\varphi}}{\partial \varphi}\,d\varphi\right) drdz \times \tfrac{1}{2}d\varphi$$

since $\sin\frac{d\varphi}{2} = \frac{d\varphi}{2}$ for a small angle.

Again disregarding infinitesimals of the second degree, we have

$$-\widehat{\varphi\varphi}drdzd\varphi$$

The shear stresses give

$$\frac{\partial \widehat{\varphi r}}{\partial \varphi}\,d\varphi drdz + \frac{\partial \widehat{zr}}{\partial z}\,dzrd\varphi dr$$

The body force $\omega^2\rho r \times rd\varphi drdz$ has been given above.

Adding the above forces and dividing by $rdrd\varphi dz$, we obtain the first of the three equations of equilibrium:

$$\frac{\widehat{rr}}{r} + \frac{\partial \widehat{rr}}{\partial r} + \omega^2\rho r - \frac{\widehat{\varphi\varphi}}{r} + \frac{\partial \widehat{\varphi r}}{\partial \varphi}\Big/r + \frac{\partial \widehat{zr}}{\partial z} = 0$$

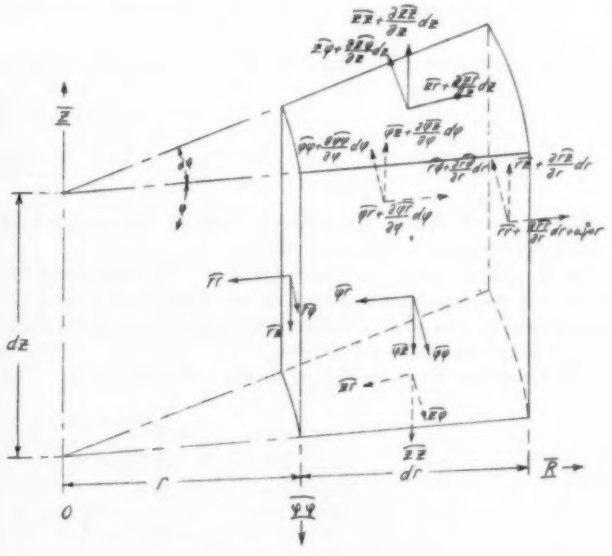

FIG. 17

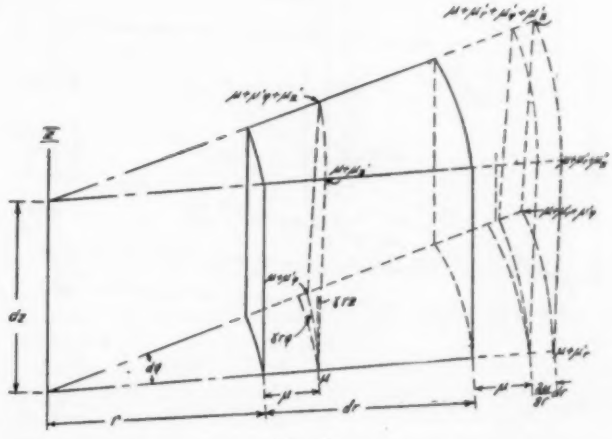

FIG. 18

which reduces to

$$\frac{d\widehat{rr}}{dr} + \frac{d\widehat{rz}}{dz} + \frac{d\widehat{\varphi r}}{d\varphi}\Big/r + \frac{\widehat{rr} - \widehat{\varphi\varphi}}{r} + \omega^2\rho r = 0 \ldots . [1]$$

Due to the symmetry of the disk the shear $\widehat{\varphi r} = 0$; therefore we have

$$\frac{d\widehat{rr}}{dr} + \frac{d\widehat{rz}}{dz} + \frac{\widehat{rr} - \widehat{\varphi\varphi}}{r} + \omega^2\rho r = 0 \ldots\ldots\ldots [2]$$

for the first equation of equilibrium.

The other two stress equations may be obtained by resolving the forces along the tangent and along the Z-axis, respectively. They are as follows:

$$\frac{d\widehat{\varphi\varphi}}{rd\varphi} + \frac{d\widehat{\varphi z}}{dz} + \frac{d\widehat{r\varphi}}{dr} + 2\frac{\widehat{r\varphi}}{r} = 0 \ldots\ldots\ldots [3a]$$

$$\frac{d\widehat{zz}}{dz} + \frac{d\widehat{zr}}{dr} + \frac{\widehat{zr}}{r} + \frac{d\widehat{\varphi z}}{rd\varphi} = 0 \ldots\ldots\ldots [3b]$$

Due to the symmetry of the disk and the loading, the shear $\widehat{\varphi r} = 0$, as mentioned above, and for the same reason the shear $\widehat{\varphi z} = 0$. Therefore [3a] reduces to $\frac{d\widehat{\varphi\varphi}}{rd\varphi} = 0$, and [3$b$] reduces to

$$\frac{d\widehat{rz}}{dr} + \frac{\widehat{rz}}{r} + \frac{d\widehat{zz}}{dz} = 0 \ldots\ldots\ldots [3]$$

The equations giving the relations between the strains and the displacements are derived as follows:

Let u, v, and w be the components of the displacements, where w is the component parallel to the Z-axis and v the component normal to a plane through the Z-axis or tangential component and u the radial component.

Fig. 18 shows the deformation in the r-direction only. The

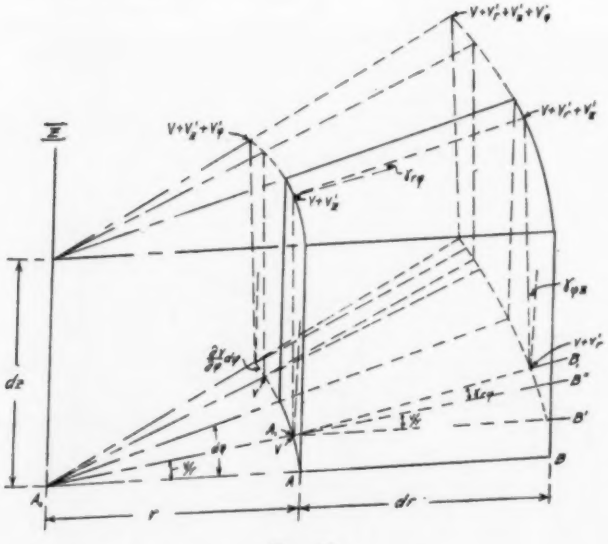

FIG. 19

increment $\frac{\partial u}{\partial r} dr$ is denoted by u_r', $\frac{\partial u}{\partial \varphi} d\varphi$ by u_φ', $\frac{\partial u}{\partial z} dz$ by u_z'.

All four edges have the same extension u in the r-direction. The outside edges of the element all have the extension $u + \frac{\partial u}{\partial r} dr$. Thus the strain $\epsilon_r = \frac{\partial u}{\partial r} dr/dr = \frac{\partial u}{\partial r}$, $rd\varphi$ becomes now $(r + u)d\varphi$, and therefore strain $\epsilon_\varphi = \frac{ud\varphi}{rd\varphi} = \frac{u}{r}$.

In this case we have $\epsilon_z = 0$.

The right angle in the $r\varphi$-plane is changed by the amount

$$\gamma_{r\varphi} = \frac{\partial u}{\partial \varphi} d\varphi/(r + u)d\varphi = \frac{\partial u}{\partial \varphi} d\varphi/rd\varphi = \frac{1}{r}\frac{\partial u}{\partial \varphi}$$

Omitting $ud\varphi$ as it is small compared with $rd\varphi$, we have in the $\overline{rz}$-plane

$$\gamma_{rz} = \frac{\partial u}{\partial z} dz/dz = \frac{\partial u}{\partial z}$$

In the $\overline{\varphi z}$-plane $\gamma_{z\varphi} = 0$ since no change can occur in u or r and remain in this plane.

Let us now consider the deformations in a tangential direction. Fig. 19 shows the deformation in the φ-direction only. The

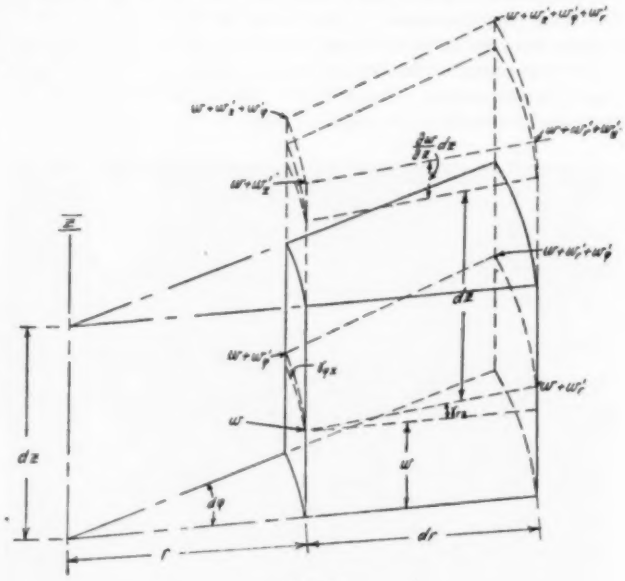

FIG. 20

increment $\frac{\partial v}{\partial r} dr$ is denoted by v_r', $\frac{\partial v}{\partial \varphi} d\varphi$ by v_φ', and $\frac{\partial v}{\partial z} dz$ by v_z'.

Upon undergoing deformation, A goes to A_1 and B to B_1, and A_1B' is parallel to AB; therefore $\tan B'A_1B_1 = \frac{\partial v}{\partial r} dr/dr = \frac{\partial v}{\partial r}$. But $\gamma_{r\varphi}$ is the angle between A_1B_1 and the radius A_0A_1 produced to B'', or in other words, the angle B_1A_1B''. Therefore $\gamma_{r\varphi} = \frac{\partial v}{\partial r} - \frac{v}{r}$, since the angle between $B''A_1$ and $B'A_1$ is equal to $\frac{v}{r}$.

There can be no ϵ_r strain since v is at right angles to r. Therefore $\epsilon_r = 0$.

The extension in the φ-direction will be $v + \frac{\partial v}{\partial \varphi} d\varphi$; thus strain $\epsilon_\varphi = \frac{\partial v}{\partial \varphi} d\varphi/rd\varphi = \frac{\partial v}{\partial \varphi}\frac{1}{r}$.

ϵ_z, the strain in the Z-direction, $= 0$ since $\overline{Z}$ is perpendicular to v-deformation.

In the $\overline{RZ}$-plane $\gamma_{rz} = 0$ since no change can occur in V or φ and remain in this plane.

In the $\overline{\varphi Z}$-plane $\gamma_{\varphi z} = \frac{\partial v}{\partial z} dz/dz = \frac{\partial v}{\partial z}$.

Let us now consider the deformations in the Z-direction only. Fig. 20 shows the deformations in the Z-direction only. The

increment $\frac{\partial w}{\partial r}\,dr$ is denoted by wr', $\frac{\partial w}{\partial \varphi}\,d\varphi$ by w_φ', and $\frac{\partial w}{\partial z}\,dz$ by w_z'.

There can be no ϵ_r or ϵ_φ strain since w is at right angles to φ and r. Therefore $\epsilon_r = 0$, and $\epsilon_\varphi = 0$; $\gamma_{r\varphi} = 0$ since it is perpendicular to w, and $\epsilon_z = \frac{\partial w}{\partial z}\,dz/dz = \frac{\partial w}{\partial z}$.

In the $\overline{ZR}$ plane $\gamma_{rz} = \frac{\partial w}{\partial r}\,dr/dr = \frac{\partial w}{\partial r}$

In the $\overline{\varphi Z}$ plane $\gamma_{\varphi z} = \frac{\partial w}{\partial \varphi}\,d\varphi/rd\varphi = \frac{\partial w}{\partial \varphi}\,\frac{1}{r}$

By addition we obtain ϵ_r total $= \frac{\partial u}{\partial r}$

$$\epsilon_\varphi \text{ total} = \frac{u}{r} + \frac{\partial v}{\partial \varphi}\,\frac{1}{r}, \text{ and}$$

$$\epsilon_z \text{ total} = \frac{\partial w}{\partial z}$$

also by addition

$$\gamma_{r\varphi} = \frac{\partial u}{\partial \varphi}\,\frac{1}{r} + \frac{\partial v}{\partial r} - \frac{v}{r}$$

$$\gamma_{\varphi z} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial \varphi}\,\frac{1}{r}, \text{ and}$$

$$\gamma_{rz} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial r}$$

From symmetry the shear strains $\gamma_{r\varphi}$ and $\gamma_{\varphi z}$ are zero; thus all we have left for shear strain is $\gamma_{rz} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial r}$, also

$$\frac{\partial v}{\partial \varphi} = 0;\ \therefore\ \epsilon_\varphi = \frac{u}{r} \text{ for tangential strain}$$

$$\epsilon_r = \frac{\partial u}{\partial r} \text{ and } \epsilon_z = \frac{\partial w}{\partial z}$$

$$\delta = \text{dilatation} = \epsilon_r + \epsilon_\varphi + \epsilon_z$$

$$= \frac{du}{dr} + \frac{u}{r} + \frac{dw}{dz} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The stress equations in terms of the strains and modulus of rigidity and bulk modulus are:

Normal Stresses

$$\widehat{zz} = (m - n)\,\delta + 2n\,\frac{dw}{dz} \text{ parallel to } OZ$$

$$\widehat{rr} = (m - n)\,\delta + 2n\,\frac{du}{dr} \text{ along } r$$

$$\widehat{\varphi\varphi} = (m - n)\,\delta + 2n\,\frac{u}{r}, \text{ perpendicular to } OZ \text{ and to } r$$

Shearing Stress: $\widehat{rz} = n\left(\frac{du}{dz} + \frac{dw}{dr}\right)$ in plane $\overline{ZR}$

As mentioned when deriving the stress equations of equilibrium, the shear stresses $\widehat{\varphi r}$ and $\widehat{\varphi z}$ for this problem are equal to zero.

Let 21 denote the thickness of the disk, a the outer radius, and a' that of its inner cylindrical surface or edge. Then assuming the disk is exposed to no surface forces, the solution should satisfy the following surface conditions:

Over the flat faces, $z = \pm$ $\widehat{lzz} = 0 \ldots\ldots\ldots\ldots [4]$

$\widehat{rz} = 0 \ldots\ldots\ldots\ldots [5]$

Over the edges, $r = a$ and $r = a'$ $\begin{cases} \widehat{rz} = 0 \ \ldots\ldots [6] \\ \widehat{rr} = 0 \ \ldots\ldots [7] \end{cases}$

Substituting for the stresses their expressions in terms of the strains and using [1], [2], and [3] become, respectively:

$$(m + n)r\,\frac{d\delta}{dr} + n\,\frac{d}{dz}\left\{r\left(\frac{du}{dz} - \frac{dw}{dr}\right)\right\} = -\,\omega^2\rho r^2 \ldots [8]$$

$$(m + n)r\,\frac{d\delta}{dz} - n\,\frac{d}{dr}\left\{r\left(\frac{du}{dz} - \frac{dw}{dr}\right)\right\} = 0 \ \ldots\ldots [9]$$

By making use of Equations [8], [9], and [1], differential equations were obtained which when integrated gave the following solutions for δ, w, and u:

$$\left.\begin{aligned} \delta &= A + C(z^2 - {}^1/_2 r^2) - {}^1/_3\omega^2\rho r^2/(m + n) \\ w &= (A - 2\alpha)z - \frac{m}{3n}\,Cz^3 + {}^1/_6\left(\frac{m + n}{n}\,C - 8\xi\right)(2z^3 - 3zr^2) \\ u &= \frac{D}{r} + \alpha r + \xi\,(4z^2 r - r^3) + {}^1/_8\left(\frac{m}{n}\,C - \frac{\omega^2\rho}{m + n}\right)r^3 \end{aligned}\right\} \ \ldots\ldots [10]$$

where all the constants are independent.

By making use of Equations [4] to [7] and equations for stresses and strains, Chree determined values for the constants α, C, and ξ, and then proved that the surface conditions [4], [5], and [6] were satisfied. The only surface condition left is [7], but this he could not exactly satisfy, unless $m = n$, by means of the present solution. For, substituting the above values of the arbitrary constants, he obtained from the expression for $\widehat{rr}$ in terms of the strains

$$\widehat{rr}_{r\,=\,a} = {}^1/_2(3m - n)A - 2na^{-2}\,D - \frac{7m - n}{16m}\,\omega^2\rho a^2 - \frac{(m - n)\,(3m - n)}{4m(m + n)}\,\omega^2\rho z^2 \ldots\ldots [11]$$

and

$$\widehat{rr}_{r\,=\,a'} \ [= \text{a similar expression, replacing } a \text{ by } a'] \ldots [12]$$

It is obvious he could not make these stresses vanish for all values of z.

If then, according to Chree, the thickness 21 of the disk be of the same order of magnitude as the radius a, this failure renders the present method inapplicable; but when $1/a$ is small it is easy to obtain a solution which according to Saint-Venant and other eminent authorities must be very approximately exact except in the immediate neighborhood of the edges.

The principle this solution is based on is that of statically equivalent systems of loading. According to this principle, when a surface of an elastic solid has a small dimension—such as the thickness of a thin disk—all systems of surface forces which in their distribution along the small dimension are statically equivalent produce, except in the immediate neighbor-

hood of their points of application, practically identical strains and stresses. We may thus for practical purposes replace any system of surface forces over the small dimension by any statically equivalent system. Chree proceeded with the following method of solution, which he believed was in accordance with the view that would have been taken by Saint-Venant:

A and D were determined from the equations

$$\int_{-1}^{+1} \widehat{rr}_r = a \qquad dz = 0 \ldots\ldots\ldots\ldots [13]$$

$$\int_{-1}^{+1} \widehat{rr}_r = a' \qquad dz = 0 \ldots\ldots\ldots\ldots [14]$$

This still left normal stresses of the order of the square of the thickness over the edges, but the forces along each generator of an edge form a system in statical equilibrium.

For the annular disk he found from [13] and [14]

$$\left.\begin{aligned} A &= \frac{7m-n}{8m\,(3m-n)}\,\omega^2\rho(a^2+a'^2) + \frac{m-n}{6m(m+n)}\,\omega^2\rho 1^2 \\ D &= \frac{7m-n}{32mn}\,\omega^2\rho a^2 a'^2 \end{aligned}\right\} \ldots [15]$$

Also he determined C and ξ explicitly, and found α in terms of A. Thus all the constants of the solution were determined.

The physical results attainable from the solution he rendered more practically serviceable by replacing the m and n of this work by Young's modulus E and Poisson's ratio η. To express the values obtained above for the arbitrary constants in terms of E and η he used the following relations:

$$\left.\begin{aligned} n &= \tfrac{1}{2}\,E/(1+\eta) \\ m &= \tfrac{1}{2}\,E/(1-2\eta)\,(1+\eta) \end{aligned}\right\} \ldots\ldots\ldots [16]$$

Substituting the expressions found for the arbitrary constants in terms of E and η in [10], he found for the strains in an annular disk

$$\delta = \frac{\omega^2\rho(1-2\eta)}{4E}\left\{(3+\eta)(a^2+a'^2) - 2(1+\eta)r^2\right\} + \frac{\omega^2\rho}{3E}\,\frac{\eta(1-2\eta)\,(1+\eta)}{1-\eta}\,(1^2-3z^2) \ldots\ldots [17]$$

$$w = -\frac{\omega^2\rho}{4E}\,\eta\left\{(3+\eta)(a^2+a'^2)\,z - 2(1+\eta)r^2 z\right\} - \frac{\omega^2\rho}{3E}\,\eta^2\,\frac{1+\eta}{1-\eta}\,z(1^2-z^2) \ldots\ldots [18]$$

$$u = \frac{\omega^2\rho}{8E}\left\{(1-\eta)\,(3+\eta)\,(a^2+a'^2)r - (1-\eta^2)r^3 + \frac{a^2a'^2}{r} (1+\eta)\,(3+\eta)\right\} + \frac{\omega^2\rho}{6E}\,\eta\,(1+\eta)r\,(1^2-3z^2) \ldots [19]$$

From these strains he found for the stresses:

$$\widehat{rr} = \frac{\omega^2\rho}{8}\,(3+\eta)\left\{a^2+a'^2-r^2-\frac{a^2a'^2}{r^2}\right\} + \frac{\omega^2\rho}{6}\,\eta\,\frac{1+\eta}{1-\eta}\,(1^2-3z^2) \ldots\ldots [20]$$

$$\widehat{\varphi\varphi} = \widehat{rr} + \frac{\omega^2\rho}{4}\left\{(1-\eta)r^2 + (3+\eta)\,\frac{a^2a'^2}{r^2}\right\} \ldots [21]$$

According to the principle of statically equivalent surface forces, this solution does not strictly apply for values of r that differ from a or from a' by quantities which do not exceed several multiples of 1. In other words, it may possibly give values for the strains and stresses over the edges differing from the true values by terms of the order 1^2. Thus in determining the greatest values of the stresses, which occur at or near the inner edge in an annular disk, we are not warranted in retaining terms of this order of small quantities. Chree proposed in determining these quantities to neglect terms of 1^2 and z^2. This has been done when determining the stresses given on the curve sheets of this paper. The following equations were thus used:

$$\widehat{rr} = \frac{\omega^2\rho}{8}\,(3+\eta)\left\{a^2+a'^2-r^2-\frac{a^2a'^2}{r^2}\right\} \ldots [22]$$

$$\widehat{\varphi\varphi} = \widehat{rr} + \frac{\omega^2\rho}{4}\left\{(1-\eta)r^2 + (3+\eta)\,\frac{a^2a'^2}{r^2}\right\} \ldots [23]$$

H. E. Jenks in 1919 derived stress equations which agree with those by Chree for rotating disks. Simplified forms of the one for tangential tension at the edge of the hole were published in *Grits and Grinds*, June, 1923.

Discussion

H. W. Wagner.[5] There are some individuals connected with the grinding industry who are not in full agreement with all the predictions made by the classical theory. One idea encountered was that if two wheels of different diameters are operated at the same surface velocity, the smaller one running at the higher r.p.m. would be stressed higher than the larger one. Another was that maximum stress is at the periphery of the wheel rather than at the edge of the hole. There were also conflicting ideas on the effect of hole diameter upon stresses and breaking speed.

Existence of contradictory conceptions was considered sufficient reason for experimental verification by the photoelastic method. It is gratifying to note by the "Summary of Results" that photoelasticity as well as actual wheel breakages show, in so far as comparisons can be made, the same trends as does Chree's equation. Thus we have a more firmly established basis on which to work for more economical and safer use of grinding wheels and other rotating members.

A. M. Wahl.[6] The writer was rather surprised to find that there was a 20 per cent discrepancy in some cases between the results for rotating disks as given by the theory of elasticity and the results given by the photoelastic method. It would seem that it should be possible to obtain a closer agreement. The writer would like to suggest that a slight curvature of the stress-strain diagram of celluloid may possibly be responsible for part of the discrepancy.

It will be noted that the test results for grinding wheels having relatively small holes indicated that the computed breaking stresses were higher than in the case of wheels having relatively large holes. In the writer's opinion, this may be due to a slight curvature of the stress-strain diagram of the material itself. If the material obeys Hooke's law exactly, as assumed in elastic theory, then the computed breaking stress as given in Fig. 15 would be the *true* stress at failure; however, if the stress-strain curve of the material has a slight curvature, then the computed stresses at failure would be higher than the true stresses. Where

[5] Research Laboratories, Norton Company, Worcester, Mass. Mem. A.S.M.E.

[6] Research Engineer, Westinghouse Research Laboratories, East Pittsburgh, Pa. Jun. A.S.M.E.

the hole is relatively large, this effect will not occur to any great extent, and in such cases there should be better agreement between the breaking stress as computed and as obtained from test. It seems to the writer that the test results thus indicated that the grinding-wheel material does have a curved stress-strain characteristic.

APM-53-2

Vibrations of Railway Bridges

By J. N. GOODIER,[1] ANN ARBOR, MICH.

The paper contains a discussion of the nature of the approximately resonant vibrations of bridges due to the pulsating forces generated by unbalanced drivers, the influence of the motion of the train, and possible action of the springs; a group of proposed approximate formulas for predicting the natural frequencies of bridges, whether unloaded or supporting trains; a description of the methods of measuring natural frequencies; a list of the sources of damping; a theoretical demonstration of the effects of a small amount of distributed damping in restraining the forced vibration, and an appendix in which the frequency formulas are derived.

Resonant Vibrations

IT IS POSSIBLE for resonant vibrations to occur in a railway bridge through the coincidence of the frequency of the pulsating forces set up by the balance weights of the driving wheels, with the natural fundamental period of vertical oscillation of the whole structure, bridge and train together. It is unfortunate that this should happen within the range of practicable locomotive speeds, but such is the fact, and on account of its practical importance the subject has received much attention in recent years. In some cases another type of oscillation, which may be termed "quasi-torsional," occurs in which the two main girders do not oscillate in phase, and a section of the bridge is subject to a periodic shearing action. This is due to the vibrating forces being eccentrically applied, as must be the case for double-track bridges loaded on one track only. The shortest bridges—say, of 40 ft. span or less—do not vibrate in resonance, being so light and stiff that their natural frequencies are too high to be approached in any practicable running speed; and even for the longer bridges where the natural frequencies are attained in ordinary running, the resonance is never of a straightforward cumulative character—as it would be if the frequency of the pulsating forces could coincide exactly for a time with the natural frequency of the structure—for the train is moving over the bridge during the building-up of the oscillation, and thus continuously modifying the mass distribution, and with it the natural frequency of the vibrating system. Provided, therefore, that the train maintains a constant speed, exact resonance cannot be more than instantaneous. But in spite of this there may be such a close approach to resonance during the passage of the train that serious vibration does ensue.

This variation of natural frequency is clearly greater in bridges of moderate size, whose mass is not so great that the mass of the locomotive is negligible in comparison. However, the smallest bridge on which resonance can occur is precisely the one which is subject to the most intense vibrating forces, for its natural frequency will be so high as to correspond to the highest speed of the locomotive.

The bigger bridges have the lower natural frequencies, and consequently resonance will occur at lower locomotive speeds, and so at smaller pulsating forces, requiring a longer time of action to build up vibrations of serious magnitude. But, in fact, they are allowed this longer time of action under conditions appropriate for resonance, since the mass of the bridge is so much greater than the mass of the locomotive that the motion of the latter cannot disturb very much the agreement between the frequencies of the structure and the pulsating forces, and also because the speed is less and the bridge is longer.

In bridges of medium length the critical conditions are reached at speeds such as those attained by express locomotives, and in longer spans, by freight trains and slow passenger trains.

It may sometimes happen that the oscillations are so violent that the springs of the locomotive begin to act. Before this occurs the locomotive moves up and down solidly with the bridge, and the structure has one fundamental natural frequency at which there may be resonance. When the accelerations in the vibration become sufficiently high, the friction resisting spring movement is insufficient to communicate the acclerations to the spring-borne mass, and the latter no longer vibrates solidly with the bridge. The action of the springs introduces an additional degree of freedom, and the original fundamental natural frequency is replaced by two natural frequencies, both of which may fall within the practicable speed range. Fig. 1[2] shows a typical amplitude-frequency diagram for a bridge of a span of the order of 200 ft. The solid-line curve corresponds to locked springs, and the broken-line curve shows the effect of spring movement. The lowering of the original resonance peak in the latter case is due to the additional damping caused by spring friction. Fig. 2 is a typical amplitude-frequency diagram for a bridge of 120 ft. span. Here there is no intermediate range of frequencies for which the springs are locked.

The existence of two points of critical acceleration as the frequency changes is to be expected from the fact that the maximum acceleration in simple harmonic motion is proportional to the square of the frequency multiplied by the amplitude. As the frequency comes near to synchronism with the natural frequency of the structure, the amplitude grows until this product reaches the critical value, and the first resonance peak with spring movement is attained. After this, as the frequency rises the amplitude decreases, but later, since it is the square of the frequency which is involved, the acceleration again rises to the critical value.

Formulas for Natural Frequencies

It is of course important that there should be some means of predicting the natural frequencies of bridges, whether loaded or not, and whether spring movement occurs or not.

---

[1] University of Michigan. Mr. Goodier was educated in England at Downing College, Cambridge University, where he studied mathematics and mechanical sciences. He took the degree of B.A. through the Mechanical Sciences Tripos, with the Rex Moir Prize for general distinction and the Ricardo Prize for thermodynamics. For two years he worked as a research student under Prof. C. E. Inglis, F.R.S., on problems of elasticity, and applied mechanics, stress distributions, bridge vibrations, and the phenomenon of rail corrugation, and together with H. S. Sayles, B.A., was awarded the John Steddy Winbolt Prize of Cambridge University for a dissertation on "Some Problems of Plane Stress." He was elected a Commonwealth Fellow in 1929. He then went to Ann Arbor to continue work under the supervision of Professor Timoshenko.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Figs. 1 to 6, with accompanying formulas, are reproduced by courtesy of Prof. C. E. Inglis, F.R.S., from his paper "Oscillations in a Bridge Caused by the Passage of a Locomotive," in Proc. Roy. Soc. (London), vol. 118, series A, 1928.

For girders, or bridges in which mass and rigidity are uniformly distributed, we may apply the simple beam formula:

$$(\text{natural frequency})^2 = n^2 = \frac{\pi^2 gEI}{4ml^4} \quad \ldots\ldots [1]$$

m being the mass per unit length, l the span, and EI having the usual significance.

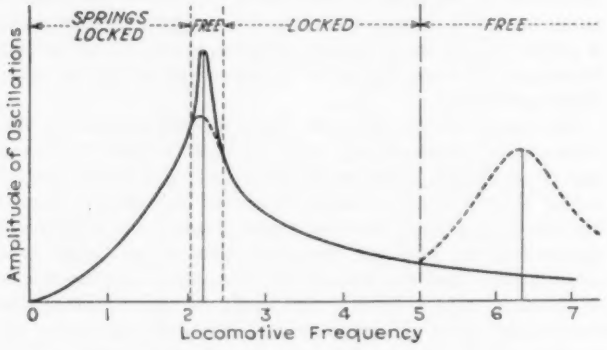

FIG. 1 TYPICAL AMPLITUDE-FREQUENCY DIAGRAM FOR A BRIDGE OF AROUND 200 FT. SPAN

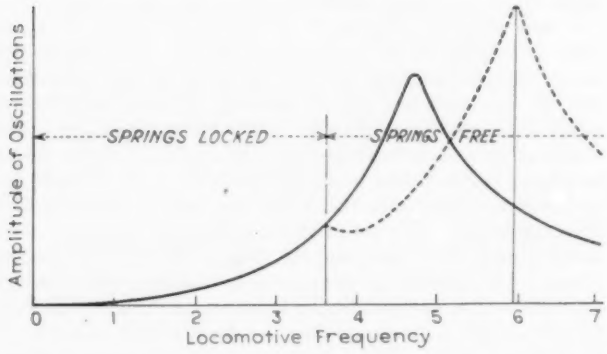

FIG. 2 TYPICAL AMPLITUDE-FREQUENCY DIAGRAM FOR A BRIDGE OF 120 FT. SPAN

Another simple formula of somewhat less restricted application, not requiring an estimate of EI, is

$$n^2 = \frac{gF}{2\pi^2 m_B} \quad \ldots\ldots [2]$$

where F is the central deflection per unit central load, and m_B is the total mass, assumed uniformly distributed. The result of applying this to three bridges for which data were available, together with the observed frequencies for comparison, are given below. The values of F were taken from actual deflection records, but they are characteristics easily obtained for any projected design.

Span in ft.	Mass in tons	F tons per ft.	Calculated frequency	Observed frequency
169	325	3690	4.23	4.00
210	626	5160	3.78	3.70
263	460	2340	2.85	2.86

Three examples are hardly sufficient to test the validity of the formula, but actual measurements of bridge frequencies do not appear to be very numerous.

The corresponding formula for a bridge whose mass cannot be regarded as uniformly distributed is

$$n^2 = \frac{gF}{4\pi^2 \int_0^l m \sin^2 \frac{\pi x}{l}\, dx} \quad \ldots\ldots [3]$$

When the mass of the locomotive is taken into account as a concentrated mass m_1 at a distance a from one end,

$$n^2 = \frac{gF}{2\pi^2 \left[m_B + 2m_1 \sin^2 \frac{\pi a}{l} \right]} \quad \ldots\ldots [4]$$

for a bridge of uniform mass distribution, and otherwise

$$n^2 = \frac{gF}{4\pi^2 \left[\int_0^l m \sin^2 \frac{\pi x}{l}\, dx + m_1 \sin^2 \frac{\pi a}{l} \right]} \quad \ldots\ldots [5]$$

The corresponding formulas when there are several loads on the bridge, or when it is desired to take into account individually the axle loads of the locomotive, say, m_1 at a distance a_1 from the end of the bridge, m_2 at a distance a_2, m_r at a distance a_r, etc., are

$$n^2 = \frac{gF}{2\pi^2 \left[m_B + 2 \Sigma\, m_r \sin^2 \frac{\pi a_r}{l} \right]} \quad \ldots\ldots [6]$$

and

$$n^2 = \frac{gF}{4\pi^2 \left[\int_0^l m \sin^2 \frac{\pi x}{l}\, dx + \Sigma\, m_r \sin^2 \frac{\pi a_r}{l} \right]} \quad \ldots\ldots [7]$$

The indications of formula [4] for the same three bridges loaded at the middle with a locomotive weighing 108 tons and having a wheelbase of 44 ft. 7½ in., together with the measured frequencies, are as follows:

Calculated	3.33	3.15	2.38
Observed	3.10	3.10	2.40

The ratio (loaded frequency)/(unloaded frequency) under the conditions of formulas [2] and [4] appears as

$$\frac{\text{Loaded frequency}}{\text{Unloaded frequency}} = \sqrt{\frac{m_B}{m_B + 2m_1 \sin^2 \frac{\pi a}{l}}} \quad \ldots\ldots [8]$$

This formula was obtained by C. E. Inglis, F.R.S., by a method different from that given in the Appendix.

The two natural frequencies which replace the above fundamental frequencies when the locomotive springs are in action are n_1 and n_2, n_1^2 and n_2^2 being the roots of the quadratic in n^2,

$$n^4 \left[1 + \frac{2m_0}{m_B} \sin^2 \frac{\pi a}{l} \right] - n^2 \left[n_0^2 + 2n_s^2 \frac{m_L}{m_B} \sin^2 \frac{\pi a}{l} \right] + n_s^2 n_0^2 = 0 \quad \ldots\ldots [9]$$

where m_0 = non-spring-borne mass of the locomotive
m_L = total mass of the locomotive
n_0 = fundamental natural frequency of the unloaded bridge
n_s = frequency of the spring mass of the locomotive on its springs, the non-spring-borne mass being fixed
m_B = mass of the bridge, as before
a = distance of the locomotive from one end.

For a single-track bridge with the following characteristics: span = 120 ft., m_B = 200 tons, n_0 = 6, and a locomotive with

the characteristics $m_e = 20$ tons, $m_L = 70$ tons, $n_s = 3$, situated at the middle of the bridge, the quadratic becomes

$$1.2n^4 - 42.6n^2 + 324 = 0$$

and the two frequencies obtained by solving this are 3.32 and 4.94.

The frequency if the locomotive springs remained locked would be 4.60, so that the two above frequencies lie on either side of this. For the lower frequency the spring mass is in phase with the bridge, and for the higher frequency it is in antiphase, its effect being the same as a reduction of bridge mass.

Measurement of Natural Frequencies

Two methods are available. The first is to use a recording deflectometer to make a diagram of the vibration after the bridge has been disturbed by the passage of the locomotive. The frequency of the residual oscillations can then be counted on the diagram. The second is the method of the "bridge oscillator." This is a machine capable of vibrating the bridge without altering appreciably its natural frequency.[3] In the experiments of the British Bridge Stress Committee, it took the form of a truck upon which were mounted two wheels geared together to rotate in opposite directions. Heavy masses are bolted eccentrically to the wheels. When rotated by an electric motor these provide vertical pulsating forces on the bridge similar to those due to the balance weights of locomotives, except that in the case of the oscillator they remain in a fixed position. Arrangements are provided to regulate the speed and to measure the power supplied to the motor, the latter for investigating the damping. The oscillator is run at varying speeds, and the natural frequency of the bridge and oscillator together is located by means of the resonance peak on the amplitude-frequency diagram.

Damping

In bridges where it is possible for resonance to be approximately attained, damping of various kinds is responsible for restricting the amplitudes of vibration to safe limits. The sources of damping may be enumerated as

1. Lack of perfect elasticity in the structure
2. Track ballast
3. Friction at the end bearings
4. Lack of rigidity in the abutments and consequent communication of energy to the ground
5. Friction of oscillating springs of locomotive and other units
6. Trains.

The relative importance of the first four appears to be still uncertain. The report of the British Bridge Stress Committee described the fifth as perhaps the most important of all the single sources of damping. This of course has reference to the British railways.

The damping effect of a train following a locomotive is appreciable, but except on the longer spans the locomotive approaches the middle of the bridge and a large oscillation is built up before the train is sufficiently far on the bridge to have any considerable damping effect. Its influence in such cases is mainly on the residual oscillations, particularly when the train is drawn by two coupled locomotives.

The undamped oscillations produced by a concentrated pulsating force $P \sin 2\pi nt$ moving at uniform speed along a girder are given approximately by

$$y = \frac{D}{2}\left[\frac{\cos 2\pi(N-n)t - \cos 2\pi n_0 t}{1-\left(\frac{N-n}{n_0}\right)^2} - \frac{\cos 2\pi(N+n)t - \cos 2\pi n_0 t}{1-\left(\frac{N+n}{n_0}\right)^2}\right]\sin\frac{\pi x}{l} \quad \ldots\ldots [10]$$

where y is the deflection at a point distant x from one end, $n = v/2l$, v is the speed, l the span, n_0 the natural frequency of the girder, and D the central deflection due to a statical force P at the center. In addition to this there is an oscillation due to the movement of the gravity load of the locomotive. This is approximately defined by

$$y = \delta\left[\sin\frac{\pi vt}{l} - \frac{v}{2ln_0}\sin 2\pi n_0 t\right]\sin\frac{\pi x}{l}$$

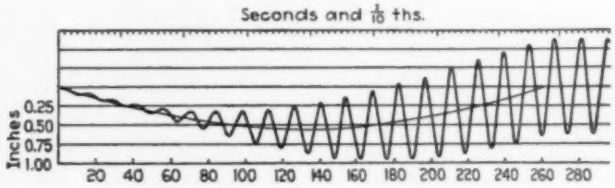

Fig. 3 Undamped Synchronous Oscillation

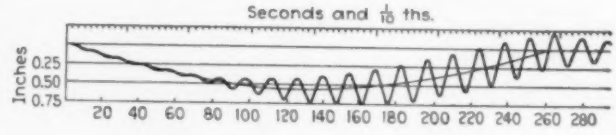

Fig. 4 Damped Synchronous Oscillation

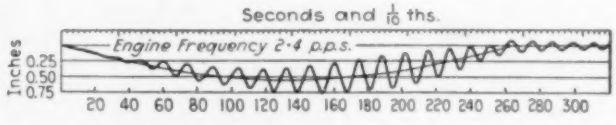

Fig. 5 Damped Synchronous Oscillation, Including Effect of Locomotive Mass

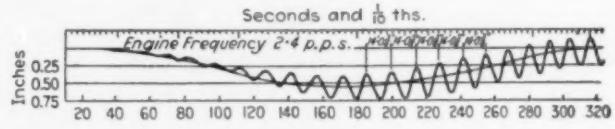

Fig. 6 Observed Oscillation

Figs. 3–6 Oscillations of Midpoint of Bridge Traversed by a Locomotive

(Span of bridge, 262.5 ft.; total mass, 480 tons; unloaded frequency, 2.88 oscillations per sec. Locomotive generates a pulsating force of 0.576 ton at 1 rev. per sec.; driving wheels, 14.0625 ft. in circumference; total weight, 107.65 tons.)

where δ is the central deflection due to the gravity load stationary at the center. This latter component is small and at worst can only contribute about 10 per cent of the whole vibration.

Fig. 3 shows the oscillation given by these formulas for the midpoint of a bridge of span 262.5 ft., total mass 460 tons, and unloaded frequency 2.88 oscillations per second, traversed by a locomotive generating a pulsating force of 0.576 ton at one revolution per second, with driving wheels 14.0625 ft. in circumference, and a total weight of 107.65 tons. The central deflection produced by the locomotive standing at the middle of the bridge is 0.55 in. The natural frequency of bridge and locomotive together is then 2.4, and the engine speed is 2.4 r.p.s.,

[3] See R. Bernhard and W. Späth, "Rein dynamische Verfahren zur Untersuchung der Beanspruchungen von Bauwerken," "Der Stahlbau," 1929, Heft 6.

about 23 m.p.h. The oscillation is building up as long as the locomotive is on the bridge, and finally the maximum deflection exceeds the crawl deflection by 75 per cent. The "crawl deflection" is the deflection due to the locomotive moving slowly over the bridge, being thus equivalent to a static load in various positions.

The effect of damping can be taken into account in such calculations if it is assumed to be equivalent to a distribution of force along the bridge proportional at any point to the velocity. For analytical convenience it may be represented as a force per unit length $4\pi n_b m \frac{\partial y}{\partial t}$, where m is the mass per unit length and n_b a damping coefficient. Then the forced oscillation becomes

$$y = \frac{D}{2}\left[\frac{\cos\{2\pi(N-n)t-\phi\}}{\left[\left\{1-\left(\frac{N-n}{n_0}\right)^2\right\}^2+\left\{\frac{n_b(N-n)}{n_0}\right\}^2\right]^{\frac{1}{2}}} - \frac{\cos\{2\pi(N+n)t-\psi\}}{\left[\left\{1-\left(\frac{N+n}{n_0}\right)^2\right\}^2+\left\{\frac{n_b(N+n)}{n_0}\right\}^2\right]^{\frac{1}{2}}}\right]\sin\frac{\pi x}{l}$$

where

$$\tan\phi = \frac{n_b(N-n)}{n_0^2-(N-n)^2} \text{ and } \tan\psi = \frac{n_b(N+n)}{n_0^2-(N+n)^2}$$

The complete oscillation is obtained by superimposing a free oscillation of the approximate form

$$y = e^{-2\pi n_b t}\,[A\sin 2\pi n_0 t + B\cos 2\pi n_0 t]\sin\frac{\pi x}{e},$$

with A and B adjusted to make the total displacement and velocity zero when the locomotive comes upon the bridge. There is also the small oscillation set up by the movement of the gravity load.

A value $n_b = 0.075$ causes the free oscillations to die out in a geometric progression with the common ratio 0.82. With this amount of damping the theoretical oscillation in Fig. 3 is modified to that shown in Fig. 4.

No account is taken in these formulas of the influence of the locomotive mass in destroying perfect resonance. The introduction of this, which causes much increased complication in the analysis, gives an oscillation represented in Fig. 5.

Fig. 6 is the oscillation actually observed.

Appendix No. 1

FREQUENCY FORMULAS

THE curve of the elastic line of the bridge at any instant during vibration may be expressed, whatever its form, by a Fourier series of the type

$$y = A_1\sin\frac{\pi x}{l} + A_2\sin\frac{2\pi x}{l} + \dots$$

where y is the deflection at a distance x from one end.

Usually it will be sufficient to take the first harmonic and thereby assume that the curve of deflection is a sine curve. This is the fact for a uniform unloaded beam with hinged ends. The deflection at any point on the bridge will be simple harmonic in time. We may therefore write

$$y = \delta\sin\frac{\pi x}{l}\sin 2\pi n t$$

and n will then be the frequency of vibration, the quantity we wish to evaluate; δ will be the amplitude of the middle of the bridge.

The maximum velocity of a point at a distance x from one end will be

$$2\pi n\delta\sin\frac{\pi x}{l}$$

occurring when the bridge is passing through its equilibrium configuration. The whole of the energy of vibration at that instant is kinetic. For the whole bridge it will be

$$\int_0^l \frac{1}{2}\frac{m\,dx}{g}\left[2\pi n\delta\sin\frac{\pi x}{l}\right]^2$$

In addition to this we have contributions from loads on the bridge. Suppose these are m_1 at a distance a_1 from the end, m_2 at a_2, and so on.

The maximum velocity of m_1 is

$$2\pi n\delta\sin\frac{\pi a_1}{l}$$

and its kinetic energy then is

$$\frac{1}{2}\frac{m_1}{g}\left[2\pi n\delta\sin\frac{\pi a_1}{l}\right]^2$$

The kinetic energy for all the loads will thus be

$$\frac{2\pi^2 n^2\delta^2}{g}\left[m_1\sin^2\frac{\pi a_1}{l} + m_2\sin^2\frac{\pi a_2}{l} + \dots\right.$$

or

$$\frac{2\pi^2 n^2\delta^2}{g}\sum m_r\sin^2\frac{\pi a_r}{l}$$

The total energy of the whole vibrating system, expressed as maximum kinetic energy, is accordingly

$$\frac{2\pi^2 n^2\delta^2}{g}\int_0^l m\sin^2\frac{\pi x}{l}\,dx + \frac{2\pi^2 n^2\delta^2}{g}\sum m_r\sin^2\frac{\pi a_r}{l} \dots [11]$$

When the bridge has swung to an extreme position in the vibration, its velocity anywhere is momentarily zero, and all the energy of vibration is stored as strain energy. We require to estimate the energy in this form.

Suppose a central force P is required to produce the central deflection δ. The deflection curve would of course not be exactly the same as the deflection curve in a vibration, but the difference is not very serious. The strain energy of the bridge in static deflection will be $\frac{1}{2}P\delta$. Taking this as an estimate of the maximum strain energy in vibration—that is, the total energy of vibration—we may equate it to [11], or

$$\frac{1}{2}P\delta = \frac{2\pi^2 n^2\delta^2}{g}\left[\int_0^l m\sin^2\frac{\pi x}{l}\,dx + \sum m_r\sin^2\frac{\pi a_r}{l}\right]$$

so that

$$n^2 = \frac{gF}{4\pi^2\left[\int_0^l m\sin^2\frac{\pi x}{l}\,dx + \sum m_r\sin^2\frac{\pi a_r}{l}\right]}$$

where $F = P/\delta$, the central force required for unit central deflection.

This is formula [7], the most general of the formulas quoted in the paper. Formulas [2] to [6] are particular cases of it

and are very simply derived. For the uniform bridge the first term in the denominator is

$$4\pi^2 m \int_0^l \sin^2 \frac{\pi x}{l} = 4\pi^2 \frac{1}{2} ml = 4\pi^2 \frac{1}{2} m_B$$

and for the unloaded bridge the second term in the denominator vanishes.

Sprung Locomotive. It may be shown that the oscillation caused in a uniform beam by a concentrated force P, which may be varying with time, at a distance a from one end of the bridge is approximately defined by the differential equation

$$EI \frac{\partial^4 y}{\partial x^4} + m \frac{\partial^2 y}{\partial t^2} = \frac{2P}{l} \sin \frac{\pi a}{l} \sin \frac{\pi x}{l} \quad \ldots\ldots [12]$$

neglecting damping, which has only a very small effect upon frequencies.

Consider the system represented in Fig. 7, a mass m_0 rigidly

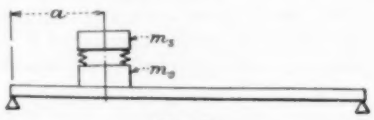

FIG. 7

attached to the beam, with a mass m_s attached to it by springs, both masses being at a distance a from one end of the bridge. Let h be the deflection of the beam under m_0 and m_s at any instant t, and z the deflection of m_s from the position of equilibrium. If μ is the spring constant, the compressive force of the spring is then $\mu(z - h)$. If P is the force between m_0 and the bridge,

$$m_0 \frac{d^2h}{dt^2} = \mu (z - h) - P$$

and

$$P = \mu (z - h) - m_0 \frac{d^2h}{dt^2}$$

This is the variable force on the bridge at a distance a from the end, so that Equation [12] gives

$$EI \frac{\partial^4 y}{\partial x^4} + m \frac{\partial^2 y}{\partial t^2} = \frac{2}{l} \left[\mu (z - h) - m_0 \frac{d^2h}{dt^2} \right] \sin \frac{\pi a}{l} \sin \frac{\pi x}{l} \quad \ldots.[13]$$

For the motion of m_s we have

$$m_s \frac{d^2z}{dt^2} = -\mu (z - h) \quad \ldots\ldots\ldots\ldots [14]$$

These equations are satisfied by oscillations of the same frequency, of the form

$$y = A \sin \frac{\pi x}{l} \sin 2\pi nt, \qquad z = B \sin 2\pi nt$$

Then

$$h = A \sin \frac{\pi a}{l} \sin 2\pi nt$$

and n is the natural frequency we wish to evaluate.

Substituting these expressions for y, z, and h in Equations [13] and [14] we obtain

$$A \left[EI \frac{\pi^4}{l^4} - 4\pi^2 n^2 m - \frac{8\pi^2 m_0}{l} n^2 \sin^2 \frac{\pi a}{l} + \frac{2\mu}{l} \sin^2 \frac{\pi a}{l} \right] = B \frac{2\mu}{l} \sin \frac{\pi a}{l}$$

and

$$A\mu \sin \frac{\pi a}{l} = B[\mu - 4\pi^2 n^2 m_s]$$

Then, by elimination of the ratio A/B,

$$n^4 16\pi^4 \left[1 + \frac{2m_0}{m_B} \sin^2 \frac{\pi a}{l} \right] - n^2 4\pi^2 \left[\frac{\mu}{m_s} \left(1 + \frac{2m_0}{m_B} \sin^2 \frac{\pi a}{l} \right) + \left(\frac{EI}{m} \frac{\pi^4}{l^4} + \frac{2\mu}{m_B} \sin^2 \frac{\pi a}{l} \right) \right] + \frac{\mu}{m_s} \cdot \frac{\pi^4 EI}{ml^4} = 0$$

where $m_B = ml$, the total mass of the bridge. If n_s is the natural frequency of the spring mass m_s on its springs, and n_0 that of the unloaded beam,

$$\mu = 4\pi^2 n_s^2 m_s \qquad \text{and} \qquad \frac{\pi^4 EI}{ml^4} = 4\pi^2 n_0^2$$

Using these, the equation becomes

$$n^4 \left[1 + \frac{2m_0}{m_B} \sin^2 \frac{\pi a}{l} \right] - n^2 \left[n_0^2 + n_s^2 \left(1 + \frac{2m_L}{m_B} \sin^2 \frac{\pi a}{l} \right) \right] + n_0^2 n_s^2 = 0$$

where $m_L = m_0 + m_s$, the total mass of the locomotive. This is Equation [9] of the paper, and is a quadratic in n^2, determining the natural frequencies for the system.

Discussion

J. B. HUNLEY.[4] The author has introduced some interesting formulas as to the frequency of loaded and unloaded spans, and has discussed in the body of the paper and has developed in the appendix a formula relating to the effect on the oscillation due to the sprung weight of the locomotive. In the tests carried on by the Bridge Stress Committee, this was found to be quite an important factor in computing impact effects on spans of medium length, which are very common on American railroads.

Unfortunately, in the impact tests made by the American Railway Engineering Association in 1910 or 1911, no attempt was made to segregate the different factors affecting impact, one of which was the resonance of the sprung weight of the locomotive or cars, nor was any attempt made to select or classify spans in reference to their stiffness and mass, nor were the loadings or spans selected in such a way as to have some fixed or known ratio of load to capacity of span.

Just as soon as conditions will permit, it is hoped that further tests will be made, taking into account and if possible segregating the effects of the various factors producing impact, and the effect of a spring-borne load of American locomotives should be given some study. It would seem that this might also apply to train loads. While it is true that we have no hammer blow resulting

[4] Engineer, Bridges and Structures, Cleveland, Cincinnati, Chicago & St. Louis Railway, Cincinnati, Ohio.

from counterbalance weights on car wheels, many of these car wheels have flat spots, and with the trend toward heavy cars, it frequently happens that the train load produces a greater static effect on the structure than the engine handling the train, and it is not difficult to imagine a train running at such a speed over a bridge that the rough wheels would produce synchronism between the sprung weight of the car and the loaded frequency of the span, and with long trains, such as are operated in this country, we might have resonance continued and oscillations amplified to a greater extent than with the passage of the locomotive alone, which at the worst can produce but a few impulses on the span.

The paper emphasizes and clarifies some of the points discussed in the report of the Bridge Stress Committee and should suggest to American engineers lines of research and study to enable them to determine, with some degree of accuracy, the impact-producing effects of American equipment. Our present impact formulas are at the best but a crude approximation, fit only for the design of new structures, and they are altogether unsuitable for determining the capacity of existing structures under any given loading.

B. S. CAIN.[5] The paper has rather a theoretical appearance, but the author could hardly show in so small a space that it is actually based on tests and that every detail of the theory accurately represents the facts. Until a few years ago the theory of bridge impact was not in this happy state, and the "impact allowance" generally used was based on facts not properly understood and was really no more than a big factor of ignorance. This old impact allowance is today a part of the railroad engineering standards of this country. Papers like the present one are valuable in showing that most of the impact effect follows definite laws and that, with the help of the theory, we can interpret tests so that no factor of ignorance need remain in our results. Bridge tests today are much easier to carry out and more reliable than they were a year or two ago. We have available simple, accurate stress recorders, operating electrically and giving as many simultaneous records of stress in different members as may be required.

These tests have value in another connection. The paper shows that the principal source of bridge impact is the unbalance of steam-locomotive driving wheels. With an electric train the impact is very small. There are today in this country several programs of main-line railroad electrification announced or already under way. It is most important to realize that electrification will reduce many bridge restrictions both on weight and particularly on speed. It must also be realized that there can be made some simple tests which will show exactly the capacity of old bridges for modern trains, and facilities at present available can be used to the greatest possible extent, employing "facts" instead of "factors."

S. TIMOSHENKO.[6] The problem of dynamical deflections of bridges has always interested engineers since the beginning of railway-bridge construction. The general feeling was that under the action of a load moving with a high velocity larger deflections and larger stresses are produced than if the same load is acting statically. A theoretical solution for a bridge of uniform cross-section and subjected to the action of a constant vertical load moving with a constant velocity v shows that there is an increase in the deflection due to the velocity of motion. If δ_d and δ_s are dynamical and statical maximum deflections, T the period of the fundamental type of natural vibration of the bridge, and $T_1 = 2l/v$ = twice the time it takes the force to pass over the bridge, then

$$\delta_d = \delta_s \frac{1}{1 - \frac{T}{T_1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

For usual conditions T/T_1 is small, and from Equation [15] it can be concluded that a smoothly running load does not produce a substantial increase in deflection.

Much more important is the action on a bridge of a pulsating force produced by unbalanced weights of a moving locomotive. If this force is in resonance with the natural vibration of the bridge and if damping is neglected, the amplitude of vibration produced under these conditions is:

$$\delta = \delta_0 \frac{T_1}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

In this equation T and T_1 have the same meaning as before, and δ_0 is the statical deflection which is produced if the maximum value of the pulsating force is applied at the middle span of the bridge.

The deflection given by Equation [16] may be a considerable one, especially for a comparatively small bridge whose frequency of natural vibration approaches the largest practical value for the number of revolutions per second of the drivers of a locomotive. Taking, for instance, the maximum number of revolutions per second of drivers as 6, it is found that pulsating forces have the largest effect on bridges with spans around 100 ft.

From the foregoing equations it is seen that the dynamical effect of a moving load depends on the frequency of natural vibration of the bridge. One can predict the magnitude of vibration only if the frequency of natural vibration of the bridge is known. The author gives several approximate formulas for calculating this frequency.

In the derivation of these formulas the deflection curve of the vibrating bridge is taken as a sine curve in calculating the kinetic energy of the bridge, and the deflection curve produced by a load at the middle is taken in calculating the strain energy. Although the formulas given are in satisfactory agreement with experiments, it seems more logical in this case to use the well-known Rayleigh method and take as a basis of calculation the actual deflection curve of the bridge. If y_1, y_2, y_3. . . . . are the deflections at the points 1, 2, 3 . . . . . along the span of the bridge, and Q_1, Q_2, ... are the portions of the weight corresponding to these points, the frequency n of the fundamental type of vibration is given by the equation:

$$n^2 = \frac{g\,(Q_1y_1 + Q_2y_2 + Q_3y_3 + \ldots.)}{Q_1y_1^2 + Q_2y_2^2 + Q_3y_3^2 + \ldots..} \quad \ldots\ldots\ldots [17]$$

This equation is used very often in calculating the frequencies of the natural lateral vibration of shafts and long rotors of modern turbo-generators.

The writer would like to mention a misprint in the line following Equation [2] for calculating frequency. F is the force necessary to produce unit deflection and not the deflection produced by unit force, as stated in the paper. It should be mentioned, also, that the notations m and m_B in Equations [2] to [9] are weights. In the appendix, in the derivation of Equation [13], the same notations are used for masses.

Equation [16] gives an exaggerated value for the effect of the pulsating load. The actual amplitude of vibration set up by an unbalanced locomotive is much smaller. This is due to damping of various kinds and to the effect of the moving masses which may change considerably the initial frequency of the natural vibration

[5] General Electric Company, Erie, Pa.

[6] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

of the bridge. The effect of damping and the effect of moving masses are discussed in the paper by the author.

It is shown that, assuming damping to be a force distributed along the length of the bridge proportional at each cross-section to the velocity of the vibratory motion, a comparatively simple solution can be obtained for the damped vibration produced by a pulsating force.

In this manner a much better agreement with experiment is obtained than that given by Equation [2].

In discussing the effect of moving masses on the frequency of natural vibration, the author considers the case of a sprung locomotive and shows that, by introducing springs between the mass of the locomotive and the bridge, two types of vibration are possible instead of the one fundamental type of vibration of the bridge. Equations for calculating the two corresponding frequencies are also given by the author. The diagram in Fig. 1, illustrating the results obtained, does not seem very satisfactory. It does not show that the frequency of the lower type of vibration is smaller than that for locked springs. The writer also would like to mention that Equation [9] for calculating the two frequencies does not coincide with the equation derived in the appendix.

The effect of moving loads on the cumulative effect of a pulsating force is only illustrated by Fig. 5, without giving any discussion of this important question.

The problem of torsional vibration and lateral vibration of bridges, although of great practical importance, is left without discussion in the paper. It is only mentioned that such vibration may occur in double-track bridges. However, torsional and lateral vibration may occur also in single-track bridges under the action of unbalanced weights and variable tractive efforts.

In connection with the development of a more rational formula for impact effect on bridges a considerable amount of experimental and theoretical work has been done in England, Germany, and Russia. There is no doubt that this kind of work must be developed in this country also, and it is desirable that the author continue his investigations on bridge vibration. The study of lateral vibrations and a comparative study of the vibration produced by steam engines and by electric locomotives are especially interesting at this time. It is important also to develop experimental work on the vibration of bridges to check the results of theoretical investigations.

George E. Beggs.[7] It would be interesting to know whether the author is of the opinion that the vibration period of a bridge can be predicted from the measured vibration period of a loaded model of the bridge. In the accompanying picture, Fig. 8, is shown a steel model of the Mt. Hope Suspension Bridge. If it be assumed that this model is a true scalar reduction of the larger structure in the ratio n to unity, and, further, if it be assumed that the weights shown suspended from this model are such that the unit stresses and unit strains in the model are equal to the corresponding dead-load unit stresses and strains in the full-sized structure, then the problem is to determine what power of the reduction factor n should be applied to the measured natural period of vertical vibration of the loaded model in order to predict correctly the corresponding period of vertical vibration of the actual bridge.

The deformations and stresses in the Mt. Hope bridge have been quantitatively checked by this model, by employing very simple conversion formulas, and one can reasonably expect that there must be a simple relationship between the measured period of this model and the corresponding period of the large suspension bridge.

[7] Professor of Civil Engineering, Princeton University, Princeton, N. J.

R. Eksergian.[8] The paper contains two distinct and valuable contributions to the subject of vibration of bridges. First, by a direct application of the energy principle, together with representation of deflections by a trigonometric series, a simple procedure is outlined for the determination of the natural frequency of a bridge with distributed concentrated masses, and, second, consideration is given to the additional degree of freedom due to the spring suspension of the locomotive.

While the simplified assumption regarding the locomotive as a concentrated mass with an equivalent single-spring suspension

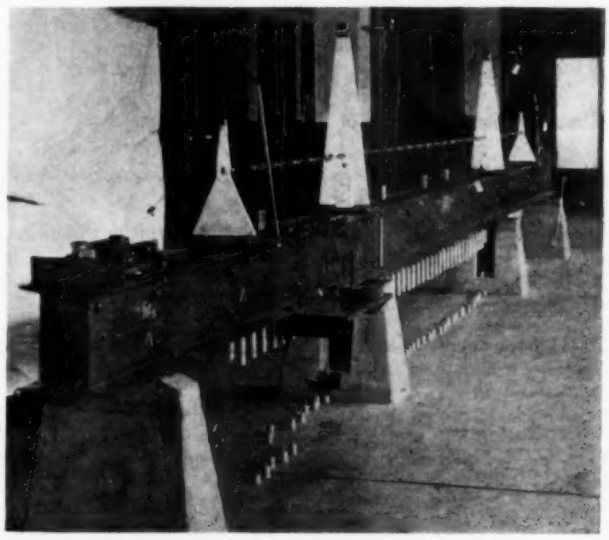

Fig. 8 Cable-Testing Apparatus on Model of Mt. Hope Suspension Bridge

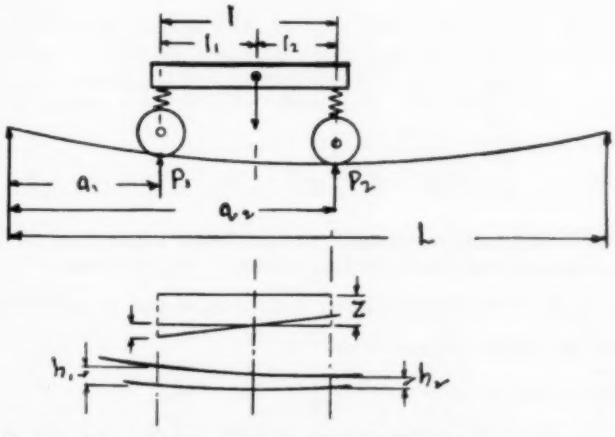

Fig. 9 Spring Suspension of Four-Wheel Vehicle, With a Front and Rear Spring Support

is the first logical step in attacking the problem, the writer believes a better approximation is needed due to the peculiar suspension and considerable spread of a modern locomotive over moderate-length spans.

I—Elementary Spring Suspension

Let us first consider the very simple case of an elementary spring suspension, i.e., of a four-wheel vehicle with a front and rear spring support, as shown in Fig. 9. The vehicle chassis has two degrees of freedom, viz., an angular motion represented by

[8] Consultant, Engineering Department, E. I. du Pont de Nemours & Co., Wilmington, Del. Mem. A.S.M.E.

the coordinate ϕ_r, and the vertical translation component of the c. of g., Z_r.

Let l_1 and l_2 = the respective distances from center of gravity to the rear and front spring supports
h_{1r} and h_{2r} = the respective deflections of the bridge under the rear and front wheels
a_1 and a_2 = the position of the wheels from the left abutment
M, m_1, and m_2 = the respective masses of the vehicle chassis and the rear and front wheels
μ_1 and μ_2 = the respective spring constants.

The compressions of the rear and front springs are

$$Z_r + l_1\phi_r - h_{1r} \quad \text{and} \quad Z_r - l_2 - h_{2r}$$

so that the potential energy of the spring system is:

$$V = \frac{1}{2}\mu_1(Z_r + l_1\phi_r - h_{1r})^2 + \frac{1}{2}\mu_2(Z_r - l_2 - h_{2r})^2$$

The work of the applied forces on the total vehicle, which includes the work of the reactions of the wheel supports, is:

$$\delta W = Mg\delta Z_r - P_{1r}\delta h_{1r} - P_{2r}\delta h_{2r} + m_1 g\delta h_{1r} + m_2 g\delta h_{2r}$$

The kinetic energy of the vehicle is

$$T = \frac{1}{2}M(\dot{Z}_r^2 + k_g^2\dot{\phi}_r^2) + \frac{1}{2}m_1\dot{h}_{1r}^2 + \frac{1}{2}m_2\dot{h}_{2r}^2$$

where k_g is the radius of gyration of the chassis about its center of gravity. We have, then,

$$M\ddot{Z}_r = -\frac{\partial V}{\partial Z_r} + Mg = \mu_1(Z_r + l_1\phi_r - h_{1r}) - \mu_2(Z_r - l_2 - h_{2r}) + Mg$$

$$Mk_g^2\ddot{\phi}_r = -\frac{\partial V}{\partial \phi_r} = -\mu_1(Z_r + l_{1r} - h_{1r})l_1 + \mu_2(Z_r - l_2\phi_r - h_{2r})l_2$$

$$m_1\ddot{h}_{1r} = -\frac{\partial V}{\partial h_{1r}} + m_1 g - P_1 = \mu_1(Z_r + l_1\phi_r - h_{1r}) + m_1 g - P_{1r}$$

$$m_2\ddot{h}_2 = -\frac{\partial V}{\partial h_2} + m_2 g - P_2 = \mu_2(Z_r - l_2\phi_r - h_{2r}) + m_2 g - P_{2r}$$

It is preferable to separate the equilibrium values from the oscillations about the equilibrium positions. We note that:

$Z_r = Z_0 + Z$, $\phi_r = \phi_0 + \phi$, $h_{1r} = h_{01} + h_0$, and $h_{2r} = h_{02} + h_2$

and the equilibrium conditions

$$Mg = \mu_1(Z_0 + l_1\phi_0 - h_{01}) + \mu_2(Z_0 - l_2\phi_0 - h_{02}),$$

$$-\mu_1(Z_0 + l_1\phi_0 - h_{01})l_1 + \mu_2(Z_0 - l_2\phi_0 - h_{02})l_2 = 0$$

so that

$$\mu_1(Z_0 + l_1\phi_0 - h_{01}) = Mg\frac{l_2}{l}, \quad \text{and} \quad \mu_2(Z_0 - l_2\phi_0 - h_{02}) = Mg\frac{l_1}{l}$$

Therefore, the oscillations about their equilibrium positions are given by

$$M\ddot{Z} = -\mu_1(Z + l_1\phi - h_1) - \mu_2(Z - l_2\phi - h_2)$$

$$Mk_g^2\ddot{\phi} = -\mu_1(Z + l_1\phi - h_1)l_1 + \mu_2(Z - l_2 - h_2)l_2$$

$$m_1\ddot{h}_1 = \mu_1(Z + l_1\phi - h_1) + \left(M\frac{l_2}{l} + m_1\right)g - P_{1r}$$

$$m_2\ddot{h}_2 = \mu_2(Z - l_2\phi - h_2) + \left(M\frac{l_1}{l} + m_2\right)g - P_{2r}$$

The dynamic loadings on the bridge due to the oscillations of the vehicle are therefore

$$P_1 = \mu_1(Z + l_1\phi - h_1) - m_1\ddot{h}_1; \; P_2 = \mu_2(Z - l_2\phi - h_2) - m_2\ddot{h}_2$$

If we assume the deflection curve of the bridge from its equilibrium position of the form

$$y = A\sin\frac{\pi x}{L}\sin\omega t = \theta\sin\frac{\pi x}{L}$$

$$\frac{\partial^2 y}{\partial x^2} = -\frac{\pi^2}{L^2}A\sin\frac{\pi x}{L}\sin\omega t = \frac{\pi^4}{L^4}\theta\sin\frac{\pi x}{L}$$

$$\frac{\partial^4 y}{\partial x^4} = \frac{\pi^4}{L^4}A\sin\frac{\pi x}{L}\sin\omega t = \frac{\pi^4}{L^4}\theta\sin\frac{\pi x}{L}$$

also

$$\dot{y} = \dot{\theta}\sin\frac{\pi x}{L} \quad \text{and} \quad \ddot{y} = \ddot{\theta}\sin\frac{\pi x}{L}$$

The kinetic energy of the bridge is

$$T = \frac{1}{2}\int_0^L m\dot{y}dx = \frac{1}{2}\int_0^L m\dot{\theta}^2\sin^2\frac{\pi x}{L}dx = \frac{mL}{4}\dot{\theta}^2$$

and the potential energy is

$$V = \frac{EI}{2}\int_0^L\left(\frac{\partial^2 y}{\partial x^2}\right)^2 dx = \frac{EI}{2}\frac{\pi^4}{L^4}\theta^2\int_0^L\sin^2\frac{\pi x}{L}dx = \frac{EI\pi^4}{4L^3}\theta^2$$

The work of the applied forces is

$$P_1\delta h_1 + P_2\delta h_2 = P_1\delta y_1 + P_2\delta y_2 = \left(P_1\sin\frac{\pi a_1}{L} + P_2\sin\frac{\pi a_2}{L}\right)\delta\theta$$

Assuming θ as a generalized coordinate according to Rayleigh and Timoshenko, we obtain, from the Lagrangian equations,

$$\frac{mL\ddot{\theta}}{2} + \frac{EI\pi^4\theta}{2L^3} = P_1\sin\frac{\pi a_1}{L} + P_2\sin\frac{\pi a_2}{L}$$

Multiplying through by $\frac{2}{L}\sin\frac{\pi x}{L}$ we obtain

$$m\frac{\partial^2 y}{\partial t^2} + EI\frac{\partial^4 y}{\partial x^4} = \frac{2}{L}\left(P_1\sin\frac{\pi a_1}{L} + P_2\sin\frac{\pi a_2}{L}\right)\sin\frac{\pi x}{L}$$

which is the form of equation used by the author.

The system of equations for solution are

$$m\frac{\partial^2 y}{\partial t^2} + EI\frac{\partial^4 y}{\partial x^4} = \frac{2}{L}\left\{[\mu_1(Z + l_1\phi - h_1) - m_1\ddot{h}_1]\sin\frac{\pi a_1}{L} + [\mu_2(Z - l_2\phi - h_2) - m_2\ddot{h}_2]\sin\frac{\pi a_2}{L}\right\}\sin\frac{\pi x}{L} \quad [18]$$

$$M\ddot{Z} = -\mu_1(Z + l_1\phi - h_1) - \mu_2(Z - l_2\phi - h_2) \quad [19]$$

$$Mk_g^2\ddot{\phi} = -\mu_1(Z + l_1\phi - h_1)l_1 + \mu_2(Z - l_2\phi - h_2)l_2 \quad [20]$$

To solve, we let

$$y = A\sin\frac{\pi x}{L}\sin\omega t, \quad Z = B\sin\omega t, \quad = C\sin\omega t$$

$$h_1 = A \sin \frac{\pi a_1}{L} \sin \omega t, \quad h_2 = A \sin \frac{\pi a_2}{L} \sin \omega t$$

hence

$$\left\{\left[m + \frac{2}{L}\left(m_1 \sin^2 \frac{\pi a_1}{L} + m_2 \sin^2 \frac{\pi a_2}{L}\right)\right]\omega^2 - \left[EI\frac{\pi^4}{L^4} + \frac{2}{L}\left(\mu_1 \sin^2 \frac{\pi a_1}{L} + u_2 \sin^2 \frac{\pi a_2}{L}\right)\right]\right\} A + \frac{2}{L}\left(\mu_1 \sin \frac{\pi a_1}{L} + \mu_2 \sin \frac{\pi a_2}{L}\right) B + \frac{2}{L}\left(\mu_1 l_1 \sin \frac{\pi a_1}{L} - \mu_2 l_2 \sin \frac{\pi a_2}{L}\right) C = 0$$

$$\left(\mu_1 \sin \frac{\pi a_1}{L} + \mu_2 \sin \frac{\pi a_2}{L}\right) A + (M\omega^2 - \mu_1 - \mu_2) B + (\mu_2 l_2 - \mu_1 l_1) C = 0$$

$$\left(\mu_1 l_1 \sin \frac{\pi a_1}{L} - \mu_2 l_2 \sin \frac{\pi a_2}{L}\right) A + (\mu_2 l_2 - \mu_1 l_1) B - (\mu_1 l_1 + \mu_2 l_2 - M k_\phi^2 \omega^2) C = 0$$

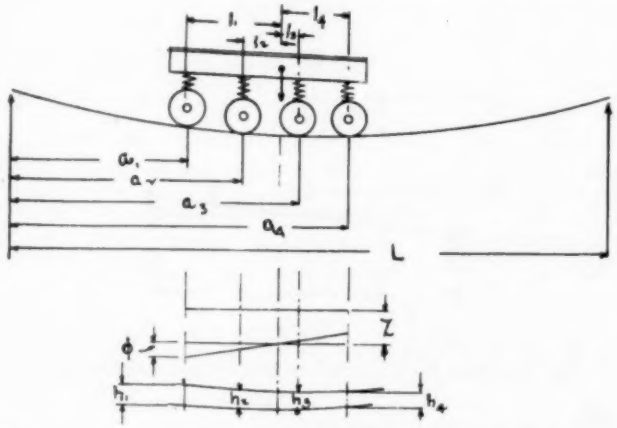

FIG. 10 SEVERAL AXLE LOADINGS, WITH INDIVIDUAL SPRING SUPPORTS PER AXLE

The system has three degrees of freedom, with three possible natural frequencies.

To obtain these frequencies, we equate the determinants of the coefficients of A, B, and C in the above equations to zero.

II—MULTIPLE-AXLE SPRING SUSPENSION

In the more complicated case with distributed axles and individual spring supports per axle supporting the locomotive chassis, we may proceed in a similar manner. The degrees of freedom and natural frequencies, however, remain the same. The space-phase relations, multiplied by the corresponding spring constants and multiplied by spring constants with distances from the locomotive chassis, can all be added vectorially. The inertia components of the dead-axle loads involve the sum of the squares of the space-phase relations multiplied by the masses of the dead-axle loads.

In the case of several axle loadings, with individual spring supports per axle, Fig. 10, let Δ_1, Δ_2, Δ_3, and Δ_4 be the static compression of the springs, so that $\mu_1\Delta_1$, $\mu_2\Delta_2$, etc., are the equilibrium values of the spring loads. Therefore we have

$$\mu_1\Delta_1 + \mu_2\Delta_2 + \mu_3\Delta_3 + \mu_4\Delta_4 = Mg$$

$$\mu_1 l_1 \Delta_1 + \mu_2 l_2 \Delta_2 - \mu_3 l_3 \Delta_3 - \mu_4 l_4 \Delta_4 = 0$$

We may regard the static compressions of the form

$$\Delta_1 = Z_0 + l_1\phi_0, \text{ etc.}; \quad \Delta_3 = Z_0 - l_3\phi_0, \text{ etc.}$$

Then

$$\mu_1\Delta_1 = \mu_1 Mg\left(\frac{C - l_1 B}{AC - B^2}\right), \text{ etc.}$$

$$\mu_3\Delta_3 = \mu_3\left(\frac{C + l_3 B}{AC - B^2}\right), \text{ etc.}$$

where

$$A = \mu_1 + \mu_2 + \mu_3 + \mu_4, \quad B = \mu_1 l_1 + \mu_2 l_2 - \mu_3 l_3 - \mu_4 l_4$$
$$C = \mu_1 l_1^2 + \mu_2 l_2^2 + \mu_3 l_3^2 + \mu_4 l_4^2$$

Assume, now, z, ϕ, h_1, h_2, etc., as the displacements from the equilibrium position. The potential energy of the spring suspension is

$$V = \frac{1}{2}\Big[\mu_1(z + l_1\phi - h_1)^2 + \mu_2(z + l_2\phi - h_2)^2 + \mu_3(z - l_3\phi - h_3)^2 + \mu_4(z - l_4\phi - h_4)^2\Big] + \mu_1(z + l_1\phi - h_1)\Delta_1 + \mu_2(z + l_2\phi - h_2)\Delta_2 + \mu_3(z - l_3\phi - h_3)\Delta_3 + \mu_4(z - l_4\phi - h_4)\Delta_4$$

The total kinetic energy of the vehicle referred to the equilibrium position is

$$T = \frac{1}{2}\Big[M(\dot{z}^2 + h_3^2\dot{\phi}^2) + m_1\dot{h}_1^2 + m_2\dot{h}_2^2 + m_3\dot{h}_3^2 + m_4\dot{h}_4^2\Big]$$

The work of the applied forces on the total vehicle is

$$Mg\delta z + (m_1 g - P_1')\delta h_1 + (m_2 g - P_2')\delta h_2 + (m_3 g - P_3')\delta h_3 + (m_4 g - P_4')\delta h_4$$

where the P's, i.e., the wheel reactions on the bridge, have the equilibrium value P_0 and the dynamic component P.

That is,

$$P_1' = (\mu_1\Delta_1 + m_1 g) + P_1, \quad P_2' = (\mu_2\Delta_2 + m_2 g) + P_2, \text{ etc.}$$

The equations of motion of the vehicle reduce to

$$M\ddot{z} = -\mu_1(z + l_1\phi - h_1) - \mu_2(z + l_2\phi - h_2) - \mu_3(z - l_3\phi - h_3) - \mu_4(z - l_4\phi - h_4) \quad [21]$$

$$Mk_\phi^2\ddot{\phi} = -\mu_1(z + l_1\phi - h_1)l_1 - \mu_2(z + l_2\phi - h_2)l_2 + \mu_3(z - l_3\phi - h_3)l_3 + \mu_4(z - l_4\phi - h_4)l_4 \quad [22]$$

$$m_1\ddot{h}_1 = \mu_1(z + l_1\phi - h_1) - P_1 \quad [23]$$

$$m_2\ddot{h}_2 = \mu_2(z + l_2\phi - h_2) - P_2 \quad [24]$$

$$m_3\ddot{h}_3 = \mu_3(z - l_3\phi - h_3) - P_3 \quad [25]$$

$$m_4\ddot{h}_4 = \mu_4(z - l_4\phi - h_4) - P_4 \quad [26]$$

Now considering the bridge proper, the potential energy is

$$V = \frac{1}{2}\,EI\int_0^L \left(\frac{\partial^2 y}{\partial x^2}\right)^2 dx + EI\int_0^L \frac{\partial^2 y_0}{\partial x^2}\frac{\partial^2 y}{\partial x^2}\,dx$$

and since

$$(\mu_1\Delta_1 + m_1 g)h_1 + (\mu_2\Delta_2 + m_2 g)h_2 \ldots = EI\int_0^L \frac{\partial^2 y_0}{\partial x^2}\frac{\partial^2 y}{\partial x^2}\,dx$$

where $EI\dfrac{\partial^2 y_0}{\partial x^2}$ is the static bending moment, the equation for the

vibration of the bridge becomes, as before,

$$m\frac{\partial^2 y}{\partial t^2} + EI\frac{\partial^4 y}{\partial x^4} = \frac{2}{L}\left(P_1 \sin\frac{\pi a_1}{L} \ldots P_4 \sin\frac{\pi a_4}{L}\right)\sin\frac{\pi x}{L} \quad [27]$$

Substituting values of P_1, P_2, etc., from Equations [23] to [26] in Equation [27], and letting $y = A \sin\frac{\pi x}{L}\sin\omega t$,

$$h_1 = A \sin\frac{\pi a_1}{L}\sin\omega t$$

$$h_2 = A \sin\frac{\pi a_2}{L}\sin\omega t;\ h_3 = A \sin\frac{\pi a_3}{L}\sin\omega t;\ h_4 = A \sin\frac{\pi a_4}{L}\sin\omega t$$

$$z = B \sin\omega t;\ \phi = C \sin\omega t$$

We have, on substituting in Equations [21], [22], and [27], the three equations in terms of the amplitudes A, B, and C. Equating the determinant of their coefficients to zero, we obtain the frequencies.

III—Equilateral Spring Suspension

However, in the majority of locomotives, the spring suspension is equalized in an equivalent front and rear system, Fig. 11. If l_r and l_f are the distances from the center of gravity of the equilization to the center of gravity of the chassis, we may roughly approximate the situation by expressing the potential energy of the spring system by

$$V = \frac{1}{2}\mu_r(Z + l_r\phi - h_r)^2 + \frac{1}{2}\mu_f(Z - l_f - h_f)^2$$

where

$$h_r = \frac{h_1 + h_2}{2} \qquad h_f = \frac{h_3 + h_4}{2}$$

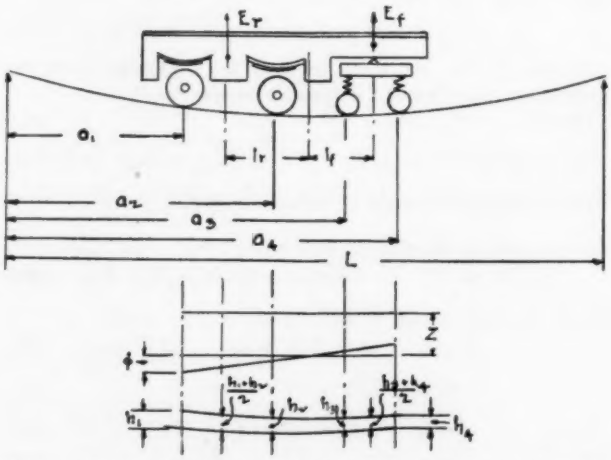

Fig. 11 Spring Suspension Equalized in an Equivalent Front and Rear System

and

$$\mu_r = \Sigma\,\mu_m + k\,\Sigma\,\mu_l = \mu_1 + \mu_2$$

$$\mu_f = \Sigma\,\mu_m + k'\,\Sigma\,\mu_l' = \mu_3 + \mu_4$$

The equations of motion then become (approximately)

$$M\ddot{z} = -\mu_r[z + l_r\phi - 0.5(h_1 + h_2)] - \mu_f[z - l_r\phi - 0.5(h_3 + h_4)]$$

$$Mk_g^2\ddot{\phi} = -\mu_r[z + l_r\phi - 0.5(h_1 + h_2)]l_r - \mu_f[z - l_r\phi - 0.5(h_3 + h_4)]l_f$$

$$m_1\ddot{h}_1 = 0.5\mu_r[z + l_r\phi - 0.5(h_1 + h_2)] - P_1, \text{ etc.}$$

Actually the analysis becomes much more complicated. Consider the rear equalization of Fig. 11, shown in detail in Fig. 12.

The angling of the equalizer beams introduces an additional degree of freedom θ. If we neglect the angular inertia of the equalizer rigging, we then can eliminate θ by the very condition of equalization.

The compressions of springs 1 and 2, are (Fig. 12)

$$\frac{1}{2}\left[(z + l_r\phi - a\theta) + (z + l_{r1}\phi)\right] - h_1$$

$$= z + 0.5(l_r + l_{r1})\phi - 0.5a\theta - h_1$$

$$\frac{1}{2}\left[(z + l_r\phi + b\theta) + (z + l_{r2}\phi)\right] - h_2$$

$$= z + 0.5(l_r + l_{r2}) + 0.5b\theta - h_2$$

But we have the condition due to equalization, i.e.,

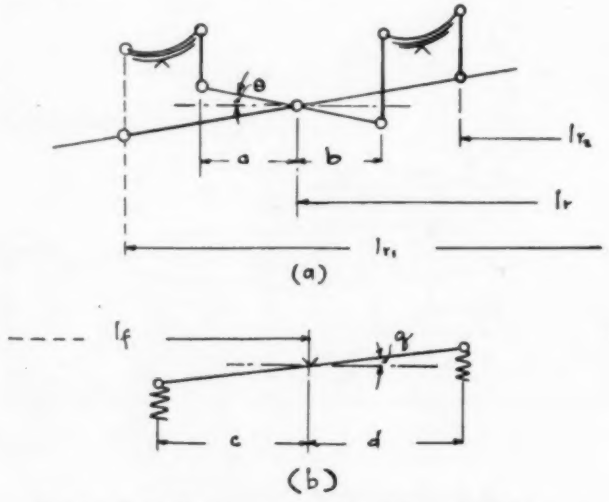

Fig. 12 Rear Equalization of Fig. 11 Shown in Detail

$$\frac{\mu_1}{2}\left[z + 0.5(l_r + l_{r1})\phi - 0.5a\theta - h_1\right]a =$$

$$\frac{\mu_2}{2}\left[z + 0.5(l_r + l_{r2})\phi + 0.5b\theta - h_2\right]b$$

so that θ can be expressed in terms of z and ϕ.

Likewise the compressions of springs 3 and 4 for the front equalization are

$$(z - l_f\phi + cq) - h_3 \quad \text{and} \quad (z - l_f\phi - dq) - h_4$$

with the condition,

$$\mu_3(z - l_f\phi + cq - h_3) = \mu_4(z - l_f\phi - dq - h_4)$$

from which q can be expressed in terms of z and ϕ.

The potential energy has the form,

$$V = \frac{\mu_1}{2}(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2)^2 + \frac{\mu_2}{2}(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1)^2$$

$$+ \frac{\mu_3}{2}(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4)^2 + \frac{\mu_4}{2}(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3)^2$$

where

$$\alpha_1 = 1 - \frac{\mu_1 a^2 - \mu_2 ab}{\mu_1 a^2 + \mu_2 b^2} \qquad \beta_1 = \frac{l_r + l_{r1}}{2} - \frac{\mu_1 a^2(l_r + l_{r1}) - \mu_2 ab(l_r + l_{r2})}{2(\mu_1 a^2 + \mu_2 b^2)}$$

$$\gamma_1 = 1 - \frac{\mu_1 a^2}{\mu_1 a^2 + \mu_2 b^2}, \qquad \xi_1 = \frac{\mu_2 ab}{\mu_1 a^2 + \mu_2 b^2}$$

$$\alpha_2 = 1 + \frac{\mu_1 ab - \mu_2 b^2}{\mu_1 a^2 + \mu_2 b^2}, \qquad \beta_2 = \frac{l_r + l_{r2}}{2} + \frac{\mu_1 ab(l_r + l_{r1}) - \mu_2 b^2 (l_r + l_{r2})}{2(\mu_1 a^2 + \mu_2 b^2)}$$

$$\gamma_2 = 1 - \frac{\mu_2 b^2}{\mu_1 a^2 + \mu_2 b^2}, \qquad \xi_2 = \frac{\mu_1 ab}{\mu_1 a^2 + \mu_2 b^2}$$

$$\alpha_3 = 1 + \frac{\mu_4 cd - \mu_3 c^2}{\mu_3 c^2 + \mu_4 d^2}, \qquad \beta_3 = l_f - \frac{\mu_3 l_f c^2 - \mu_4 l_f cd}{\mu_3 c^2 + \mu_4 d^2}$$

$$\gamma_3 = 1 - \frac{\mu_3 c^2}{\mu_3 c^2 + \mu_4 d^2}, \qquad \xi_3 = \frac{\mu_4 cd}{\mu_3 c^2 + \mu_4 d^2}$$

$$\alpha_4 = 1 - \frac{\mu_4 d^2 - \mu_3 cd}{\mu_3 c^2 + \mu_4 d^2}, \qquad \beta_4 = l_f + \frac{\mu_3 l_f cd - \mu_4 l_f d^2}{\mu_3 c^2 + \mu_4 d^2}$$

$$\gamma_4 = 1 - \frac{\mu_4 d^2}{\mu_3 c^2 + \mu_4 d^2}, \qquad \xi_4 = \frac{\mu_3 cd}{\mu_3 c^2 + \mu_4 d^2}$$

The kinetic energy from the equilibrium position is,

$$T = {}^1/_2[M\dot{z}^2 + Mk_\theta^2\dot{\phi}^2 + m_1\dot{h}_1^2 + m_2\dot{h}_2^2 + m_3\dot{h}_3^2 + m_4\dot{h}_4^2]$$

and the work of the reaction of the bridge is

$$-(P_1\delta h_1 + P_2\delta h_2 + P_3\delta h_2 + P_4\delta h_4)$$

The equations of motion reduce to,

$$M\ddot{z} = -\mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2)\alpha_1 - \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1)\alpha_2 - \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4)\alpha_3 - \mu_4(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3)\alpha_4 \quad [28]$$

$$Mk_\theta^2\ddot{\phi} = -\mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2)\beta_1 - \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1)\beta_2 + \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4)\beta_3 + \mu_4(\alpha_4 z - \beta_4\phi - \mu_4 h_4 - \xi_4 h_3)\beta_4 \quad [29]$$

and

$$m\frac{\partial^2 y}{\partial t^2} + EI\frac{\partial^4 y}{\partial x^4} = \frac{2}{L}\left(P_1 \sin\frac{\pi a_1}{L} + P_2 \sin\frac{\pi a_2}{L} + P_3 \sin\frac{\pi a_3}{L} + P_4 \sin\frac{\pi a_4}{L}\right)\sin\frac{\pi x}{L} \quad [30]$$

where

$$P_1 = \mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2)\gamma_1 + \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1)\,\xi_2 - m_1\ddot{h}_1$$

$$P_2 = \mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2)\xi_1 + \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1)\,\gamma_2 - m_2\ddot{h}_2$$

$$P_3 = \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4)\gamma_3 + \mu_4(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3)\,\xi_4 - m_3\ddot{h}_3$$

$$P_4 = \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4)\xi_3 + \mu_4(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3)\,\gamma_4 - m_4\ddot{h}_4$$

Alternately, we note

$$\theta = f(z,\phi,h_1,h_2) \text{ and } q = f(z,\phi,h_3,h_4)$$

The potential energy has the form

$$V = \frac{1}{2}\left[\mu_1\left(z + \frac{l_r + l_{r1}}{2}\phi - \frac{a\theta}{2} - h_1\right)^2 + \mu_2\left(z + \frac{l_r + l_{r2}}{2}\phi + \frac{b\theta}{2} - h_2\right)^2 + \mu_3(z - l_f\phi + cq - h_3)^2 + \mu_4(z - l_f\phi - dq - h_4)^2\right]$$

$$-\frac{\partial V}{\partial h_1} = \mu_1\left(z + \frac{l_r + l_{r1}}{2}\phi - \frac{a\theta}{2} - h_1\right)\left(1 + \frac{a}{2}\frac{\partial\theta}{\partial h_1}\right) - \mu_2\left(z + \frac{l_r + l_{r2}}{2}\phi + \frac{b\theta}{2} - h_2\right)\frac{b}{2}\frac{\partial\theta}{\partial h_1}$$

$$-\frac{\partial V}{\partial h_3} = \mu_3(z - l_f\phi + cq - h_3)\left(1 - c\frac{\partial q}{\partial h_3}\right) + \mu_4(z - l_f\phi - dq - h_4)d\frac{\partial q}{\partial h_3}$$

But since

$$\mu_1\left(z + \frac{l_r + l_{r1}}{2}\phi - \frac{a\theta}{2} - h_1\right)a = \mu_2\left(z + \frac{l_r + l_{r2}}{2}\phi + \frac{b\theta}{2} - h_2\right)b \text{ and}$$

$$\mu_3(z - l_f\phi + cq - h_3)\,c = \mu_4(z - l_f\phi - dq - h_4)d$$

we have

$$-\frac{\partial V}{\partial h_1} = \mu_1\left(z + \frac{l_r + l_{r1}}{2}\phi - \frac{a\theta}{2} - h_1\right), \text{ and}$$

$$-\frac{\partial V}{\partial h_3} = \mu_3(z - l_f\phi + cq - h_3)$$

Proceeding in a similar manner for the other coordinates and then substituting for θ and q, we obtain the equations of motion in the following more simplified form:

$$M\ddot{z} = -\mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2) - \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1) - \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4) - \mu_4(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3) \quad [31]$$

$$Mk_\theta^2\ddot{\phi} = -\mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2)\frac{l_r + l_{r1}}{2} - \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1)\frac{l_r + l_{r2}}{2} + \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4)l_f + \mu_4(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3)l_f \quad [32]$$

and

$$m\frac{\partial^2 y}{\partial t^2} + EI\frac{\partial^4 y}{\partial x^4} = \frac{2}{L}\left(P_1 \sin\frac{\pi a_1}{L} \ldots P_4 \sin\frac{\pi a_4}{L}\right)\sin\frac{\pi x}{L} \quad [33]$$

where now

$$P_1 = \mu_1(\alpha_1 z + \beta_1\phi - \gamma_1 h_1 - \xi_1 h_2) - m_1\ddot{h}_1$$

$$P_2 = \mu_2(\alpha_2 z + \beta_2\phi - \gamma_2 h_2 - \xi_2 h_1) - m_2\ddot{h}_2$$

$$P_3 = \mu_3(\alpha_3 z - \beta_3\phi - \gamma_3 h_3 - \xi_3 h_4) - m_3\ddot{h}_3$$

$$P_4 = \mu_4(\alpha_4 z - \beta_4\phi - \gamma_4 h_4 - \xi_4 h_3) - m_4\ddot{h}_4$$

$$y = A\sin\frac{\pi x}{L}\sin\omega t, \qquad z = B\sin\omega t, \qquad \phi = C\sin\omega t$$

$$h_1 = A\sin\frac{\pi a_1}{L}\sin\omega t, \qquad h_2 = A\sin\frac{\pi a_2}{L}\sin\omega t$$

$$h_3 = A\sin\frac{\pi a_3}{L}\sin\omega t, \qquad h_4 = A\sin\frac{\pi a_4}{L}\sin\omega t$$

On substituting we obtain three equations in terms of the amplitudes A, B, and C. Equating the determinant of their coefficients to zero, we obtain the frequency equation.

In the actual case of an extended equalization the problem is more complicated, but the system still reduces to one of three degrees of freedom.

The friction of a spring equalization is usually considerable, and from a practical aspect, due to this large damping, ordinarily the secondary oscillation of the spring system of the locomotive can often be neglected. If, however, the spring system is considered, the two additional degrees of freedom should be considered.

On the whole the author must be congratulated for an interesting method of attack on a very complicated subject. The object of the discussion is possibly an additional feature, rather than any criticism on this very ably presented paper.

Author's Closure

It is encouraging to find that this necessarily brief outline of what is now an extensive subject should stimulate so much valuable discussion. It was not the author's intention to include anything which has not yet been substantiated by direct measurement, and it was for this reason that he omitted anything more than a mention of the torsional and lateral vibrations to which Dr. Timoshenko refers, important though they undoubtedly are. The author is not aware of any practical investigations of such vibrations, and without experimental guidance theory would be apt to become too speculative.

Professor Inglis' analysis of the very intractable problem of determining the vibrations of a heavy uniform beam carrying a moving mass together with a pulsating force, is such, that although it has yielded some results of striking accuracy, it cannot be conveniently summarized. The author would refer those interested in this matter to paper No. 4 of the Bibliography.

The author's thanks are due to Mr. Erksergian for extending the rudimentary calculation for the sprung locomotive to more realistic cases. It seems very desirable that the effects of friction in the spring mountings should be considered, but the author has not found any measurements of this quantity for American locomotives or cars. In the locomotives used by the Bridge Stress Committee, it was of the order of eight tons.

The question Mr. Beggs raises does not admit of a simple answer. The effect of the cable makes the vibrations of a suspension bridge more complicated than those of a simple girder with which we have been concerned in the paper itself.

The modes of vibration fall into two classes. In the first we have an antinode at the middle as in the fundamental and "odd" modes of a simple beam. The cable is stretched and its tension consequently increased in the vibration, and this prevents the motion from being simple harmonic. Only when this increase in tension is negligible in comparison with the equilibrium tension do we have an approach to simple harmonic motion.

In the modes of the second class there is a node at the middle. In the first of these modes, for example, consisting of two loops, one half of the cable is moving upward and contracting while the other is moving downward and extending. The total stretch is zero to the first order in the small quantity deflection divided by span. There is consequently no appreciable alteration of cable tension and a simple harmonic vibration is possible. A closely approximate investigation of this class is easily made. The author finds that the frequency for the rth mode, r being the (even) number of loops in the deflection curve, is given by

$$n^2 = \frac{\pi^2 EI\frac{r^4}{l^4} + H\frac{r^2}{l^2}}{4(m_G + m_C)} \qquad [34]$$

n being the frequency, EI referring to the girder, l the span, H the horizontal component of the (constant) cable tension, m_G the mass per unit length of the girder, and m_C the mass per unit length of the cable.

This formula will hold also, as an approximation, for the other class of vibrations, the extensional modes, for which r is odd, provided the amplitude is small, since we may then neglect the variation in tension.

It follows that the ratio of frequencies of the rth mode of two bridges characterized by subscripts 1 and 2 is

$$\frac{n_1^2}{n_2^2} = \frac{E_1 I_1\frac{r^4}{l_1^4} + H_1\frac{r^2}{l_1^2}}{E_2 I_2\frac{r^4}{l_2^4} + H_2\frac{r^2}{l_2^2}}\,\frac{m_{G2} + m_{C2}}{m_{G1} + m_{C1}} \qquad [35]$$

We have now to consider the relative magnitudes of the quantities involved for two geometrically similar bridges, the linear dimensions of one being l_1/l_2 times those of the other, and the stresses being the same.

Taking the curve of the cable as a parabola, its equation is expressible in the form

$$y = \frac{x^2}{4a}$$

where a is a linear dimension. The load per unit length sustained in this configuration is $H\frac{d^2y}{dx^2}$, that is, $\frac{H}{2a}$. The total load per unit length applied to the girder is then

$$m_G g - \frac{H}{2a}$$

producing a maximum bending stress

$$\frac{1}{8}\left(m_G g - \frac{H}{2a}\right) l^2 \frac{d}{EI}$$

where d is half the depth of the girder. If this stress is to be the same in both bridges we must have

$$\left(m_{G1} g + \frac{H_1}{2a_1}\right)\frac{l_1^2 d_1}{I_1} = \left(m_{G2} g + \frac{H_2}{2a_2}\right)\frac{l_2^2 d_2}{I_2} \qquad [36]$$

the material being the same in each girder. On account of the geometrical similarity,

$$\frac{a_1}{a_2} = \frac{l_1}{l_2};\quad \frac{I_1}{I_2} = \frac{l_1^4}{l_2^4};\quad \frac{d_1}{d_2} = \frac{l_1}{l_2};\quad \frac{m_{C1}}{m_{C2}} = \frac{l_1^2}{l_2^2} \qquad [37]$$

so that we require, for [36]

$$\frac{m_{G1} g + \frac{H_1}{2a_1}}{m_{G2} g + \frac{H_2}{2a_2}} = \frac{l_1}{l_2} \qquad [38]$$

Since the stress is the same in both cables, the total tensions are in the ratio of the squares of the linear dimensions, i.e.,

$$\frac{H_1}{H_2} = \frac{l_1^2}{l_2^2} \quad \text{and therefore} \quad \frac{H_1}{2a_1}\Big/\frac{H_2}{2a_2} = \frac{l_1}{l_2}$$

In view of this it is sufficient, to satisfy [38], to make

$$\frac{m_{G1}}{m_{G2}} = \frac{l_1}{l_2}$$

that is, the loadings per unit length of the girders are in the ratio of the linear dimensions.

Since

$$\frac{I_1}{l_1^4} = \frac{I_2}{l_2^4}; \quad \frac{H_1}{l_1^2} = \frac{H_2}{l_2^2}$$

we have from [35]

$$\frac{n_1^2}{n_2^2} = \frac{m_{G2} + m_{C2}}{m_{G1} + m_{C1}}$$

and since

$$\frac{m_{C1}}{m_{C2}} = \frac{l_1^2}{l_2^2}; \quad \frac{m_{G1}}{m_{G2}} = \frac{l_1}{l_2}$$

this is not a function of l_1/l_2 only. It can be written as

$$\frac{n_1^2}{n_2^2} = \frac{l_2}{l_1}\left\{1 + \left(\frac{l_1}{l_2} - 1\right)\frac{m_{C1}}{m_{G1} + m_{C1}}\right\}$$

and is seen to depend on the ratio of cable mass to girder mass. The latter term signifies, of course, all the mass which moves with the girder, excluding tie rods and cable.

The whole subject of suspension-bridge vibrations, however, calls for a more exacting investigation than can be included in this brief discussion, and the author hopes to present further considerations in a future paper.

Equation [9] of the paper, to which Dr. Timoshenko has called attention, is incorrectly copied. The form given in the Appendix is correct. The "m-symbols" may be taken as either masses or weights since they occur only in ratios. The quadratic at the top of page 15, first column, should be

$$1.2n^4 - 51.3n^2 + 324 = 0$$

and the two frequencies obtained from this are 3.28 and 5.66.

Plastic Torsion

An Experimental Determination of the Stress Distribution in a Bar Which Has Been Twisted to the Limit of Plasticity

By A. NADAI,[1] EAST PITTSBURGH, PA.

Among the locally varying distributions of stress with partial yielding, that of a twisted bar is treated, for which the transition from a state of equilibrium with purely elastic deformations to one with plastic deformations was investigated. An analogy described on an earlier occasion was utilized to determine by an experimental method the distribution of stress in the twisted bar. This distribution of stress was compared with the position of the thin layers of slip observed in the etched cross-sections of twisted steel bars.

IN RECENT years it has repeatedly been noted by engineers and mathematicians that the same means by which cases of the equilibrium of the internal forces in continuously distributed elastic masses have been treated in the past, might to a certain extent also be applied with success in the analysis of cases concerning the beginning of plastic flow in solids. It was possible by methods similar to those used in the theory of elasticity to treat cases in which the internal forces or stresses in certain portions of material bodies reach the limits at which permanent deformations of considerable amount start to develop, while in other portions of these bodies the deformations still remain small and purely elastic. Although, due to the beginning of plastic flow, the internal forces in such cases cannot be considered as being in a state of true equilibrium, the disturbances in this latter in the case of slow changes of shape may be regarded as slight and negligible.

Among the locally varying distributions of stress with partial yielding, one in which the equilibrium of the internal forces might be looked upon as only slightly disturbed and in which it was possible to follow more precisely the transition from a state of equilibrium with purely elastic deformations into one with gradually increasing permanent deformations, is that of a twisted cylindrical or prismatical bar of constant cross-section subjected to a slowly increasing torque acting about its axis. Since the methods used to determine the distribution of stresses in a bar twisted above the yield point utilize more visual and experimental rather than analytical means and are analogous to those used in the elastic-torsion problem, they may be of interest to engineers.

There are, however, reasons to believe that from a description of the transition from the elastic into the plastic state in a special case such as that of a twisted bar, valuable information regarding the yielding process in ductile metals under more complicated states of stress may be obtained.

A peculiar and, from the point of view of mechanics, very interesting phenomenon accompanying the transition from the elastic to the plastic state in mild steel—or, more precisely, in a metal or substance having a sharply defined elastic and well-defined plastic range—is the formation of thin plastic layers in which the metal apparently has been deformed more than in the immediate neighborhood thereof. The intersections of these thin layers with the surface of a structural member or a test piece frequently form regular lines known to engineers as "Lüders lines" or as "slip lines." These thin layers, where they intersect the surface of well-polished test specimens, appear as fine, dull strips, often of a very regular shape, and may easily be observed. They can also be made easily visible by etching in the cross-sections. These thin layers of plastically deformed metal, or inner *surfaces of slip*, have a close connection with the fields of stress under which they were produced. They may therefore serve to check the assumptions on which the computation of the stresses in the plastic state were based. They also make possible the verification not only of the intensity of the stress, but of the geometrical distribution of the directions of principal stress in the plastic state for cases for which these stresses and their directions were predicted. In other cases, where this is not possible, they may serve to determine the position of the principal-stress directions (of the trajectories of principal stress). It was found, further, that the process of fracture is related in certain cases to the presence of these thin layers, in which the iron apparently is more severely distorted and the grain structure weakened than in the surrounding portions of material.

As has already been pointed out,[2] among the ordinary methods for testing the mechanical properties of the ductile metals, the torsion test of a cylindrical bar with a circular cross-section has an advantage over the ordinary tensile test in that it allows the determination of the maximum breaking stress. From a torsion test with a round bar it is possible to determine the true stress which will cause fracture of the material in pure shear; this, however, cannot be said of an ordinary tensile test, because the actual distribution of the stresses across the surface of rupture in the necked portion of the tensile-test bar at the moment of rupture is not known. To determine the breaking stress by means of a torsion test, it is necessary to observe the torque M as it changes with the angular twist θ per unit of length of the twisted cylinder, and to compute from the observed moment-twist diagram or curve $M = F(\theta)$ the stress-strain diagram in pure shear. This leads to a yield stress s, which in low-temperature tests gradually increases with the unit shearing defor-

[1] Research Laboratories of the Westinghouse Elec. & Mfg. Co. Dr. Nadai was for three years assistant to Prof. Dr. Eugene Meyer, Director of Laboratory of Testing of Materials and Professor of Applied Mechanics at the Technical University (Technische Hochschule), Berlin. For ten years he worked at the Institute of Applied Mechanics of the University of Göttingen in Germany with Prof. Dr. L. Prandtl. He was extraordinary professor of applied mechanics at the University of Göttingen. Since March, 1929, he has been connected with the Research Laboratories of the Westinghouse Company and with the Graduate School of the University of Pittsburgh.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

mation to the breaking point, thus showing what is known as "work hardening" of the metal.

So far it has not been possible to compute the distribution of the stresses in twisted bars of other than circular cross-section if the bar is stressed above the plastic limit and the effect of work hardening is considered. There exists, however, a case in which it is possible to determine the distribution of stresses in twisted bars of other than circular cross-section after the yield point has been reached. This is the case for mild steel or metals having a torsion diagram similar to that shown in Fig. 1.

Pure Shear in Mild Steel

If a torsion test is made with a round bar of mild steel, the initial portion of the moment-twist diagram [$M = F(\theta)$] which is recorded by means of exact torsion instruments has a shape like that in Fig. 1. The torque M first increases linearly with the angle of twist θ to a point A. The line then gradually bends in to a curve AB, after which the moment M remains for a while (BC) nearly constant ($M = M_1$), and then finally starts again to increase (CD). Sometimes with very mild steels (having a sharply defined yield stress in pure tension), the torque M may even drop for a while after reaching B, and then start again to increase. The following discussion will be limited to the deformations of twisted steel bars which correspond to the portion ABC (Fig. 1) of the torque-twist diagram $M = F(\theta)$ of a bar of circular cross-section. In other words, it will be assumed that the deformations are limited to such amounts as correspond to the twist θ for points such as B or C in Fig. 1. The shape of this latter diagram indicates that for mild steel the corresponding stress-strain diagram $s = f(\gamma)$ for pure shear (s is the shearing stress which produces a unit shearing deformation γ, as a first approximation and for not too large deformations may be considered as consisting of two separate straight lines, one steeply inclined and one horizontal, as shown in Fig. 2.

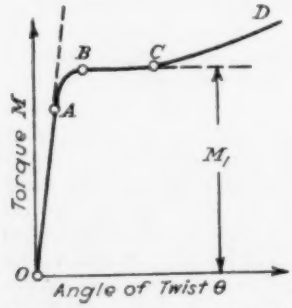

Fig. 1 Moment-Twist Diagram for Mild Steel [$M = F(\theta)$]

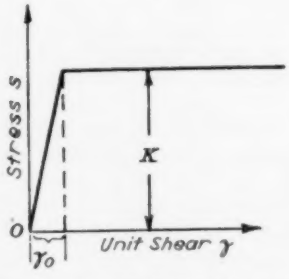

Fig. 2 Stress-Strain Diagram in Pure Shear

If $\gamma < \gamma_0$, i.e., in the elastic range the shearing stress according to Hooke's law is proportional to the unit shear,

$$s = G\gamma \quad [1]$$

where G is the modulus of rigidity of the bar; and if $\gamma > \gamma_0$, i.e., in the plastic range the shearing stress s remains constant,

$$s = k \quad [2]$$

The constant k is the yield stress of the bar in pure shear and evidently the unit shear γ_0 is equal to k/G.

Since all elements of a bar subjected to pure torsion are stressed in the same manner and the only stress in them is pure shear, it will be possible under these assumptions to predict to a certain extent the distribution of stresses in a twisted bar having an arbitrary shape of cross-section as the stresses gradually tend to approach the yield stress k in pure shear. It can therefore be assumed that where the resultant shearing stress s in a bar is smaller than the yield stress k in pure shear ($s < k$), stress and strain are proportional according to Equation [1], and the equations hold, which are valid for elastic torsion, and that where yielding occurs in the bar, the resultant shearing stress $s = k$ remains constant regardless of further increases of the shearing deformations. It will furthermore be assumed that the three components of the displacement of an arbitrary point within the bar with respect to certain fixed and immovable axes remain small quantities compared to the dimensions of the cross-section. If the permanent unit shears do not exceed more than perhaps 20 to 40 times the value of $\gamma_0 = k/G$, it will be permissible to use the simplifications which have been introduced above.

Elastic Torsion

The Elastic-Stress Function for Torsion. Let us first refer briefly to the case of the elastic torsion of a bar with a constant cross-section as treated by St. Venant. Let the z-axis coincide with the (unknown) axis of twist of the bar and the x- and y-axes be chosen in the plane of one of the cross-sections of the bar. Also let

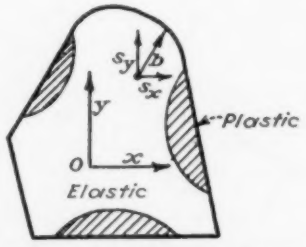

Fig. 3 Elastic and Plastic Areas in Cross-Section of a Twisted Bar

θ = angle of twist per unit of length

G = modulus of rigidity of the bar

s_x, s_y = components of shearing stress acting at the point x, y, z, in the plane z = const. and parallel, respectively, to the x- and y-axes.

$s = \sqrt{s_x^2 + s_y^2}$ = resultant shearing stress acting in the same plane and at the same point.

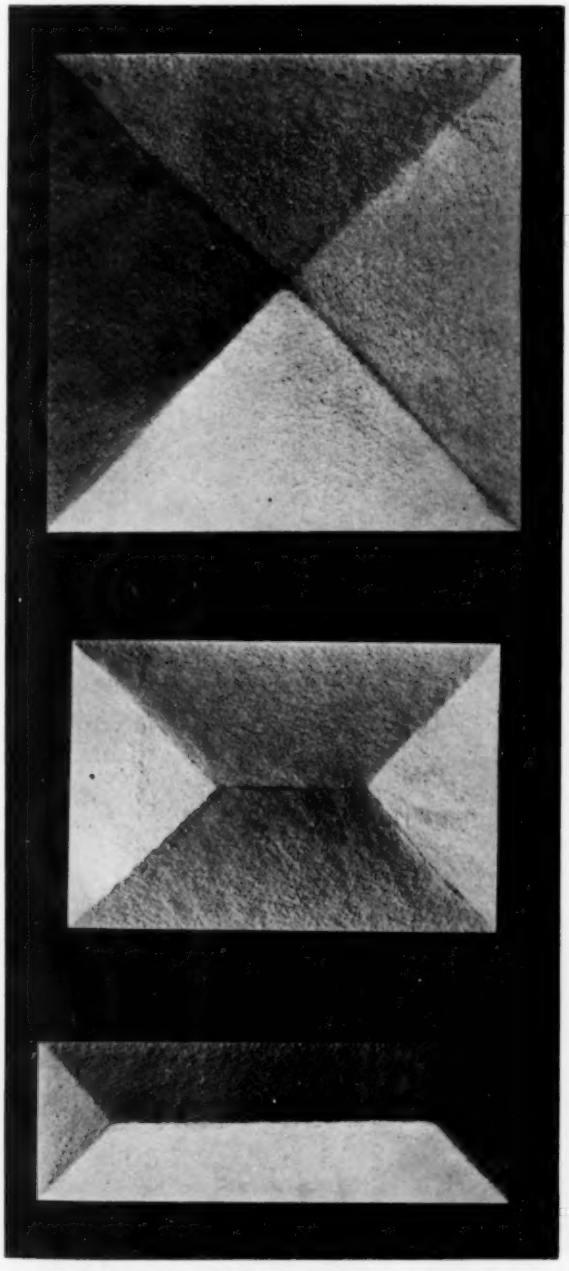
The elastic-torsion problem of a bar with a cross-sectional area A with simply connected boundary lines requires that the two components of the shearing stress s_x and s_y satisfy the equations:

$$\frac{\partial s_x}{\partial x} + \frac{\partial s_y}{\partial y} = 0 \quad [3]$$

$$\frac{\partial s_x}{\partial y} - \frac{\partial s_y}{\partial x} = -2G\theta = \text{const.} \quad [4]$$

with the condition at the boundary:

$$\frac{s_y}{s_x} = \frac{dy}{dx} \quad [5]$$



where $y = f(x)$ designates the equation of the boundary curve of the cross-sectional area A. The condition of equilibrium of a small element of the bar is expressed by Equation [3]. Equation [4] is a consequence of Hooke's law and the subsequent rotation of cross-sections through an angle proportional to z. Equation [5] expresses the fact that the resultant shearing stress s along the boundary line $y = f(x)$ must be tangent to this line at every point.

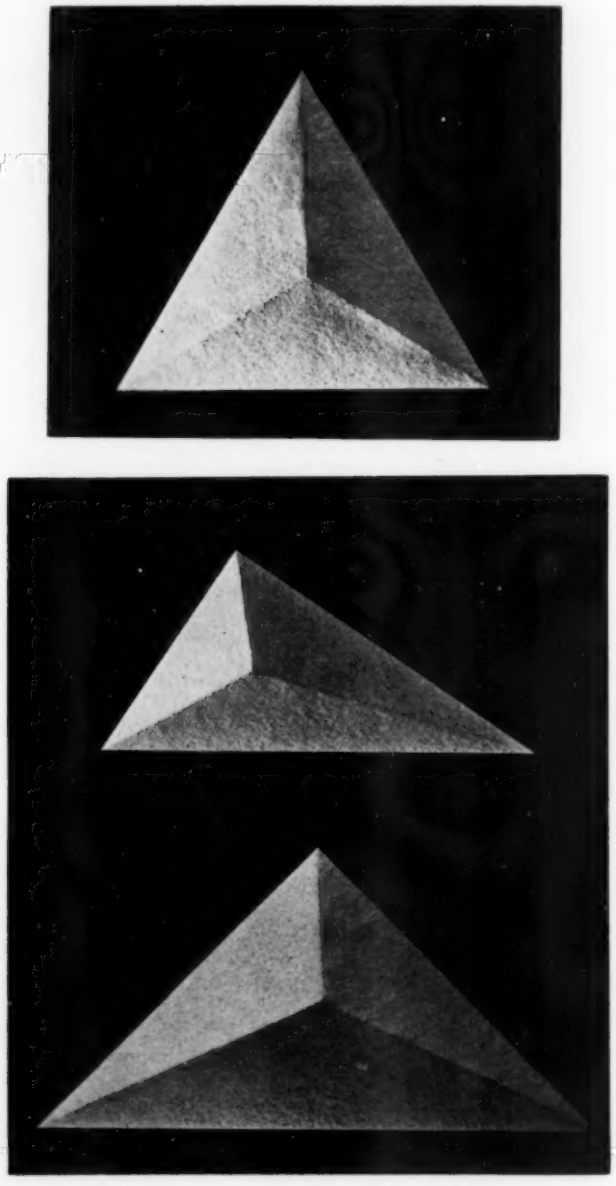
To solve the three equations, a function $F(x, y)$ can be introduced. Equation [3] is satisfied if

$$s_x = \frac{\partial F}{\partial y}, \qquad s_y = -\frac{\partial F}{\partial x} \ldots\ldots\ldots\ldots\ldots [6]$$

and Equation [4] if the function F satisfies the equation

$$\frac{\partial^2 F}{\partial x^2} + \frac{\partial^2 F}{\partial y^2} = \Delta F = -2G\theta = \text{const.} \ldots\ldots\ldots [7]$$

FIGS. 4–6 SAND HEAPS PRODUCED OVER RECTANGLES



while the condition [5] is equivalent to

$$\frac{\partial F}{\partial x}\,dx + \frac{\partial F}{\partial y}\,dy = 0$$

from which it is seen that on the boundary curve $y = f(x)$

$$F = \text{const.}\ (= 0) \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

Equations [7] and [8] contain the "membrane analogy" of Prandtl. The function F satisfying [7] and [8] for a given boundary curve $y = f(x)$ may be called *the elastic stress function of the cross-section*. If a thin, perfectly flexible skin or membrane, which has been stretched in its plane by a uniform tension t per unit of length and acting in all directions, is considered as attached to the boundary curve $y = f(x)$ of the cross-section for which the torsion problem is to be solved and loaded by a lateral pressure p, this membrane will be slightly deflected out of its

FIGS. 7–9 SAND HEAPS OVER TRIANGLES

plane. The deflections w of such a thin skin must satisfy the equation

$$\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} = \Delta w = -\frac{p}{t} \ldots\ldots\ldots\ldots [9]$$

with the boundary condition $w = 0$ along the curve $y = f(x)$. A comparison of Equations [7] and [9] and of the correspond-

ing boundary conditions shows that they are identical in form. The curved surface w (x, y) into which this membrane is distorted is an image of the elastic stress function F (x, y) of the cross-sectional area which determines the torsional stresses. The curved surface representing the elastic stress function

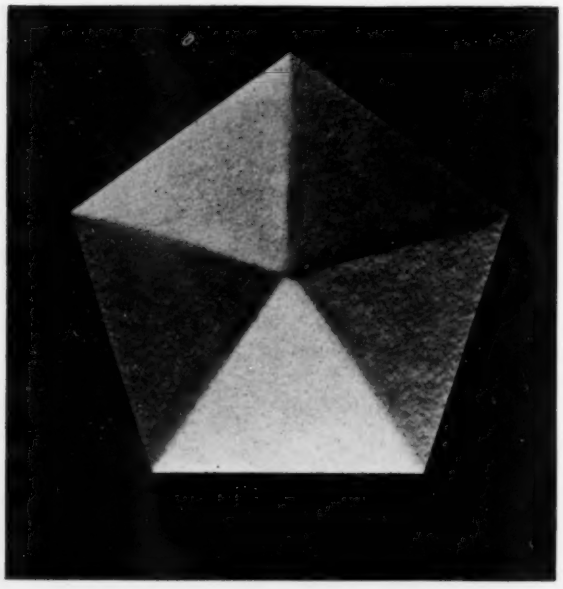


FIG. 10 SAND HEAP OVER PENTAGON

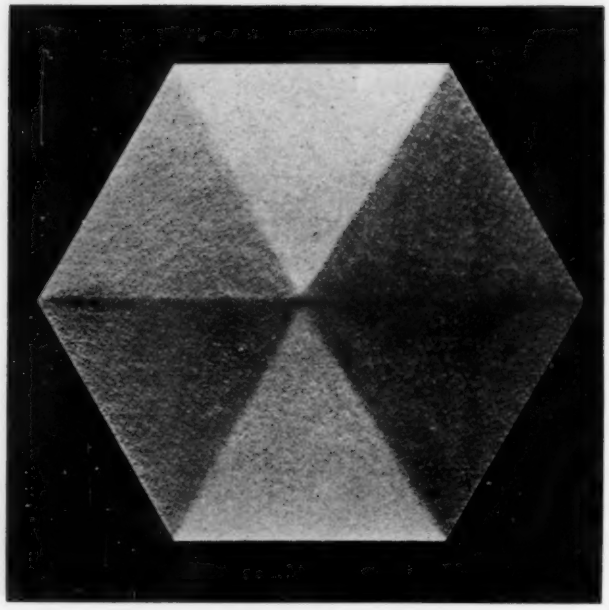

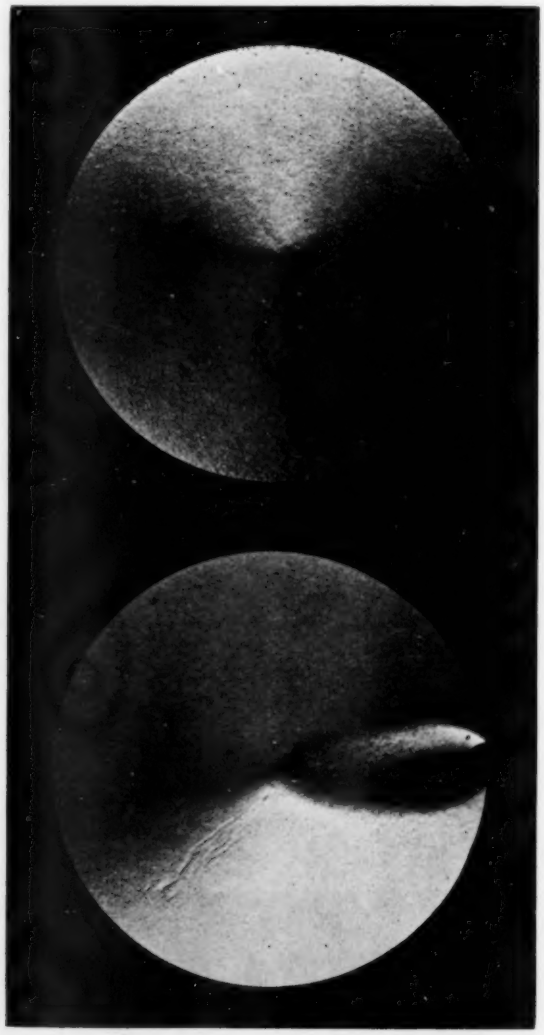

FIG. 11 SAND HEAP OVER HEXAGON

F (x, y) may therefore also be called the "stress bulge" of the cross-sectional area A. According to Prandtl's membrane analogy, the following statements hold: (1) The absolute value of the resultant shearing stress s at any point x, y of the cross-section of a twisted bar is equal to the gradient (to the greatest slope) of the elastic stress function F (x, y) or of the stress bulge of the cross-section, because the resultant shearing stress s is

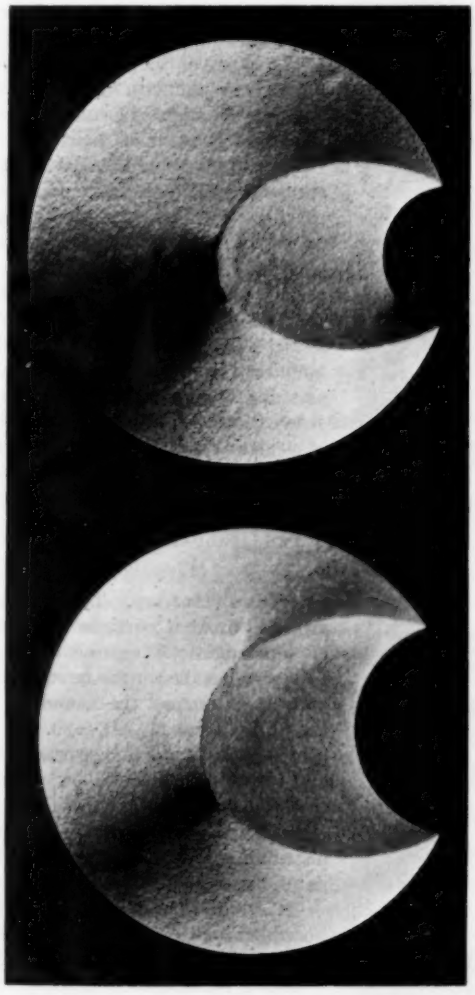
$$s = \sqrt{s_x^2 + s_y^2} = \sqrt{\left(\frac{\partial F}{\partial x}\right)^2 + \left(\frac{\partial F}{\partial y}\right)^2} \quad \ldots\ldots [10]$$

(2) The resultant shearing stress s is tangent to the contour lines of the stress function F (x, y). The contour lines of F (x, y) are the stress lines of the cross-sectional area of an elastically twisted bar. (3) The torque M is equal to twice the volumetric content of the stress function F over the cross-sectional area, or

FIGS. 12 AND 13 SAND HEAPS OVER CIRCLE AND CIRCLE WITH SMALL CIRCULAR NOTCH

$$M = 2 \int\int F\ (x,\ y)\ dx\ dy \quad \ldots\ldots [11]$$

As the absolute values of the ordinates of the elastic-stress function F, according to Equation [7], are proportional to the angle of twist θ of the bar, Equation [11] determines the torsional rigidity of the cross-sectional area.



PLASTIC TORSION

The Plastic Stress Function for Torsion. If the torque M by which the bar is twisted is gradually increased, the ordinates of the elastic stress function F (x, y) and consequently the slopes of this surface, which latter determine the shearing

stresses s, will also increase. There will exist a certain twisting moment M_0 at which the greatest shearing stress s_{max} in the cross-section of the bar will just become equal to the yield stress k of the metal in pure shear:

$$s_{max} = k \quad [12]$$

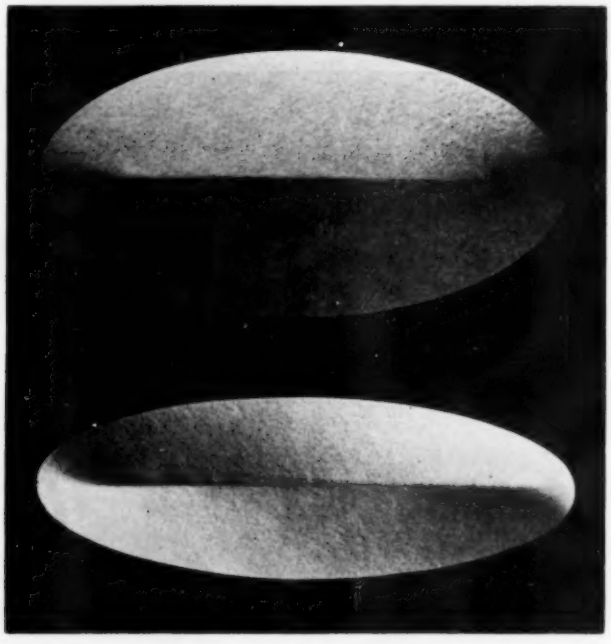
The first yielding in the bar will occur under this torque M_0. If the twisting moment M is further increased, so that $M > M_0$, the yielding will spread out. As the maximum shearing stress under pure elastic torsion will occur mostly at one point of the boundary line of the cross-sectional area (or in more than one point on this line), if $M > M_0$, yielding will spread out, starting from this or these points. For torques M greater than M_1, we must therefore distinguish between certain "plastic" areas A_1, A_2, ...in the cross-section (see shaded portion of Fig. 3) where

FIGS. 14 AND 15 SAND HEAPS OVER AREAS BOUNDED BY TWO CIRCULAR ARCS

the shearing stresses s will reach the yield stress k and in which plastic flow will start to develop and an elastic portion A_0, where $s < k$ and the material of the bar will be stressed only elastically.

In the plastic areas A_1, A_2, ...the components s_x and s_y of the shearing stress s must obviously satisfy the two equations

$$\frac{\partial s_x}{\partial x} + \frac{\partial s_y}{\partial y} = 0 \quad [13]$$



and

$$s_x^2 + s_y^2 = s^2 = k^2 = \text{const} \quad [14]$$

The first of these is the condition of equilibrium. The second expresses the fact that the resultant shearing stress s now reaches the limiting or yield stress k.

Using again

$$s_x = \frac{\partial F}{\partial y}, \qquad s_y = -\frac{\partial F}{\partial x} \quad [15]$$

FIGS. 16 AND 17 SAND HEAP OVER ELLIPSES

FIG. 18 SAND HEAP OVER AREA BOUNDED BY TWO CIRCULAR ARCS AND TWO STRAIGHT LINES

[13] is satisfied, and from [14] is seen that now the function F must satisfy the equation:

$$\left(\frac{\partial F}{\partial x}\right)^2 + \left(\frac{\partial F}{\partial y}\right)^2 = k^2 = \text{const} \quad [16]$$

This new function F will be called *the plastic stress function of the cross-sectional area.* As obviously in the areas A_1, A_2, ...

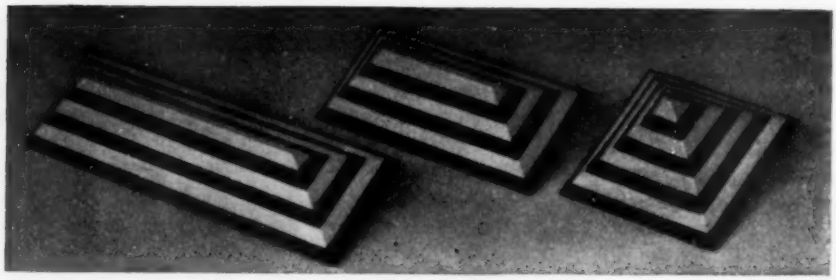


Fig. 19

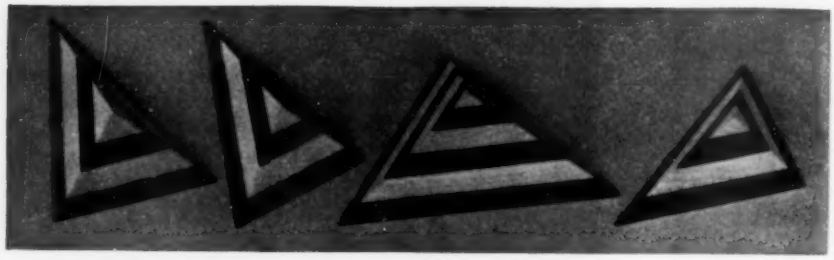

Fig. 20

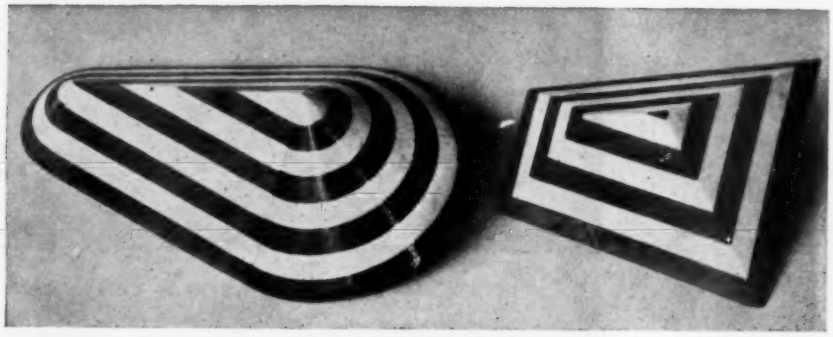

Fig. 21

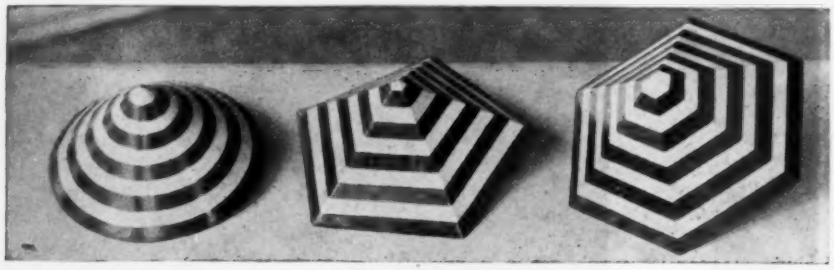

Fig. 22

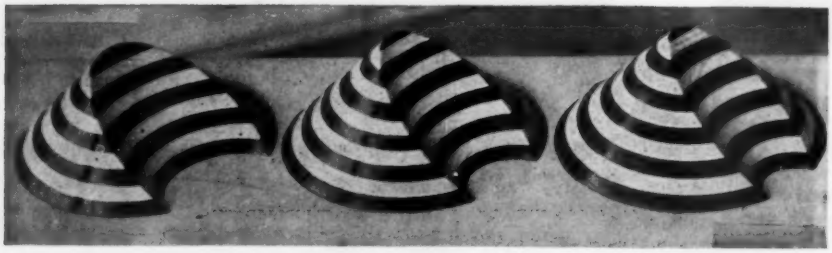

Fig. 23

FIGS. 19–23 WOODEN MODELS OF PLASTIC STRESS FUNCTION FOR TORSION FOR VARIOUS CROSS-SECTIONS

the resultant shearing stress $s = k =$ const. and this latter is also determined by the greatest slopes of the surface $F(x, y)$, it is seen that the surface F must now within $A_1, A_2, \ldots$ have a constant slope. Hence the plastic stress function $F(x, y)$ is determined by one or the other of the two *surfaces of constant slope, which can be erected over the boundary line on both sides of the cross-sectional area of the twisted bar.* The shape of this surface is easily found by sprinkling a fine powder on a piece of cardboard held in a horizontal position and having the same shape as the cross-sectional area. Using sufficient powder, the sloping surface or a "heap" will cover the area, and will be an image of the plastic stress function F of the cross-section.

The slopes of the plastic stress function for a given boundary curve $y = f(x)$, can easily be constructed geometrically or represented by means of their contour lines. Obviously, these lines must be a set of curves equidistant from the boundary curve $y = f(x)$. If, for example, the boundary line is a circle, the contour lines of F will be concentric circles; if in a certain part it is a straight line, the contour lines in the neighborhood will be straight lines parallel thereto. If the boundary curve consists only of circular arcs and of straight portions, the plastic stress function $F(x, y)$ will consist only of straight circular cones and of inclined planes. Several examples of such cross-sections will be referred to later on.

THE GRADUAL TRANSITION INTO THE PLASTIC STATE

Sandheap Analogy. The question now arises as to what portions of the surfaces of constant slope represent the plastic regions when the torque increases further, and also how may the boundary lines of the plastic areas $A_1, A_2, \ldots$ (see Fig. 3) be determined or found, corresponding to a given torque $M > M_0$. The answer to these questions is given by the following experimental representation of the stress distribution in a twisted bar after the yield point has been passed.

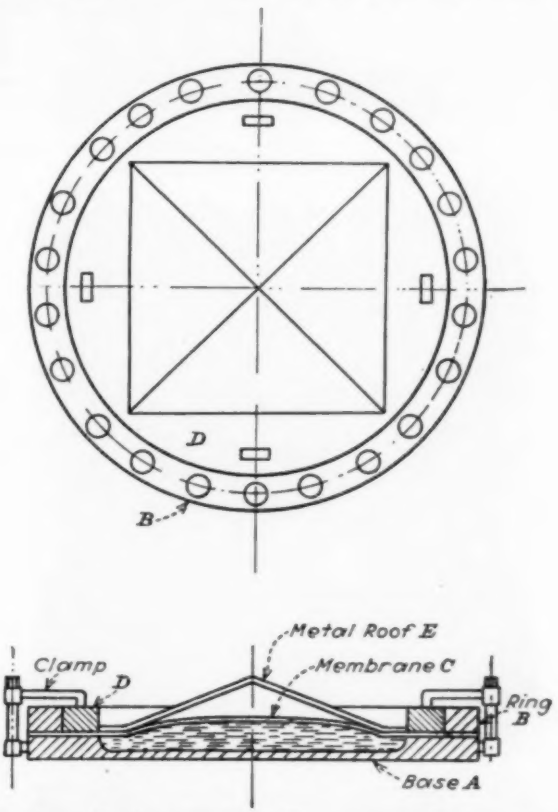
On a horizontally placed piece of cardboard having the geometrical shape of the cross-section, sand is heaped so as to form a sloping surface under gravity over the section. From this heap, a negative or "hollow" may be made, or a flat roof of constant slope may be erected above the boundary of the section. If the plane base of this flat roof is closed with a thin membrane stretched in its plane and this latter is loaded by pressure, when the pressure reaches a certain value, certain parts of the membrane will touch the sloping surface of the roof erected above the section.

The free parts of the membrane and those resting on the sloping surface together form the stress surface or the "stress bulge" for a plastically deformed bar in torsion. At those portions of the membrane touching the sloping surface, the metal yields, while at those corresponding to the free parts of the membrane, the metal remains elastic.

The following rules stated for the elastic torsion still hold true: After the yield point has been reached the resulting shearing stress at an arbitrary point x, y of the cross-section is the gradient of the stress surface $F(x, y)$; the twisting moment M of the bar is equal to twice the volume $M = 2\int\int F(x, y)dxdy$ enclosed by this surface; the contour lines $F(x, y) = \text{const.}$ of the complete elastic and plastic stress surface are the stress lines of the cross-section of the plastically twisted bar.

Shape of Plastic Stress Function Produced by Sand Heaps

From the preceding is seen that for a given cross-section, the distribution of stress in a twisted bar at the moment of first yielding will be found by using the shape of the stretched membrane when it first touches the flat roof as the elastic stress function of torsion. However, if the torque is further increased beyond its value M_0 corresponding to first yielding, the thin skin will partially cover the flat roof. In this case the stress function will be represented by the shape of the free part of the membrane, together with the parts of the roof covered by it. There will exist a certain torque M_{max} under the action of which the flat roof will be completely covered by the membrane. Under this torque the twisted bar will yield completely. The stress lines for complete yielding are exactly the contour lines of the flat roof or of the surface of constant slope erected above the boundary line of the cross-sectional area of the twisted bar.



The shape of this latter surface for a given cross-section can be produced by the sloping surfaces of a sand heap having the cross-sectional area as a base. Figs. 4 to 18 are photographs of such heaps of a loose powder which were obtained above brass plates of different shape.[3]

The shape of these surfaces of constant slope can be seen more exactly on the sets of wooden models shown in Figs. 19 to 23. These models were prepared from two different kinds of wood. A dark and a light-colored wood were glued together in alternate layers of constant thickness, and the models cut out from blocks thus formed. In this way the contour lines of the surfaces of constant slope can be obtained automatically. Thus a projection of these contour lines on the base of the wooden models furnishes at once the picture of the stress lines for the case of complete yielding of a twisted bar, or of the plastic-stress function for torsion corresponding to the given cross-section.

Apparatus for the Experimental Determination of Stress Distribution in Torsion Under Partial Yielding

The sand-heap analogy permits, by means of a special apparatus, the study of how plastic flow will penetrate into a twisted prismatical or cylindrical bar of steel. In this apparatus the shape of the stress function is experimentally determined with the help of a thin rubber sheet uniformly stretched in its plane and then loaded by lateral pressure.[4]

The apparatus (Figs. 24, 25, and 26) consists of an aluminum disk A about 12 in. in diameter, upon which a very uniformly stretched thin rubber sheet C is fastened by means of an aluminum ring B and screws. The rubber sheet is partly supported on one side by a flat surface on the aluminum disk, but a central circular portion of the rubber membrane is completely free. The membrane covers a depression in the aluminum disk in which space, by means of a tire pump, pressure can be applied. (See Figs. 24 and 25.) A second exchangeable disk D fitting snugly in the ring B contains the flat roof E. Several such exchangeable disks with different surfaces of constant slope were made. One was of glass, thus permitting observation of the movement of the rubber membrane. In other cases accurately machined brass plates were used. After the disk (with either the glass or metal roof) was fastened on the aluminum disk, pressure was applied below the rubber membrane and the latter allowed to bulge out until finally it partly or almost entirely covered the flat solid surfaces of the roof.

To make visible the boundaries of the plastic parts in a cross-

---

[3] The author is greatly indebted to Mr. H. Friedman, of Boston, for having carefully prepared and photographed these sand heaps and also for having carried out tests with two special pieces of apparatus, and which served to demonstrate the stress distribution in twisted bars.

[4] For the case of elastic torsion, Prandtl's membrane analogy was first applied experimentally by Anthes, who photographed the picture of a rectangular network of lines which was reflected by a soap film produced over a hole in a metal sheet. Another method also utilizing soap films was worked out by A. A. Griffith and G. F. Taylor, who measured the deflections of such films by an electric-contact method (Proc. 1st Int. Congress of Applied Mechanics, Delft, 1924, p. 39). A very handy apparatus serving for the same purpose and consisting of a uniformly stretched rubber sheet, over which a difference of pressure could be produced by evacuating the air on one side of the membrane, was demonstrated to the writer by Professor Enger Urbana at the University of Illinois in 1928. The means used in this latter apparatus were adapted somewhat in the one described above and constructed at the suggestion of the writer by H. Friedman at the Research Laboratories of the Westinghouse Electric & Mfg. Company in East Pittsburgh, Pa. Another experimental method for determining the distribution of stress in elastic torsion has been proposed by A. Piccard and W. Tohner utilizing a meniscus of a fluid. (Compare "Stodola Festschrift," J. Springer, Berlin, 1929.)

(The white areas are those stressed above the yield stress.)

section of a twisted bar (see following paragraph), the rubber membrane was covered with fine white powder and the roof with a thin film of oil. After pressure was applied to the apparatus and the rubber sheet forced against the faces of the flat roof, the powder adhered to those portions where the rubber membrane touched the roof, thus making visible the plastic parts of the cross-section which appeared white in the photograph taken of the hollow side of the roof after it had been removed. Fig. 26 at the right side shows one of the exchangeable disks filled with a flat four-sided pyramid of glass plates. A series of tests showing the gradual extension of the plastic regions in a twisted bar with different cross-sections (square, rectangular, trapezoidal section with rounded edges) are illustrated in Figs. 27–43.

(*a*) *Square.* In Figs. 27–31 it will be seen that the white areas are first formed in the middle of the sides of the square, where the shearing stress first reaches the yield point. With increasing twist or torque these white areas representing the portions which become plastic in the cross-section extend inward, finally leaving only a narrow, black cross (Fig. 31); this shows that the elastic portion in the cross-section is reduced until it practically consists of two narrow strips crossing at right angles and coinciding with the diagonals of the square, these diagonals being the projections of the corresponding four edges of the four-sided pyramid, which in this case is the plastic stress function of the cross-section.

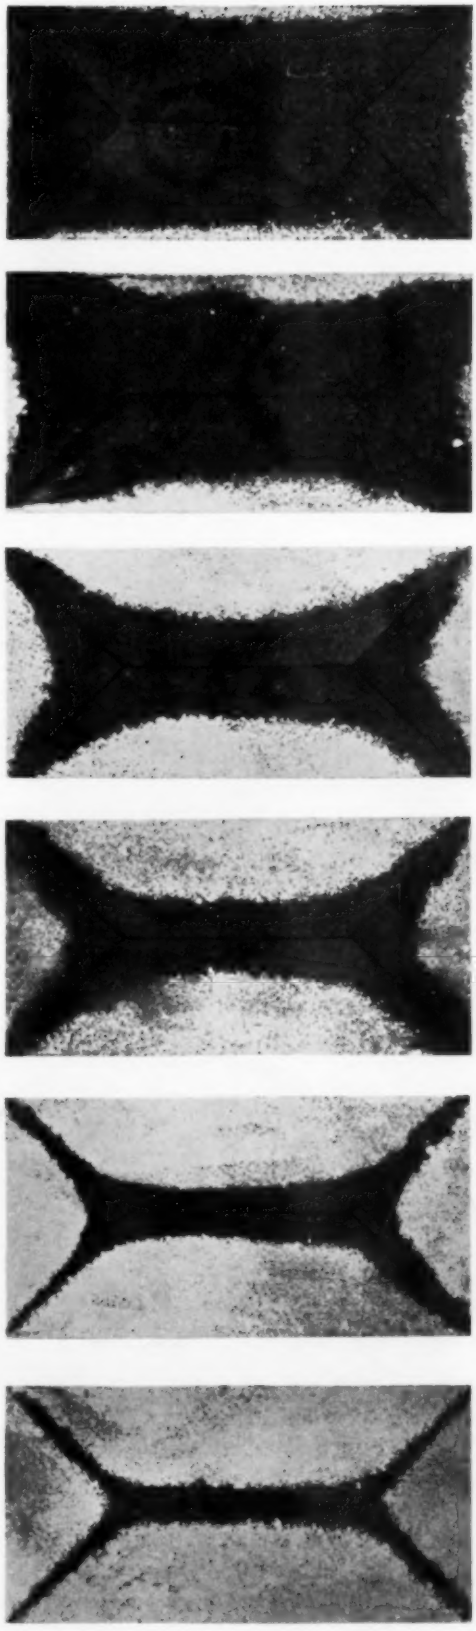
(*b*) *Rectangular Section* (ratio of sides 2:1). Figs. 32–37 show how the plastic area increases with increasing torque. Yielding first starts in the center of the long sides, but soon after two further plastic areas begin to develop along the short sides. In the last two photographs only a narrow region along the five edges of the roof remains black.

(*c*) The mode of penetration of the plastic regions for a twisted bar whose cross-section consists only of straight lines and circular arcs is shown in Figs. 38–43. Compare also Figs. 18 and 21, which show the corresponding sand heaps and surfaces of constant slope.

(*d*) *Torque for Complete Yielding.* In any of the preceding cases it is easy to compute the torque M_{max} under which the bar will yield completely.

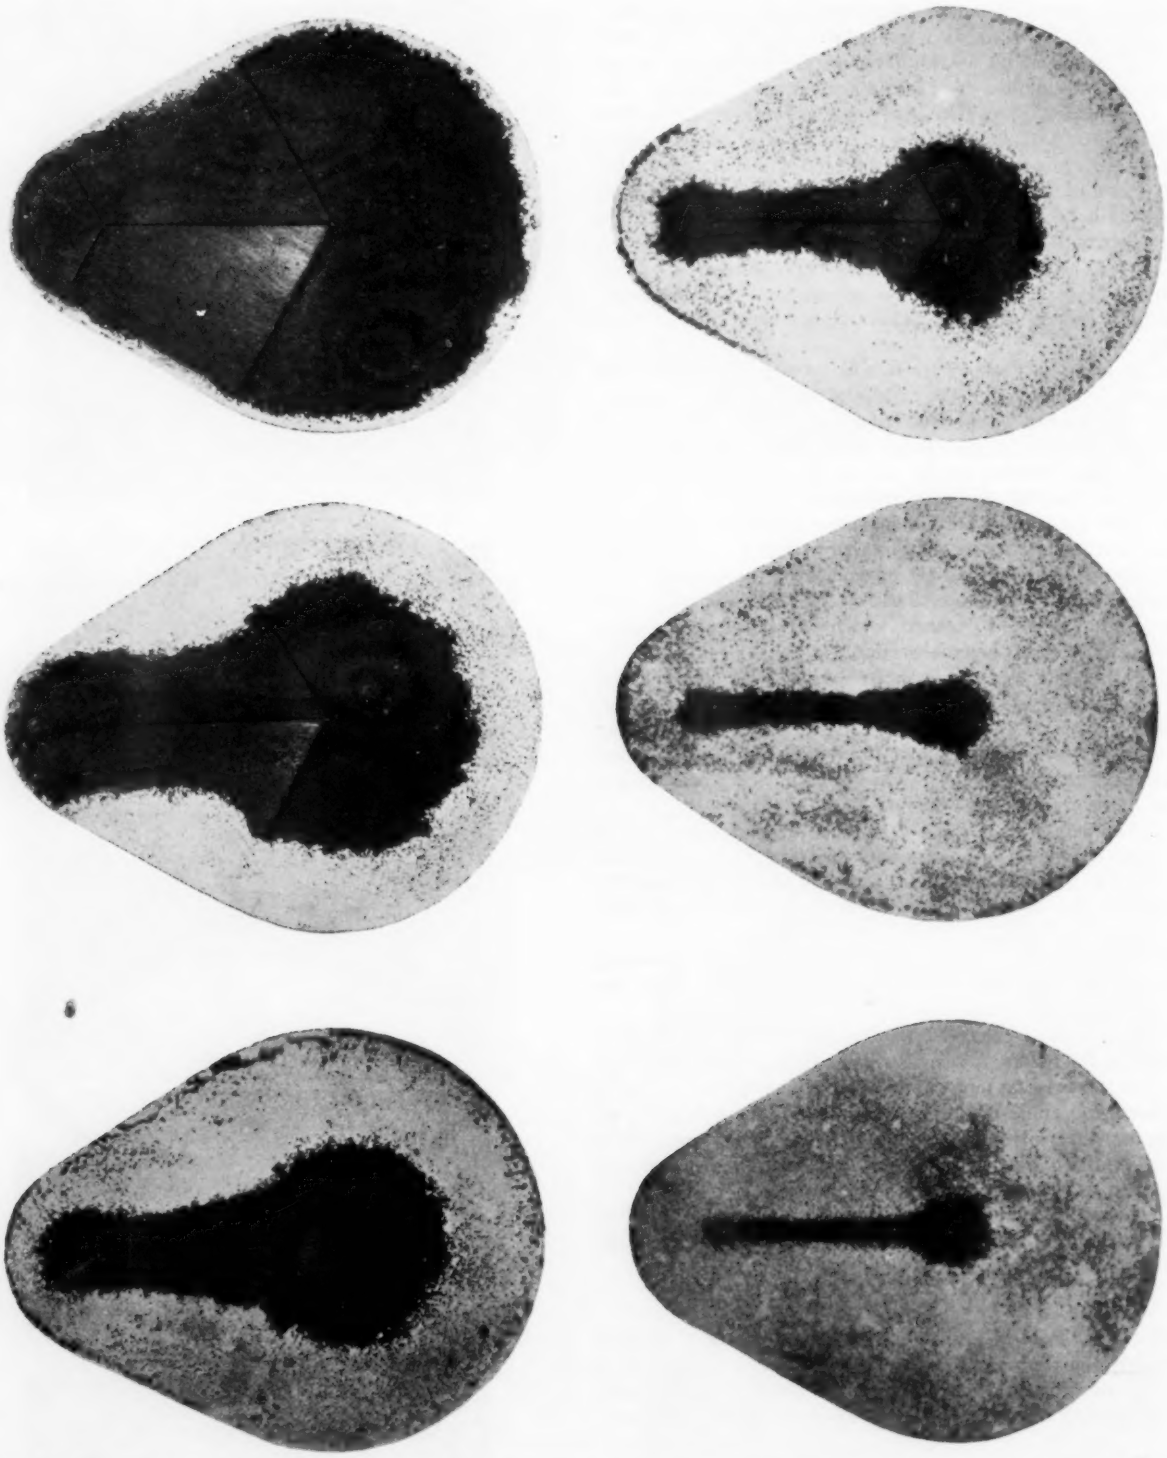
On the assumption that deformations are independent of yield stresses, it follows from this schematic representation that the values of the twisting moment M approach asymptotically with the increasing angle θ a value M_{max}, which latter is given by twice the value of the space enclosed *by the plastic stress surface.*

The condition where all parts of a twisted bar yield may be designated as the completely plastic state.



For example, taking a bar with a circular cross-section of radius r, the plastic-stress surface is a circular cone having the equation

$$F = k\,(r - a)$$



In this, k is the yield stress for pure shear. For $r = 0$, $F = -ka$, and the cone has a height $h = ka$ and a volume $V = \pi a^2 h/3$. According to our analogy, the twisting moment acting on the bar is equal to twice the volume of the cone, or

$$M_{max} = 2V = \frac{2\pi k a^3}{3}$$

For a bar having a cross-section of the shape of an equilateral triangle, the plastic-stress surface is a three-sided pyramid. Each side has a slope equal to $\partial F/\partial n = k$, since the shearing stress is equal to the slope of the stress surface. Therefore the pyramid has the height $h = ka/2\sqrt{3}$. The area of the base is $a^2\sqrt{3}/4$, its volume $V = a^3 h/4\sqrt{3}$, and the twisting

$$M_{max} = \frac{ka^3}{6} + \frac{ka^2(b-a)}{4}$$

EFFECT OF SMALL HOLES OR GROOVES IN A REGION SUBJECTED TO PURE SHEAR

(*a*) *Longitudinal Groove With Semicircular Cross-Section.* For the case of a cylindrical bar in torsion, having a small longitudinal groove of semicircular cross-section, qualitative estimates of the mode of yielding may easily be made. We shall first assume that the radius a of the groove is small in comparison with the diameter d of the bar. It is then permissible to replace

FIGS. 47 AND 48 APPARATUS FOR EXPERIMENTAL DEMONSTRATION OF HOW YIELDING SPREADS FROM A CYLINDRICAL HOLE

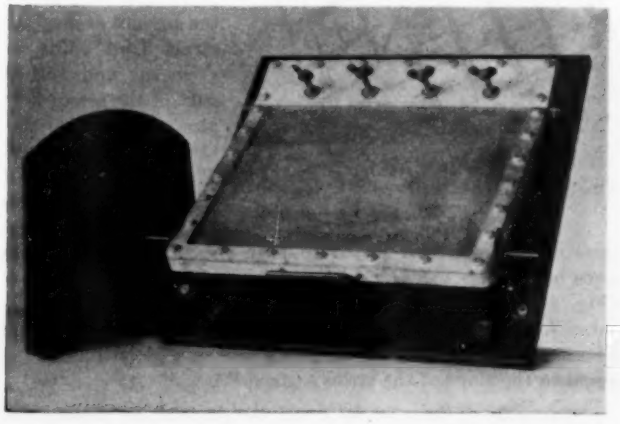

FIG. 49 APPARATUS FOR THE EXPERIMENTAL DEMONSTRATION OF SPREADING OF PLASTIC REGION FROM A CYLINDRICAL HOLE OR NOTCH

the boundary circle by the tangent. The disturbances in the shape of the stress lines may be determined under the assumption that at a considerable distance from the groove a constant shearing stress acts.

If a perfectly elastic material having a straight edge with a small semicircular groove is subjected to pure shear acting in

a direction parallel to the straight edge (Fig. 44), the stress lines in the neighborhood of the groove may be determined easily by means of the potential theory or also with the help of the membrane analogy. At considerable distances from the groove the stress lines will be parallel to the straight parts of the

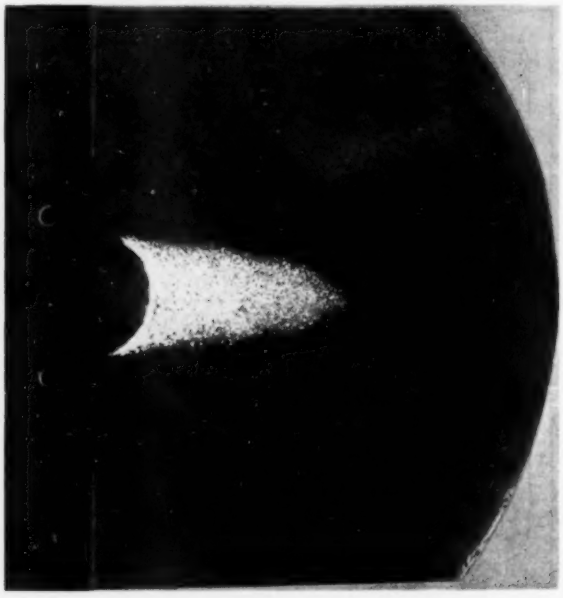

FIG. 50 FRONT VIEW OF FLAT CONE. WHITE AREA IS PLASTIC REGION DESCRIBED IN TEXT

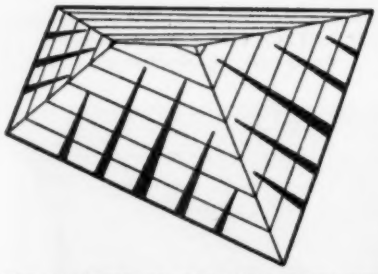
edge; in the neighborhood of the groove, however, they will follow the semicircle.

One has only to conceive of a thin membrane attached along an edge *ABCDE* of the body, this membrane being stretched in a plane inclined to the plane of the cross-section (Fig. 44). The slope of the inclined plane is a measure of the amount of shearing stress (the value of s) in the undisturbed part of the stress field at a considerable distance from the groove. The contour lines of the stretched membrane are the stress lines of the region subjected to pure shear. Evidently these lines are closest together in the neighborhood of the point C (Fig. 44) at the edge of a groove, and at a considerable distance from it they become more and more nearly parallel to the edge. The shearing stress s which exists at a given point P is equal to the slope of the stress surface F.[5]



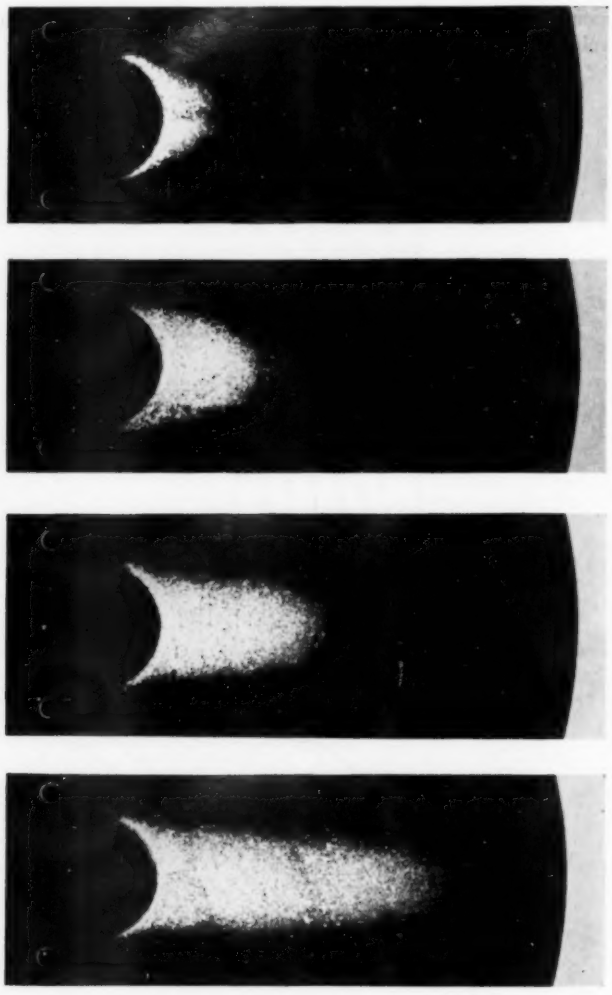


FIG. 55 POSITION OF SLIP LINES RELATIVE TO PLASTIC-STRESS SURFACE

[5] By means of the potential theory the shape of the elastic stress surface F may easily be determined in the polar coordinates r and α:

$$F = c \cos \alpha \left(\frac{a^2}{r} - r \right)$$

By forming the derivatives of this surface the maximum shearing stress is found to occur at the edge of the groove at C, where $r = a$ $\alpha = 0$, and $s = 2c$, and is twice as large as the shearing stress $s = c$ at a great distance from the groove. Since for great values of x $F = -cx$, the shearing stress there is $s = -\frac{\partial F}{\partial x} = c$. The figure

FIGS. 51–54 SPREADING OF PLASTIC REGION FROM A CYLINDRICAL HOLE

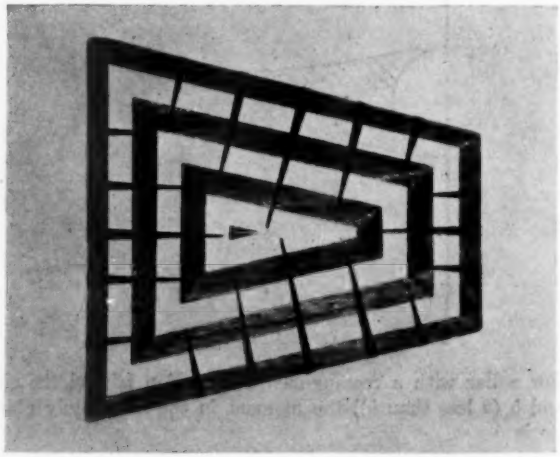

FIG. 56 POSITION OF SLIP LAYERS IN CROSS-SECTION OF TWISTED BAR RELATIVE TO CONTOUR LINES OF PLASTIC SURFACE

of the contour lines in this case is exactly the same as that of the well-known streamlines of a fluid flowing along a straight wall on which the half of a long circular cylinder has been fastened (Fig. 44).

As the inclination of the plane of the thin membrane is increased, all shearing stresses are increased until finally the stress at the point C reaches the yield point k. Then the membrane must be inclined in a plane $F = kx/2$ with respect to the plane of the cross-section. In order to determine the limits of the plastic area as the inclination of the plane of the thin membrane is further increased, we must think of a sloping surface in the form of a cone with radius $r = a$, erected as shown in Fig. 45, the cone being pointed downward. If the slope of the membrane at C (Fig. 44) becomes larger than $k/2$, certain neighboring parts of the membrane will lie upon the cone. These parts lying on the

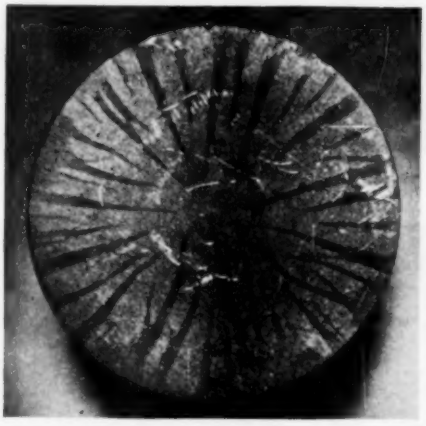

FIG. 57 ETCHING OF CROSS-SECTION OF A TWISTED BAR

cone (the corresponding area is shaded in Fig. 44) represent the plastic area of the cross-section.

At the suggestion of the author, E. Trefftz[6] has determined mathematically the shape of the membrane for this case.

From the standpoint of an experimental comparison, the limiting case (not considered by Trefftz) of what shape the flow areas assume if the shearing stress $s = c$ approaches the value of the yield stress $s = k$ for pure shear is of a special interest. The writer found[7] that in the case of a small semicircular groove, plastic flow penetrates into the stressed material with the increasing shearing stress along a narrow strip the width of which finally approaches a finite value $b = 4a/\pi$.

Thus in a body stressed by pure shear and having a well-defined yield stress in shear or tension, a thin plastic layer starts at a semicircular notch of diameter d. When at greater distances from the notch the shearing stress approaches the yield stress of the material for pure shear, this plastic area extends to infinity and has a width $2/\pi$ times the diameter d of the notch. (Fig. 46.)

The plastic stress function is in this case a circular cone

$$F = k\,(a - r),\ (r > a)$$

These considerations lead to a somewhat paradoxical conclusion; for, according to what has been stated previously, the presence of a small longitudinal groove on the surface of a material strained by pure shear is sufficient to cause the small

[6] Über die Spannungsverteilung in tordierten Stäben bei teilweiser Überschreitung der Fliessgrenze. *Zeit. Ang. Math. Mech.*, vol. 5 (1925), p. 64. In this a second noteworthy case is treated, namely, the origin of the first flow area at the inner reentrant edge of a twisted steel angle iron.

[7] Proc. 2nd Int. Congress for Applied Mechanics, Zürich, 1926.

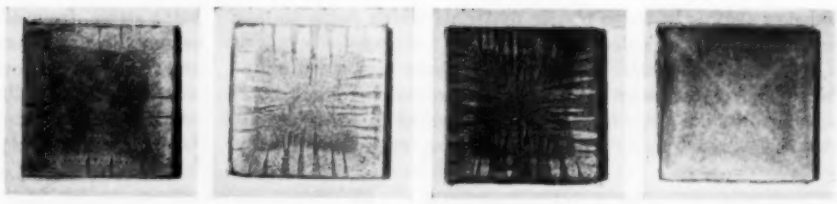

Fig. 58

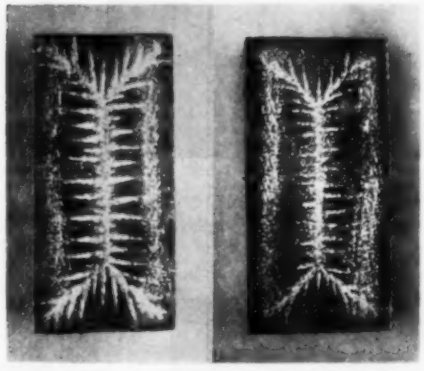

Fig. 59

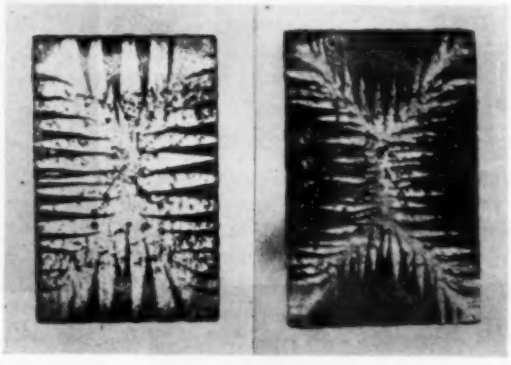

Fig. 60

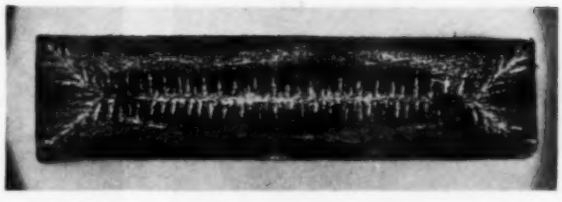

Fig. 61

FIGS. 58–61 ETCHINGS OF CROSS-SECTIONS OF TWISTED BARS

plastic area at the edge of the groove to extend deeply into the material, if the shearing stress at this edge is increased to the yield point. Moreover from this it follows that it is not possible, by increasing the shearing stress, to produce plastic deformation elsewhere than in the narrow flow area. The apparent discrepancy between this conclusion and actual test results which would show that it is possible to raise the stresses higher than the yield point is easily explained in recalling one of the idealizing assumptions, on which it was based; namely, that the yield stress should be considered as independent of deformation. On the other hand, the above conclusions have been confirmed by many observations on the development of the thin flow layers

and flow figures in those plastic materials which begin to flow under a constant or a decreasing stress.

(*b*) *Cylindrical Hole.* In the neighborhood of a small cylindrical hole of diameter d in a region stressed by pure shear, two narrow flow areas of width $2d/\pi$ develop in an analogous way as described under (*a*) if the shearing stress is gradually increased to the yield point. The stress distribution in the neighborhood of a cylindrical hole in a plate of infinite extension, which is subjected to pure shear, corresponds completely with that of the above-mentioned case of a cylindrical groove; the two cases are mathematically the same.

From these considerations, it must be concluded that in a plastic material, which begins to flow under approximately constant stress, from all those places where the stresses were concentrated in the elastic state, narrow plastic regions will radiate and the plastic deformation will be localized to thin layers of a comparatively small thickness, along which it will spread inward into the stressed material.

(*c*) *Mechanical Apparatus for Demonstrating Spreading of Plastic Flow Starting at a Small Notch or Hole.* The preceding conclusions can be confirmed by means of a mechanical apparatus (Figs. 47–49) consisting of a sheet of rubber uniformly stretched in its plane on a rectangular frame of metal, which may be tilted about one of its sides. Above the rubber membrane, a flat truncated semi-cone with a semicircular cross-section, machined from a block of black micarta, is rigidly fastened by means of

the screws shown in Fig. 47 to the flat stationary plate of the frame in the manner indicated in Figs. 47 and 49. The flat cone of black micarta required for the model test is also shown at the left of Fig. 49 and in a front view in Fig. 50. The rubber membrane was covered with a white powder and the cone with a thin coating of oil. Then the frame with the rubber membrane was tilted through a certain angle. Where the micarta and rubber surfaces came in contact, the white powder adhered to the black micarta. The white areas thus obtained on the surface of the cone could be photographed and illustrate the shape of the plastic region (of the shaded area in Fig. 44) as it spreads inward from the edge of the semicircular notch or groove, as the slope of the tubber sheet is gradually increased.[8]

The spreading of the plastic region from the edge of a semicircular notch as the shearing stress s increases is shown in the set of photographs (Figs. 50 and 51–54) taken by Mr. Friedman. The angles of inclination of the plane of the rubber sheet are proportional to the shearing stress in the undisturbed parts of the body subjected to pure shear.

Slip Layers in Twisted Steel Bars

(*a*) *Flow Layers. Torsion Tests With Iron Bars.*[9] The position of the slip layers in the plastically deformed parts of a twisted bar may be predicted with the help of the plastic stress surface. For a soft metal such as wrought iron, the slip layers coincide approximately with the surfaces of maximum shear or of maximum shearing displacements. These slip layers are therefore approximately perpendicular to each other. At an arbitrary point inside a twisted bar one surface of maximum shearing stress coincides continuously with the plane of the cross-section. The other surface of maximum shear is parallel to the axis of the bar. The traces of the second system of slip layers must remain perpendicular to the cross-section.

After the yield point has been passed in a twisted iron bar, very regular layers or markings may actually be shown to exist. In these the iron is apparently deformed more than in the neighboring layers. These layers may subsequently be made visible in the cross-section of the bar by means of Fry's etching method. In such etched sections the flow layers appear as dark strips and lines. A series of such etchings on soft-iron bars, using Fry's method, are shown in Figs. 57–70: In Fig. 57 for circular cross-sections, in Figs. 58 to 61 for rectangular cross-sections, in Fig. 62 for triangular cross-sections, and in Figs. 63–64 for two other cross-sections. In the etched cross-sections the traces of one system of slip layers are indicated. Traces of the second system of slip layers could only be noted in exceptional cases.

In a twisted iron bar, the flow layers appear uniformly when the twisting moment reaches values corresponding to those along the horizontal portion BC of the moment curve $M = f(\theta)$, Fig. 1.

The first flow layers occur at such values of the twisting moment at which the outermost part of the cross-section has already been plastically deformed and the moment curve begins to bend over into the horizontal branch. With increasing twist new layers form beside the old ones, while the latter become longer and thicker. The flow layers appear in the etched cross-sections of the photographs as wedge-shaped areas, the apexes of the wedges pointing toward the less-stressed parts of the cross-section (Fig. 57).

As a rule, it may be concluded that the black flow lines in the cross-sections run mainly perpendicular to the stress lines (the projections of the contour lines of the plastic stress surface). Moreover these flow lines always remain perpendicular to the edge of the cross-section. Thus they run in the direction of the projections of the lines along which water will run off the flat roof erected above the cross-section and representing the plastic-stress surface (Figs. 55, 56). With the more severe deformations, the black strips finally cover the whole cross-section. In the extreme right etching of the square cross-section of Fig. 58, for example, which corresponds to the most severely twisted bar, the elastic areas may only be recognized as bright areas along the diagonals of the square. In other words, the four ridges of the stress surface F, which is here a four-sided pyramid, are projected on these diagonals.

(*b*) *Bars With Longitudinal Grooves.* In Figs. 65–70 are shown etchings of twisted bars having longitudinal grooves of different shapes and dimensions, obtained by W. Bader. On the flow figures found on the cross-sections of a cylindrical bar with a small semi-circular groove, Fig. 65, it will be noticed that three wide flow layers extend from the groove.

Construction of the contour lines of the plastic-stress surface for complete yielding is in these cases much facilitated by the condition that the surfaces in question consist entirely of either planes or straight circular cones. Therefore the intersections of the surfaces of constant slope which correspond to the edge of the cross-section can be obtained easily by constructing the mutual intersections of these planes and circular cones. In the photographs of the wooden models, the contour lines may be seen.

According to the assumptions made, in the completely plastic condition the elastic area in the cross-section must shrink until it coincides with the ridges (more exactly the projections of the ridges upon the cross-sectional area) of the plastic-stress surface of the sand heap which may be conceived to be erected over the cross-section. It will be seen by comparison of the etchings with the corresponding contour figures that the middle lines of the white, jagged, ridge areas in the photographs of the etchings agree quite well with the curves of the ridges of the plastic-stress surface shown in the photographs of the wooden models or the corresponding sand heaps.

Acknowledgment

The author wishes to acknowledge his indebtedness to S. M. Kintner, assistant vice-president of the Westinghouse Elec. & Mfg. Company, and to J. M. Lessells, manager of the Mechanics Division of the Westinghouse Research Laboratories, for the use of facilities needed to conclude this investigation begun in Germany. Special acknowledgments are due to Dr. W. Bader for having prepared the etchings of the cross-sections of twisted steel bars, and to H. Friedman for having prepared the two sets of apparatus, the sand heaps, and wooden models, and photographed them.

Addendum

Since the paper was presented, three wire models mounted on micarta plates have been prepared from surfaces of constant slope of elliptical cross-sections. These surfaces can easily be represented by wire models since the curve in which the surface of constant slope of an ellipse intersects the vertical plane of symmetry erected above the base ellipse and containing the major axis, is itself an ellipse. Furthermore, if the generatrices of the surface of constant slope are so chosen that they start

[8] E. G. Coker in his valuable paper, "Elasticity and Plasticity" (Thomas Hawsley lecture, Proc. Inst. Mech. Eng., vol. 1, 1926), has published some photographs which show the shape of the plastic stress function by means of sand heaps in a similar case; namely, for a twisted shaft having one or more keyways.

[9] The author is much indebted to Dr. W. Bader, who has carried out these tests—see his Doctor thesis, 1927, Univ. of Göttingen. See also *Zeit. V.D.I.*, No. 10, p. 317, 1927.

in points along the base ellipse which are situated on a set of equally spaced lines perpendicular to the major axis of the ellipse, the generatrices will intersect the vertical symmetry plane in a set of points, which are in their horizontal projection also equidistant from each other. Figs. 71–73 showing three such wire models of surfaces of constant slope erected above ellipses having ratios of major axis to minor axis of 1:2, 1:4, 2:3 were constructed in this way. Fig. 74 shows a wire frame on which

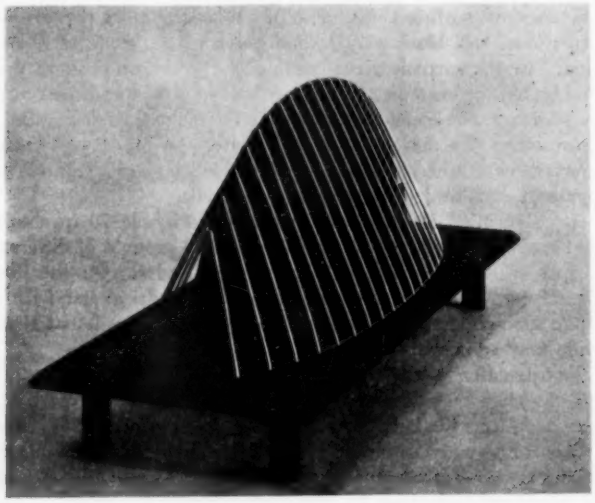

FIG. 71

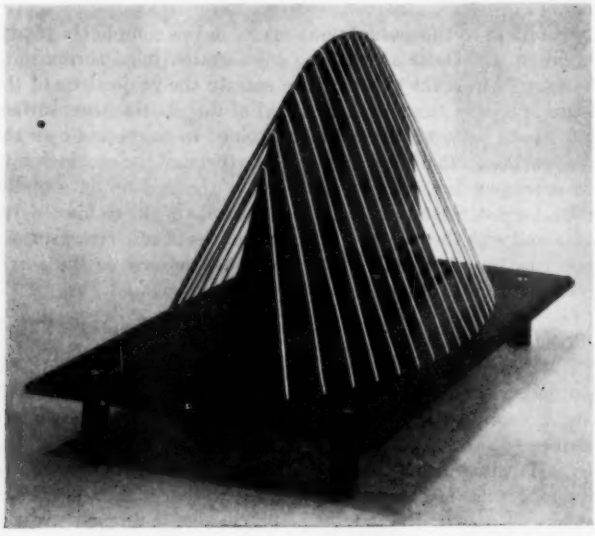

FIG. 72

brass disks of various shapes can be attached and covered by sand for demonstrating sand heaps.

Discussion

E. G. COKER.[10] The author has explained the subject matter so lucidly that there seems little to criticize, but there is one matter which appears to call for some further explanation in the last section dealing with slip layers in twisted steel bars. Referring to the right-hand photograph of Fig. 58, there are faint traces of a square band of light inside and bordering the contour of this specimen, and similarly there are more marked indications of light-colored bands bordering the longer sides of the sections shown in the photographs, Fig. 59 and 61. These ultimately join up with the feathery diagonals connecting the central ridges with the angular points of the sections. It would be of interest if the author would describe in some detail the meaning to be attached to these bands running parallel to the contours and near to them. The author is to be congratulated on a paper of such scientific interest and importance.

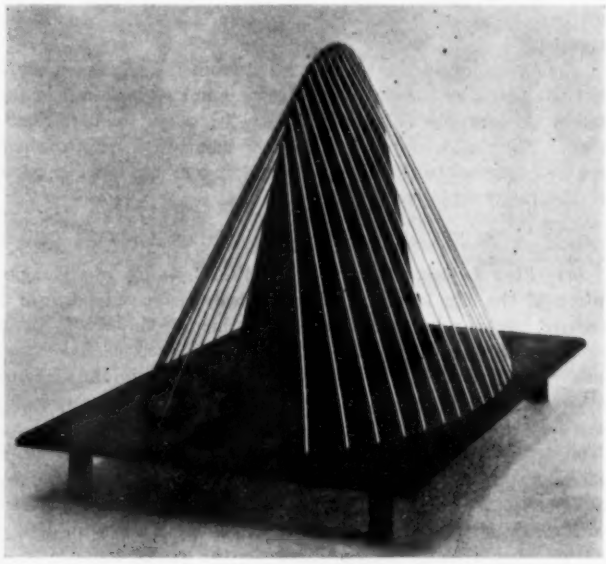

FIG. 73

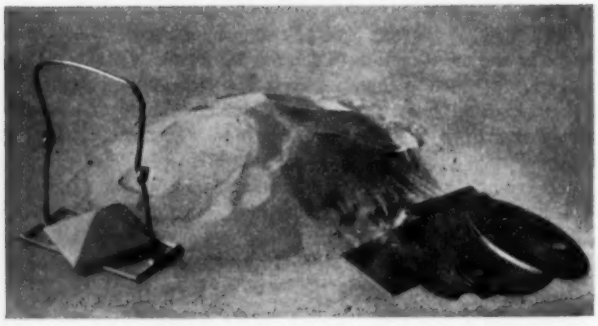

FIG. 74

G. M. EATON.[11] The mathematician to whom a complicated equation conveys a physical picture may consider it almost childish and at least of small practical value to resort to models as the author did in the research which preceded his paper. But to the average mechanical engineer he offers a new tool. He enables us to start developing in our minds a qualitative sense of plastic actions, which we cannot achieve from equations.

If we can sharpen this new sense finely enough to warn us when we are working in a dangerous range, then we shall know when to call for the assistance of the specialist in plastic phenomena.

The writer sincerely hopes that the author will continue to

[10] Professor of Civil and Mechanical Engineering, University of London, University College, London, England. M.Inst.C.E.

[11] Spang-Chalfant & Co., Inc., Ambridge, Pa. Mem. A.S.M.E.

work along this line and give us periodic reports similar in form to the present paper, because we can put this kind of information to work promptly.

This paper is an illustration of one way that applied mechanics can be "sold" to industry.

GLEASON H. MACCULLOUGH.[12] The paper is so excellent and valuable that the writer hesitates to raise a question on even one relatively minor point.

In considering the effect of a small longitudinal groove of semicircular cross-section in a twisted cylindrical bar, the author states in the third paragraph below Fig. 57 that the plastic area extends to infinity in a direction perpendicular to the longitudinal axis and has a width of $2/\pi$ times the diameter d of the notch. From this it follows, so he says, that it is not possible, by increasing the shearing stress, to produce plastic deformation elsewhere than in the narrow flow area. As we interpret this statement, it means that in an overstrained cylindrical bar with a small semicircular keyway, the plastic area never extends outside of the radial region of width $2d/\pi$ mentioned above. The author admits a seeming paradox here.

How to reconcile this view with the picture of the plastic area that would be obtained by the orthodox method, namely, the membrane stretched over the hole with an opening like that of the shaft and inflated until it touches the "roof" of the plastic stress function as per Fig. 13, is a puzzle to the writer. The smaller the hole, the more nearly this membrane (in the so-called orthodox method) touches the roof in equal width zones all the way round the circumference, however large it may be.

To be sure, the author's arguments at a first reading seem convincing. While they may hold for the initial appearance of the plastic area, the writer wonders if they do really hold at the greater distances from the notch. He would add here that he is not questioning the dimension $2d/\pi$ obtained in the tilted-sheet analogy.

It would seem that perhaps the roof which the author implicitly used in the tilted-sheet method is not the same as would be used with the circle. In this latter or orthodox method, the roof consists of a circular cone (no matter how large the radius) and an inverted cone. In the tilted-sheet analogy the circular cone has been transformed into an inclined plane, but the inverted cone remains an inverted cone of the same size.

The point the writer wishes to emphasize is this: Should not this inverted cone have been transformed into some other surface by the same transformation which carried the upright cone over into the oblique plane? It is agreed that at the edge the conditions of the problem are the same in the two methods, but as one penetrates into the shaft, he begins to doubt if they are. In fact, the center of the round bar or the vertex of the upright cone has been changed from a point to a line equal in length to the circumference, yet the inverted cone has not been changed. The distortion is akin to that on a map made according to Mercator's projection: the map of Canada undergoes a distortion; can we leave that of Greenland unchanged?

The radial lines in the etched bar of Fig. 65 appear to bear out the author's conclusion if we fail to note that the plastic area is not confined to lines radiating from the keyway. Thus the writer still wonders if the above views may not explain away the paradox.

M. F. SAYRE.[13] The author is to be congratulated on the success with which he has shown the results both of the "Sand-heap" method and of the "slip-layer" method in his illustrations.

There are only two possible additions which the writer might make to the discussion. One is to emphasize the point that the "sand-heap" results are essentially limited to mild steel and that they will not apply rigorously to non-ferrous metals, for which no yield point can be found, nor will they apply to the full extent to the high-strength, heat-treated or cold-worked materials which are commonly used for springs. The same basic idea, of course, applies to plastic flow in these cases, but due to the absence of a sharply defined yield point, the solution is not quite as simple.

The present paper does not include a discussion of the residual stresses in the bar as a result of previous plastic flow. This, it is believed, the author has treated in a previous paper. The experimental work carried on under the Research Committee for Mechanical Springs has brought out rather clearly that in many cases one effect of plastic flow is to change the modulus of elasticity of the material under future loadings. This change in modulus may be great enough to have a relatively large quantitative effect upon the magnitude of the residual stresses.

C. R. SODERBERG.[14] The general problem of "strength" of engineering structures involves problems in elasticity for the determination of deformations and stresses, and problems connected with the failure of our materials for determining the effects of these stresses. It is only fairly recently that some one has had the courage to ask questions concerning the plastic behavior of our materials as well. The writer believes that the incentive for studies in plasticity actually came from the geologists, and the direct returns have possibly been greater in that science than in engineering. Restricting ourselves to engineering, however, the general problem of strength will include elasticity, plasticity, and failure. The last heading is somewhat unsatisfactory; the German word *Anstrengung* is more to the point, but unfortunately there is no equivalent of this word in the English language. It is a regrettable fact that, among engineers, the problem of strength is frequently approached as a problem in elasticity. When the stresses are known the problem is considered as solved, while in reality the most difficult part of the problem lies in determining the ultimate effects of the stresses.

The work of the author and others in clearing up many difficult problems of plasticity is of great value in this connection, because the most important of our engineering materials are ductile materials having a stress-strain diagram which very closely resembles that of Fig. 2 of the paper. The ultimate outcome of these studies still remains hidden; there are very few positive results which can be shown to have a definite cash value in engineering practice. A disappointment is inevitable, therefore, if the present paper is approached with the object of obtaining ready-made and simple solutions for predicting the failure of ductile materials under torsion. The writer does not by any means consider it necessary to justify every bit of our brain work by the practical value of the results obtained, but industry is not always of the same opinion. The only thing that he can add to the author's interesting paper, therefore, is a plea for further efforts along the path that he and his collaborators have started.

S. TIMOSHENKO.[15] The paper gives a derivation of Prandtl's well-known analogy as well as the application of this analogy in studying plastic torsion. The illustrations and photographs

give a very clear picture of the distribution of plastic flow in twisted bars. The example of a small groove is especially interesting.

Referring to the apparatus for experimental investigation of stress distribution, a further development is very desirable to show us with what accuracy the magnitude of stresses can be obtained from such experiments. From the experiments made at the University of Michigan by Prof. L. H. Donnell, the writer knows that it is necessary to give to the rubber membrane a very large uniform initial stretching, which is very difficult to do accurately. Another point which must be kept in mind is the necessity of keeping the slope of the surface of the loaded membrane very small. Only for such a surface does the analogy between membrane and torsion problems hold.

If a sufficient accuracy for the rubber-membrane method can be established by further experimenting, this will be an important result which can be utilized in solving our torsional problems.

Author's Closure

The author appreciates very much the further points that have been brought out by the discussion, and will endeavor to answer the various questions raised and to reply to the interesting remarks expressed in connection with the matter treated in the paper.

Prof. E. G. Coker's valuable observations refer to certain bright bands in the etched cross-sections of twisted steel bars. In some of the etchings these light-colored bands run in a parallel direction with the boundaries of the cross-sectional areas. According to what was said in the paper, such bands should not be expected to appear. The undisturbed "fluidal structure" or the changes in the structure of the twisted steel bars due to plastic flow, as they were made visible in the etchings of the cross-sections by using Fry's method, consist, in the case of torsion, of narrow dark strips, which were described in the paper and made visible in many of the etched sections by Dr. Bader. These were found to progress in a direction perpendicular to the boundary line of the cross-sectional areas.

When comparing some of the other etchings (Figs. 57 to 70), however, it will perhaps be noticed that in these figures more or less pronounced differences in the density of color within the darkened areas can be well recognized. The tendency of this darkening effect can especially be seen in the first and third figures (from the left) of the four etched sections of the bar with a square cross-section shown in Fig. 58. In these etchings, in the center of the figure, a square appears which is darker than the surrounding parts. It was shown by former tests that this darkening within a square area could be detected in many rolled bars of both square and circular cross-section. This darkening is due to a non-uniformity of the structure of the steel ingot from which the bars were rolled. In general, the inner portions of cast ingots contain all the impurities (segregations) due to the more rapid solidification of the outermost layers of the ingots, and to the further concentration of the impurities in the inner core. These segregations are well known to the rolling-mill engineer[16] since they can still be detected by suitable methods after a bar has undergone considerable amount of reduction in cross-section by rolling.

That this explanation is correct is further checked by the two etchings in Fig. 62. These are the etched sections of a twisted bar having an equilateral triangle as its cross-section. These bars were machined from a bar with a square cross-section (the same bar as that of the specimens shown in Fig. 58). Parts of the dark square can be seen in the triangular areas of the etchings in Fig. 62, leaving an outer portion brighter, while the fluidal structure, consisting of the dark streaks, runs in these cross-sections perpendicular to the edges, as it should be. In the bars with a flat rectangle as cross-section, the core, later appearing dark, was further deformed by the rolling process into the central longitudinal areas, the border lines of which were the faint traces of a white band running parallel to the long edges of the rectangular cross-sections.

Coming now to Professor MacCullough's remarks, the question which he raises and wishes to answer in arriving at conclusions different from those drawn by the author in the paper, seems to be more a geometrical than a mechanical one and might perhaps, if repeated in a slightly different form than it was stated, be expressed as follows: Given are two circles in a plane, a large one of radius R and a small one of radius a, intersecting each other at right angles (Fig. 75). A thin membrane uniformly stretched in its plane is considered to be fastened to the periphery $ABCDA$ of the figure bounded by the two arcs of circles, and loaded by lateral pressure p until it is slightly disturbed. The inclination of this very flat membrane with respect to the plane of reference along the periphery of the figure $ABCD$ under a given lateral pressure p is to be known. The membrane along the greater part of the periphery of the large circle CDA will obviously have about the same inclination; this latter will, however, decrease toward the corners A and C, where it will vanish. Along the circumference of the smaller circle ABC the membrane will be inclined steeper than along ADC. If now while the radius of the smaller circle a is kept constant, the radius of the larger circle is increased gradually, while at the same time the *average inclination of the membrane along the larger circle and the stresses which hold the membrane stretched are kept constant*, obviously the pressure p must gradually be decreased in order to maintain above the larger span the same slopes along the circumference ADC. If R tends to become larger and larger compared to a, the lateral pressure p will tend to gradually become zero. The membrane will no longer need to be loaded by lateral pressure, but only through the stresses which hold it stretched. The parts of the circle ADC near the corners A and C will become straight lines, when R/a increases indefinitely. If we confine the further discussion only to the portion of the membrane in the neighborhood of the circle ABC, considering, for example, only distances r from the center C_2, which are still small if compared with R but large when compared with a (say, e.g., $r = 20a$, while $R = 100r$), the

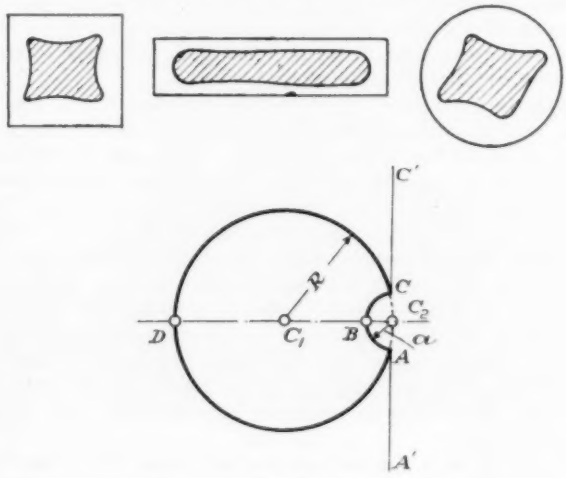

Fig. 75

[16] Cf., for example, some etchings of the sections of rolled bars obtained from steel ingots in Oberhoffer's book, "Das technische Eisen," 2nd Ed., 1925, J. Springer, Berlin. (Fig. 412 on p. 416.)

membrane can be fastened along a "*plane*" or a "rectangular frame" instead of along the circle with "infinite radius R." This frame would consist of four straight lines and contain the semicircular indentation ABC on one side, as indicated in Fig. 45 or as realized by the rubber model, Fig. 49.

Similar reasoning must now also apply to the shape of the limiting roofs or to that of the two cones by means of which the lateral deformation of the free membrane above $ABCDA$ is to be restricted. For the finite figure $ABCDA$ there are two equal straight circular cones of the same angle of inclination to be constructed above the two circles, one with its apex above the plane and the large circle ADC, and the other one, "inverted," above the arc ABC. The arc ABC is not changed when R is increased. Hence the inverted cone does not change. The radius R of the base of the other cone is, however, gradually increased. This means that its axis is displaced toward the left of Fig. 75, its apex C_1 finally moving toward an infinitely distant point on the line BC_1, while B still is kept stationary. The region of this cone, in which one will finally be interested, thus more and more closely approaches a certain plane containing the straight lines CC' and AA' and still having the same inclination as both former cones. It can easily be seen that the inverted cone erected above the small circle ABC intersects the cone erected above the large circle ABC in an ellipse (the line of intersection of both cones degenerates in the special case considered here into an ellipse). In the case where $R = \infty$, while a = constant, the ellipse obviously becomes a parabola, because a plane which is parallel to *one* generatrix of a circular cone intersects this cone in a parabola.

The author does not agree with one of the conclusions arrived at by Professor MacCullough, namely, that the smaller the semicircle ABC, the more nearly the membrane would touch the conical roof, consisting also of the *larger* of both cones along a zone of equal width all around the entire circumference (of the larger circle ADC). If one conceives of an inverted cone being erected above the semicircle ABC together with the plane containing AA' and CC', and inclined by the same angle as the cone, both will intersect in the parabola just mentioned. If he now considers a membrane pressed for a moment against the concave side of a roof which would consist of these two intersecting surfaces, he sees at once that such a membrane, if, *permitted again to deflect freely*, could never cover the regions near the parabola and the two corners A and C. The membrane will touch only the inverted cone along the line BC_1, but not the straight or plane portions of the roof—at least not at finite distances from the semicircular indentation ABC. Employing metaphor to explain these things in a simpler manner, Professor MacCullough asks whether, considering the distortions on a map of Canada made according to Mercator's projection, we can leave those of Greenland unchanged. Might not the question be answered in this manner? "To get a picture of the surroundings of Toronto or Quebec with sufficient accuracy, can we not leave Greenland out altogether since it is too far distant from the part which we are at this moment interested in mapping?"

The author agrees with Professor Sayre that the analogies used to visualize the stress distributions of bars are limited to those materials which have a stress-strain curve like that in Fig. 2. This was clearly stated when enumerating the restrictions under which the conclusions were arrived at.

With reference to the question of residual stresses in a bar which has been twisted above the plastic limit and then unloaded, the author would point out the possibility of getting—at least under certain restricting assumptions—also a first picture of those stresses. All that would be necessary would be to subtract from the "plastic-stress function," as it was represented for the case of complete yielding (by the slope of the sand heaps), the ideal "elastic-stress function" corresponding to the same cross-section and having the same volume as the first one. The differences of the ordinates of the functions would represent the stress function for the residual stresses. However, how far this could be utilized for spring steel is not clear, on account of the considerably different shape of the stress-strain curve of such steels as compared with that of Fig. 2.

Mr. Soderberg points to certain important problems in which mechanical engineers are directly and immediately interested in receiving answers. It must indeed be admitted that immediate applications of torsion cases where plastic flow enters are not often encountered, at least not in machine design. However, the questions raised by Professor Sayre would seem to indicate that some further useful applications of methods, similar to those treated here could be found in springs, where, for example, torsion is often carried to very high stresses and where a deviation from Hooke's law is apparent. On the other hand, knowing about certain cases in which certain important quantities can be more exactly predicted or determined by model tests or by other mechanical means, may perhaps aid in predicting what must be expected in more complicated cases.

The matter of failure brought up by Mr. Soderberg might also perhaps be looked upon from a similar point of view. As far as plastic deformations would precede the final breaking of a member subjected to high stresses—and a more exact discussion of the conditions of rupture would be considered as constituting the main part of the problem—the author thinks that a future analysis of such more or less complicated phenomena might sometime be approached by trying to describe more exactly what processes combine in the act of failure. A discussion of the question of rupture of ductile metals, for example, would then lead automatically to a description of what occurs first during the small plastic deformations and then later during the large ones which precede the rupture. Thus one would be led to considerations similar to those treated in the paper in the case of torsion. In other cases, however, where, for example, fatigue enters, ductility might not be of such importance inasmuch as the change of the actual distribution of stresses while fracture was proceeding might, to a certain extent perhaps, be determined from the theory of elasticity.

The case of the small hole in a material subjected to pure shear treated in the paper might, for example, throw light on a number of phenomena observed in mild steel, which heretofore have been thought to be caused by what might perhaps be termed more metallurgical than mechanical reasons. The conditions under which the Lüders lines (the narrow layers of plastically deformed material) appear in mild steel were formerly thought to depend on metallurgical reasons; however, the author has endeavored to show that the formation of these well-known lines can be explained by considering mainly mechanical reasons: namely, a well-defined yield stress and a local stress concentration combined with a slight instability of the plastic equilibrium.

Referring to certain difficulties encountered if numerical values of the quantities used in the paper were to be obtained by using similar apparatus, as those mentioned here, the author has pointed out on a former occasion that some of these difficulties mentioned by Prof. Timoshenko might be overcome. To obtain, for example, a membrane of rubber with a uniform stress in all directions, it is advisable to hold it stretched above a circular disk or ring by means of a large number of screws spaced at equal distances along the circumference of a circle. If the holes in the membrane are bored along a circle having a diameter that is considerably smaller than the circle on which

the centers of the screws are situated, a uniform stretch will result, if, by stretching the membrane, the holes in the membrane are made to coincide with the centers of the screw holes in the disk.

APM-53-4

Flow of Gases at a Rate Exceeding the Acoustic Velocity

By O. G. TIETJENS,[1] EAST PITTSBURGH, PA.

This paper deals with the flow of gases at high velocities, that is, at velocities exceeding the velocity of sound in the gas under the existing conditions of temperature and pressure. The discussion starts with the development of the fundamental equations of flow and shows why the acoustic velocity assumes such critical importance. In particular, the flow of gas through a De Laval nozzle is considered, the natural assumption of adiabatic flow being made. The so-called compression shock is discussed and the conditions under which these shocks occur, their connection with the acoustic velocity, and their effect on the flow through the nozzle, are pointed out.

IT IS well known that gases and steam change their behavior completely as soon as their velocities exceed the acoustic velocity. This happens in several cases. Not only does the velocity of flow in steam and gas turbines almost always exceed the acoustic velocity, but in internal-combustion engines, especially in the flow through the valves and into the cylinders, this condition also exists. In addition, the behavior of gases in explosions has to be mentioned in this connection. Here the velocities are usually extremely high, in some cases twenty times the acoustic velocity, and even higher. Also many phenomena in the extensive field of ballistics come under this classification.

The theoretical treatment of flow at velocities far below the acoustic velocity is widely known, especially the application of the Bernoulli equation and the equations of the potential theory. However, this cannot be said of the theoretical treatment of high-velocity flow. The statement that the acoustic velocity connotes a sort of limit velocity is often loosely adopted without a clear idea as to just why the acoustic velocity plays this role.

It is hoped, therefore, that this paper may contribute to broadening the knowledge of this interesting and important part of aerodynamics. In this field Dr. L. Prandtl at the University of Goettingen has been one of the outstanding contributors and on his lectures there much of this discussion is based. To make its perusal easier, references to other papers or textbooks, which might somewhat shorten the text, are intentionally omitted. Instead, it is attempted to develop from the very beginning the fundamental formulas with the simplest use of mathematics possible, and in particular to apply these formulas to the flow through a nozzle as an example.

I—Relation Between Pressure and Velocity

We start with the fundamental law of mechanics: namely, that the product of the mass of a particle times its acceleration is equal to the sum of the forces acting on the particle. Applying this fundamental law to an infinitesimal gas particle having the shape shown in Fig. 1 we have, using the notation given in that figure,

$$\underbrace{\rho dF ds}_{\text{mass}} \times \frac{dw}{dt} = \Sigma X \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where $\rho = \gamma/g$ is the density, i.e., the mass per unit volume.

Since the motion of the particles of a fluid takes place along certain streamlines, it is possible to express the velocity w of the particle at any instant as a function of the time t and the distance s measured along its particular streamline, or $w = f(s, t)$. We can write for the total differential

$$dw = \frac{\partial w}{\partial s} ds + \frac{\partial w}{\partial t} dt$$

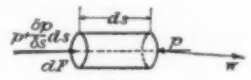

Fig. 1

and therefore for the longitudinal acceleration of the particle,

$$\frac{dw}{dt} = \frac{\partial w}{\partial s} \frac{ds}{dt} + \frac{\partial w}{\partial t}$$

or, since $ds/dt = w$,

$$\frac{dw}{dt} = w \frac{\partial w}{\partial s} + \frac{\partial w}{\partial t}$$

Although for some problems which deal with high-velocity flow of gases, for example, the flow of gas through engine valves, the change of velocity with time is essential and may not be neglected, still for most problems we can make the assumption that the flow is steady, i.e., that the velocity is the same at any point throughout the period of flow but of course generally varies from point to point. Such kind of flow we have, for instance, in the nozzles of steam and gas turbines. Neglecting $\partial w/\partial t$, therefore, we have

$$\frac{dw}{dt} = w \frac{\partial w}{\partial s}$$

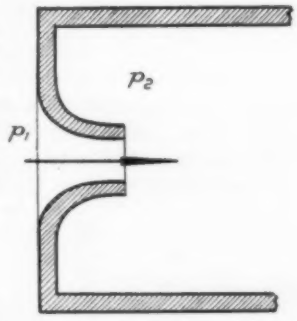

Fig. 2

Regarding the forces summated in the right-hand member of [1], it should be stated that the force of gravity acting on each particle is eliminated by the aerostatic lift.[2]

With respect to the forces due to the internal friction or viscosity of gases, we know that they are generally very small compared with the inertia forces in the left-hand member of [1]. Therefore in most cases it is permissible to neglect the friction forces altogether. Consequently the pressure difference, or,

[1] Research Department, Westinghouse Electric & Manufacturing Company. Mem. A.S.M.E.

Contributed by the Applied Mechanics Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] However, in cases of flow where the force of gravity causes differences in density due to large differences in altitude (meteorology), it has to be taken into account.

more exactly, the pressure gradient, remains as the only force in the right-hand member of [1]. However, as the pressure gradient generally has almost the same direction as the velocity—meaning by this that in surfaces perpendicular to the cylinder axis the pressure is constant—the pressure forces acting on the wall of the cylinder can be neglected. The only remaining forces, therefore, are the pressure forces on the two bases on the cylinder.

Thus we have for [1]

$$\rho dF ds \times w \frac{\partial w}{\partial s} = pdF - \left(p + \frac{\partial p}{\partial s} ds\right) dF$$

or

$$w \frac{\partial w}{\partial s} = -\frac{1}{\rho} \frac{\partial p}{\partial s} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Integrating this expression along a streamline from point 1 to point 2,

$$\frac{w_2^2 - w_1^2}{2} = \int_2^1 \frac{1}{\rho} dp \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

In those cases where the pressure differences from 1 to 2 (and therefore also the velocity differences) are small enough to permit neglecting the change in density due to them, we have, with ρ = constant, the well-known Bernoulli equation for incompressible fluids:

$$\frac{w_2^2 - w_1^2}{2} = \frac{p_1 - p_2}{\rho}$$

or with $\rho = \gamma/g$ and $p = \gamma h$,

$$\frac{w_2^2 - w_1^2}{2g} = \frac{p_1 - p_2}{\gamma} = h_1 - h_2$$

In this paper, however, we are interested in high-velocity flow of gases, where the changes in density due to pressure differences cannot be neglected. In order to integrate [3] it is therefore necessary to make a particular assumption regarding the manner in which density depends on pressure. The flow of gases in all cases considered in this paper being at very high velocities, we can assume that all changes of state of the gas are adiabatic, or

$$pv^k = \text{const} \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

where $k = c_p/c_v$ depends on the kind of gas, and to a certain extent on its pressure and other conditions. For dry air and normal pressure, $k = 1.405$.

Substituting $\rho = \gamma/g = 1/vg$ in [3],

$$\frac{w_2^2 - w_1^2}{2g} = \int_1^2 v dp$$

and since

$$pv^k = p_1 v_1^k$$

or

$$v = p_1^{1/k} v_1 \times \frac{1}{p^{1/k}}$$

we have

$$\frac{w_2^2 - w_1^2}{2g} = p_1^{1/k} v_1 \int_2^1 \frac{dp}{p^{1/k}}$$

Integrated, this expression becomes

$$\frac{w_2^2 - w_1^2}{2g} = \frac{k}{k-1} p_1 v_1 \left[1 - \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}\right] \quad \ldots\ldots [5]$$

Equation [5] gives the relation between velocity and pressure along a streamline for a gas in the same way that Bernoulli's equation describes the motion of an incompressible fluid. In this connection, however, it must be borne in mind that Bernoulli's equation applies not only to incompressible fluids but also to gases when their compressibilities can be neglected.

As the specific volume v_1 generally cannot be measured very easily, it is advisable to introduce the temperature T_1 (deg. fahr. abs.), using the relation

$$p_1 v_1 = RT_1$$

where for dry air $R = 53.34$ per deg. fahr. (p_1 in lb. per sq. ft. and v_1 in cu. ft. per lb.); thus

$$\frac{w_2^2 - w_1^2}{2g} = \frac{k}{k-1} RT_1 \left[1 - \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}\right] \quad \ldots\ldots [6]$$

Considering, for instance, the flow of air through a nozzle into a vessel in which a lower pressure p_2 exists (see Fig. 2), we can calculate the velocity for each pressure p_2 in the vessel. Since the initial velocity of flow is zero, we have $w_1 = 0$ and hence, for the velocity which corresponds to the pressure p_2 in the vessel,

$$w_2 = \sqrt{\frac{2gk}{k-1} p_1 v_1 \left[1 - \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}\right]}$$

$$= \sqrt{\frac{2gk}{k-1} RT_1 \left[1 - \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}\right]} \quad \ldots [7]$$

For $p_2 = 0$, i.e., for flow into a perfect vacuum, the maximum velocity will be

$$w_{2\max} = \sqrt{\frac{2gk}{k-1} RT_1}$$

Assuming, for instance, a temperature $T_1 = 523$ deg. abs. equal to about 63 deg. fahr., $k = 1.405$, and $R = 53.34$, the maximum velocity will be 2500 ft. per sec.

In order to obtain a higher velocity, it would be necessary to start with air of a higher temperature. According to [7], the velocity of a gas is the same whether the gas expands from a pressure of five atmospheres to one atmosphere or from one atmosphere to one-fifth of an atmosphere, assuming the same initial temperatures in both cases. Fig. 3 shows graphically the relation between velocity and pressure ratio for an initial temperature of $T_1 = 523$ deg. abs., etc., and $k = 1.405$.

II—Importance of Acoustic Velocity

In order to give a clear idea of the fundamental importance of acoustic velocity to the flow of gases at high velocities, let us consider the weight per second (W) flowing through the nozzle shown in Fig. 2. From considerations of continuity we see that the weight per second has to be the same for each cross-section A of this nozzle. Thus

$$W = Aw\gamma = A \frac{w}{v} = \text{const} \quad \ldots\ldots\ldots\ldots [8]$$

Assume that the pressure p_1 may be constant (atmospheric pressure) and that the pressure p can be changed. The product $w\gamma$ as a function of the pressure ratio p/p_1 can be easily obtained from Fig. 3 by multiplying together the two curves

$$w = f\left(\frac{p}{p_1}\right) \quad \text{and} \quad \gamma = \gamma_1 \left(\frac{p}{p_1}\right)^{1/k}$$

(adiabatic condition). The curve in Fig. 4 has been obtained in this way and we see from it that the value $w\gamma$ is zero for $p = 0$ and for $p = p_1$. This is due to the fact that for $p = 0$ (absolute vacuum) the specific weight γ is zero and that for $p = p_1$ (no

pressure difference) the velocity w is zero. Consequently $w\gamma$ has a maximum value for a certain intermediate value of p/p_1. This value can be easily determined by multiplying [7] by the specific weight $\gamma = 1/v$ and then obtaining the derivative of this expression with respect to p/p_1. Equating this derivative to zero gives the value of p/p_1 for which $w\gamma$ is a maximum. Thus

$$w\gamma = \frac{w}{v} = \sqrt{\frac{2gk}{k-1}\ \frac{p_1 v_1}{v^2}\left[1 - \left(\frac{p}{p_1}\right)^{\frac{k-1}{k}}\right]}$$

or, remembering that

$$pv^k = p_1 v_1^k, \quad \text{or} \quad \frac{1}{v^2} = \left(\frac{p}{p_1}\right)^{2/k}\frac{1}{v_1^2}$$

then

$$w\gamma = \sqrt{\frac{2gk}{k-1}\ \frac{p_1}{v_1}\left[\left(\frac{p}{p_1}\right)^{2/k} - \left(\frac{p}{p_1}\right)^{\frac{k+1}{k}}\right]} \quad \ldots\ldots [9]$$

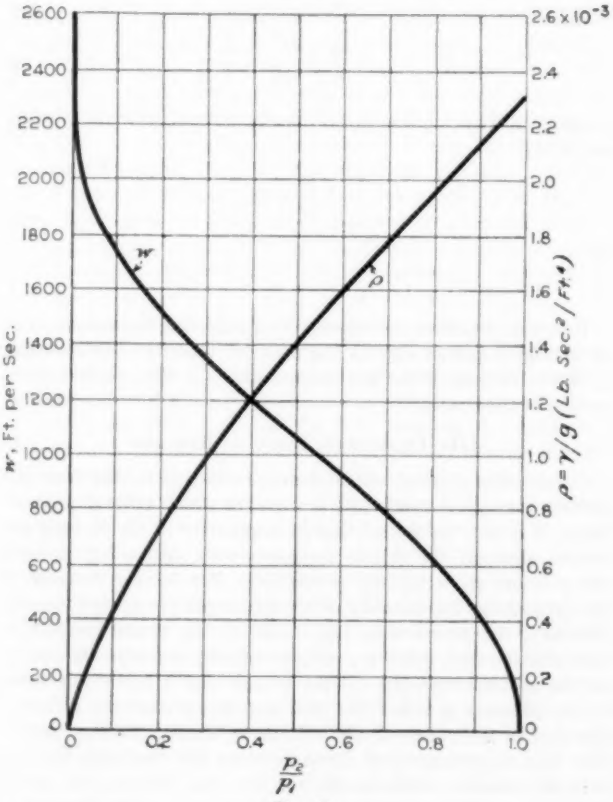

FIG. 3

Also, since

$$\frac{p_1}{v_1} = \frac{p_1^2}{p_1 v_1} = \frac{p_1^2}{RT_1}$$

$$w\gamma = p_1\sqrt{\frac{2gk}{k-1}\ \frac{1}{RT_1}\left[\left(\frac{p}{p_1}\right)^{2/k} - \left(\frac{p}{p_1}\right)^{\frac{k+1}{k}}\right]} \quad \ldots\ldots [9a]$$

According to the [9a], $w\gamma$ is a maximum if $\left[(p/p_1)^{2/k} - (p/p_1)^{\frac{k+1}{k}}\right]$ is a maximum, and so it is sufficient to put the derivative of this expression equal to zero, or

$$\frac{\partial\left[\left(\frac{p}{p_1}\right)^{2/k} - \left(\frac{p}{p_1}\right)^{\frac{k+1}{k}}\right]}{\partial\left(\frac{p}{p_1}\right)} = 0$$

Performing this differentiation and solving the equation for p/p_1, we get

$$\frac{p}{p_1} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} = 0.528 \text{ for, } k = 1.405$$

For this pressure ratio the product $w\gamma$, and therefore, according to [8], also W/A (i.e., the weight of gas per unit of cross-sectional area), becomes a maximum.

Considering now especially the flow in the smallest cross-

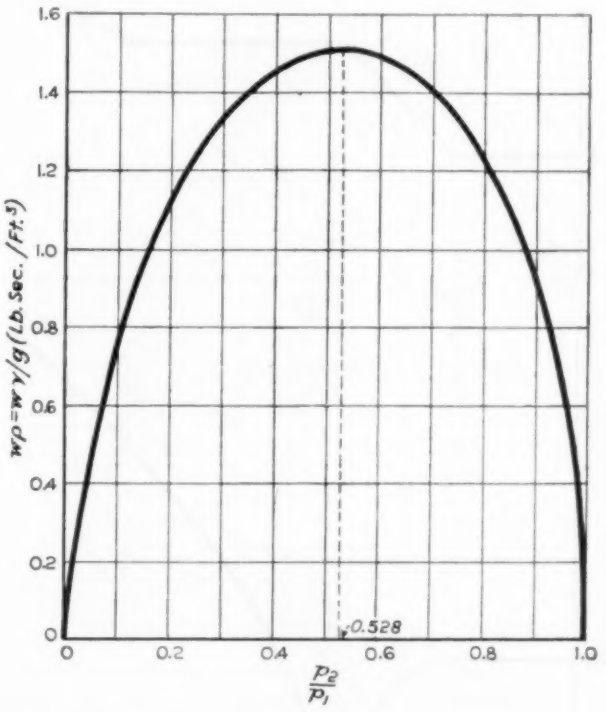

FIG. 4

section A' of the nozzle, let us gradually decrease the pressure p in the vessel (noted in Fig. 2 as p_2). According to Equation [9] and to Fig. 4, the weight of gas flowing per second through the nozzle, i.e., $W = A'w\gamma$, will increase until the pressure p is equal to $0.528p_1$. If, however, we decrease the pressure p in the vessel still further, getting thus pressure ratios smaller than 0.528, the flow of gas per second cannot decrease as indicated by [9] and Fig. 4, but will maintain a constant value corresponding to the maximum value of $w\gamma$. This implies that the velocity in the cross-section A' cannot exceed a certain critical value which corresponds to the pressure ratio $p/p_1 = 0.528$. For if the velocity in A' could exceed this critical value, the pressure at A' would have to be less than $0.528\ p_1$. This would mean that at some cross-section A'' reached before A' and larger or at least equal to A', the pressure $0.528\ p_1$ itself would be established. Since for this critical pressure $w\gamma$ is a maximum, this would imply that more fluid passes through section A'' than through A', which is impossible.

We can now easily demonstrate that this critical velocity is exactly the acoustic velocity. The pressure p_1 being kept constant, $w\gamma$ depends only on p, and as the critical velocity occurs for the maximum of $w\gamma$ we have to write the derivative of $w\gamma$ with respect to p and put this expression equal to zero:

$$\frac{d(w\gamma)}{dp} = w\frac{d\gamma}{dp} + \gamma\frac{dw}{dp} = 0$$

or, since $\gamma = \rho g$,

$$w \frac{d\rho}{dp} + \rho \frac{dw}{dp} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

For the second term of [10], we have, according to [2],

$$\rho \frac{dw}{dp} = \frac{1}{w} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

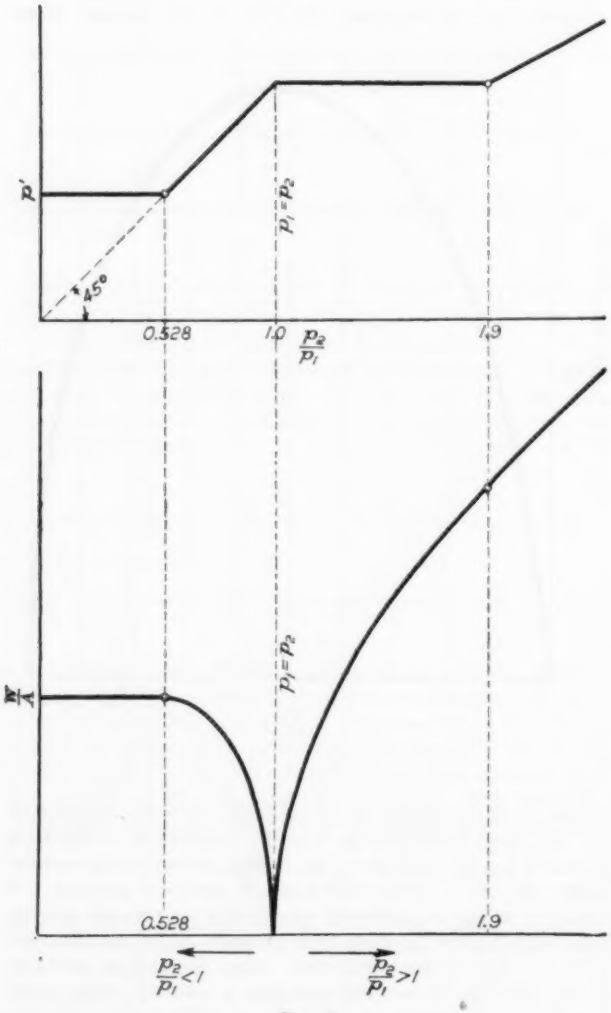

FIG. 5

The first term can be rewritten as

$$\frac{d\rho}{dp} = \frac{\rho}{\frac{dp}{d\rho}\rho}$$

and this can be reduced to the form

$$\frac{d\rho}{dp} = \frac{\rho}{-\frac{dp}{\frac{1}{v}dv}}$$

by virtue of the relations

$$\rho v = \frac{1}{g} = \text{const.}$$

$$\rho \frac{dv}{dp} + v \frac{d\rho}{dp} = 0$$

and

$$\rho \frac{dp}{d\rho} = -\frac{dp}{\frac{dv}{v}}$$

But

$$\frac{dp}{-\frac{dv}{v}} = E$$

where E is the modulus of elasticity, consequently

$$\frac{d\rho}{dp} = \frac{\rho}{E} = \frac{1}{E/\rho} \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

Furthermore the acoustic velocity c is equal to $\sqrt{E/\rho}$, so that

$$\frac{d\rho}{dp} = \frac{1}{c^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

Finally, substituting this expression for $d\rho/dp$ in [10] and making use of [11],

$$\frac{1}{w} - \frac{w}{c^2} = 0$$

or

$$w = c$$

It is thus seen that the velocity of a gas flowing through a nozzle as in Fig. 2 cannot exceed the acoustic velocity corresponding to the conditions of the gas (temperature) in the smallest cross-section of the nozzle.

III—Discharge Through Nozzles

Considering a gas at atmospheric pressure p_1 flowing from the outside through a nozzle into a vessel in which a lower pressure exists (Fig. 2), we found that the quantity of air flowing per second through the nozzle increases with decreasing p_2 until the pressure $p_2 = 0.528 p_1$ is reached. For further decrease of the pressure p_2 the quantity of air discharged per second remains constant, the pressure at the throat of the nozzle remains at the critical value, 0.528 p_1, and the velocity corresponds exactly to the acoustic velocity. Thus we see that a further decrease of the pressure p_2 below the critical pressure does not influence the flow in the nozzle at all. However, due to the fact that in this case a pressure drop exists between the discharge opening and the interior of the vessel, the gas after leaving the nozzle will be accelerated above the acoustic velocity. This is possible since the gas jet now has more room for expansion and can leave the nozzle in diverging streamlines.

Considering now the flow of gas discharging from a vessel of high pressure (p_2) into the atmosphere (p_1), the formulas previously given will hold in case we take account of the fact that the higher pressure is denoted by p_2 and is generally variable, while the lower pressure is denoted by p_1 and is considered as constant (atmospheric pressure). Therefore, for example, in [7] we must write p_1/p_2 instead of p_2/p_1. Increase of the pressure p_2 in the vessel corresponds to an increase of the velocity until the critical pressure ratio $p_2/p_1 = 1/0.528 = 1.895$ is reached and the acoustic velocity in the smallest cross-section of the nozzle is obtained. Up to this critical pressure ratio the pressure at the discharge opening of the nozzle is equal to p_1; with further increase of the pressure in the vessel, however, the pressure and therefore also the specific weight at the dis-

charge opening will increase proportionally to p_2. Due to this fact we have in the case of a pressure $p_2 > 1.895p_1$ an increase of the weight of gas proportional to the increase of p_2. In Fig. 5 it is shown in what manner the pressure in the discharge opening and the weight per second per square foot depends on the pressure ratio. Here $p_2/p_1 < 1$ means flow from the atmosphere into a vessel of lower pressure, and $p_2/p_1 > 1$ means flow from a vessel in which a higher pressure exists into the atmosphere.

IV—Flow Through a De Laval Nozzle

(*a*) *Flow Without Loss of Mechanical Energy.* Let us now investigate the flow in detail within the nozzle itself, assuming at first, as was done earlier, that the flow is without any losses due to friction or other causes. As an example, we shall consider the flow through a so-called De Laval nozzle as shown in Fig. 6(*a*).

It is desired to determine the pressure at different points along the nozzle or in the x direction as in Fig. 6. As the weight of gas W flowing per second through the nozzle must be the same for each cross-section A of the nozzle for reasons of continuity, we can, for a given W and for a given nozzle shape, consider the ratio W/A as a known function of x. Fig. 6(*b*) shows this function for the nozzle shape of Fig. 6(*a*) and for three values of W. On the other hand, the ratio W/A can be determined by using Equation [9a] or from Fig. 4 or Fig. 6(*c*). Making use of the two figures, 6(*b*) and 6(*c*), the variation of pressure along the nozzle can easily be determined for a certain value of W, i.e., a certain curve W/A in Fig. 6(*b*). It is only necessary to determine in Fig. 6(*b*) for different points of the x-axis the corresponding W/A and then to obtain from Fig. 6(*c*) the p/p_1 value, corresponding thereto. Fig. 6(*d*) has been constructed in this way, and shows the variation of pressure along the nozzle for three different weights per second, corresponding to three different pressures p_1 inside the vessel.

The upper W/A curve in Fig. 6(*b*) gives at the same time the curve of the maximum weight per second flowing through the nozzle since the maximum of $W/A = w\gamma$ has been reached at the smallest cross-section. This corresponds to a certain pressure p_I at the discharge opening of the nozzle. For this pressure p_I in the vessel we have the critical pressure in the smallest cross-section, and therefore the acoustic velocity. Nearer the discharge opening the velocity decreases with increasing pressure. In order to obtain in the nozzle a velocity higher than the acoustic velocity it is necessary to have a much lower pressure in the vessel. How low this pressure has to be in order to enable the gas to expand sufficiently depends on the shape of the nozzle. For the nozzle shown in Fig. 6(*a*) we see in 6(*d*) that a very low pressure p_{II} is necessary to fulfil this condition. For a nozzle diverging less than that in 6(*a*), the pressure would not need to be as low as p_{II}. For a nozzle of given shape, therefore, there is but one pressure at the discharge opening that will allow the gas to expand with a velocity above the acoustic velocity. Of course, this holds only as long as the assumption that the process can be considered adiabatic obtains, and that there are no losses due to friction or other causes. The question now naturally arises as to what does happen if the pressure in the vessel lies between p_I and p_{II}. In this case flow without losses is impossible, and only a flow in which part of the mechanical energy is converted into heat can be obtained.

(*b*) *Flow Through Nozzles With Compression Shocks.* Experiments made by Stodola and by Buechner show that where the pressure in the vessel is between p_I and p_{II}, the gas flowing through the smallest cross-section at first expands at a velocity above the acoustic velocity, and then, at some point in the diverging part of the nozzle, is suddenly compressed, suffering a considerable loss in velocity. The loss of kinetic energy occasioned by this sudden compression is much larger than the gain in pressure energy, indicating that part of the kinetic energy has been converted into heat energy.

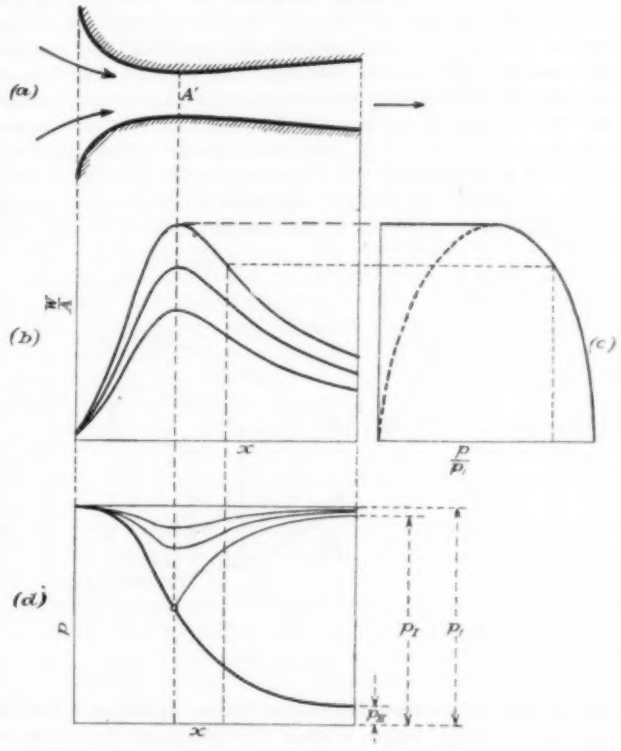

Fig. 6

Without going into the details of these so-called compression shocks now, we shall merely state that this strange behavior of gas flowing with velocities exceeding the acoustic velocity is indicated qualitatively in Fig. 7. The velocity decreases abruptly[3] to a lower value, while the pressure increase is also abrupt and like a shock. As mentioned before, the pressure increase is smaller than it would be under reversible adiabatic conditions, i.e., smaller than the value given by Equation [3]. This difference in pressure energy is just that part of the mechanical energy which is converted after the shock into heat energy.

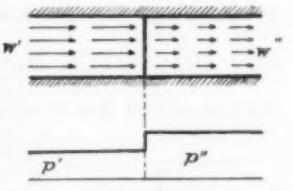

Fig. 7

Having constructed in Fig. 6(*d*) the curve of pressure variation along the nozzle, taking into account that according to [3] the mechanical energy, i.e., the sum of kinetic energy and pressure energy, has to be constant, we have now to construct the curves corresponding to pressures in the vessel between p_I and p_{II} for which the total energy, including the heat energy, is constant. In Fig. 8 the heavy line is the course of pressure variation for adiabatic expansion for the given shape of the nozzle. The three dotted lines are curves of constant total energy for three different pressures at the discharge opening. (The formulas by which those curves can be calculated will be given later.) Calculating now for each point of the expansion curve—but only

[3] Taking into account the conduction of heat, L. Prandtl has shown that this change of velocity and pressure takes place along a length of about $^1/_{20,000}$ in.

for the diverging part of the nozzle—the pressure increase caused by a compression shock and then connecting the resulting points of increased pressure by a dash-and-dot line as in Fig. 8, we obtain a curve which intersects the curves of total energy. The pressure variation along the nozzle for a pressure p in the vessel proceeds now as follows: Up to the smallest cross-section the gas expands adiabatically, reaching the critical pressure and the acoustic velocity. The pressure then follows further the adiabatic-expansion curve according to the increase of the velocity above the acoustic velocity. At the cross-section A_0 the pressure p' increases suddenly to the value p'', involving a considerable decrease of velocity below the acoustic velocity; finally the pressure increases slowly from p'' to p_0 along the curve of constant total energy. The fact that this

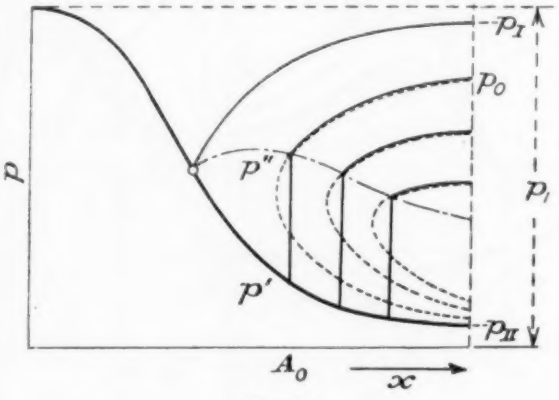

FIG. 8

sort of flow is always accompanied by an appreciable loss of mechanical energy makes it clear that Equation [3], which is based on the constancy of the mechanical energy, cannot be adequate.

In order to obtain an equation which holds also for those cases where portions of the mechanical energy are converted into heat, it is necessary to relate Equation [2] with the heat equation applied to a gas particle moving along a streamline. If u represents the internal energy per pound of the gas and dq the heat supplied, both measured in mechanical units, then

$$dq = du + pdv$$

Or, if we assume that no heat is supplied from outside,

$$du + pdv = 0$$

If we now substitute vg in [2] for $1/\rho$,

$$\frac{w}{g}\,dw + v\,dp = 0$$

Thus

$$du + pdv + vdp + \frac{w}{g}\,dw = 0$$

or

$$du + d(pv) + d\frac{w^2}{2g} = 0$$

which, integrated along a streamline from 1 to 2, gives

$$\frac{w_2^2 - w_1^2}{2g} = u_1 + p_1v_1 - (u_2 + p_2v_2)$$

Assuming the behavior of a permanent gas and considering that

$$u = \frac{1}{k-1}\,pv \quad \text{and} \quad u + pv = \frac{k}{k-1}\,pv$$

we have

$$\frac{w_2^2 - w_1^2}{2g} = \frac{k}{k-1}\,(p_1v_1 - p_2v_2) \ldots\ldots\ldots [14]$$

Eliminating v_1 and v_2 through the continuity equation: namely,

$$W = A_1\frac{w_1}{v_1} = A_2\frac{w_2}{v_2}$$

we obtain

$$p_1w_1 - p_2w_2 = W\frac{k-1}{2gk}\left(\frac{w_2^2}{A_2} - \frac{w_1^2}{A_1}\right)$$

By means of this relation and the assumption of constant entropy for each curve, it is possible to construct the dotted curves of Fig. 8.

Compression shocks can only occur if the velocity is higher than the acoustic velocity and the decreased velocity after the shock is always lower than the acoustic velocity. A remarkable deduction from these considerations is the fact that the product of the velocities before and after the shock is equal to the square of the acoustic velocity. Denoting the velocity and the pressure before the shock by w' and p', respectively, and after the shock by w'' and p'', we may say first of all that the time rate of change of momentum must be equal to the forces acting from outside on the system, and thus that

$$\frac{W}{g}\,(w' - w'') = (p'' - p')A$$

Substituting for W first $\frac{Aw''}{v''}$ and then $\frac{Aw'}{v'}$ according to the continuity equation

$$W = A\frac{w''}{v''} = A\frac{w'}{v'}$$

we obtain

$$\frac{w'w''}{g}\left(\frac{1}{v''} - \frac{1}{v'}\right) = p'' - p' \ldots\ldots\ldots\ldots [15]$$

Now making use of [14], we have, in case the flow starts with zero velocity ($w_1 = 0$),

$$\frac{w'^2}{2g} = \frac{k}{k-1}\,(p_1v_1 - p'v')$$

and

$$\frac{w''^2}{2g} = \frac{k}{k-1}\,(p_1v_1 - p''v'')$$

or, subtracting one equation from the other,

$$p'' - p' = p_1v_1\left(\frac{1}{v''} - \frac{1}{v'}\right) - \frac{k-1}{2gk}\left(\frac{w''^2}{v''} - \frac{w'^2}{v'}\right)$$

We may now use the continuity equation in the form

$$\frac{w''}{v''} = \frac{w'}{v'}$$

since the areas before and after shock are sensibly equal, and get

$$p'' - p' = p_1v_1\left(\frac{1}{v''} - \frac{1}{v'}\right) + \frac{k-1}{k}\,\frac{w'w''}{2g}\left(\frac{1}{v''} - \frac{1}{v'}\right)$$

Also by means of [15] we may eliminate $p'' - p'$ and drop the common factor $\left(\frac{1}{v''} - \frac{1}{v'}\right)$ as follows:

$$\frac{w'w''}{g} = p_1v_1 + \frac{k-1}{k}\,\frac{w'w''}{2g}$$

or simply

$$w'w'' = 2g\,\frac{k}{k+1}\,p_1v_1$$

Returning to Equation [7], substituting therein the critical pressure ratio $\left(\frac{2}{k+1}\right)^{\frac{k}{k-1}}$ for the ratio $\frac{p_2}{p_1}$ and then simplifying, it is easily seen that the right-hand member of this last expression is the square of the acoustic velocity. Thus

$$w'w'' = c^2$$

Considered from a purely mathematical standpoint, the above expression includes the possibility of an expansion shock as well as a compression shock. Such an expansion shock, however, would involve a decrease of entropy instead of an increase, and so would be physically impossible.

Discussion

J. M. Spitzglass.[4] The author presents a vivid demonstration of the following interesting facts about the so-called critical velocity of gases:

First, that the critical, or highest obtainable, velocity of a gas at the smallest section of a nozzle is the same as the velocity of sound through the medium at that section.

Second, that for true adiabatic expansion this critical velocity is reached at a corresponding critical-pressure ratio of

$$\frac{p_2}{p_1} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}}$$

which is equal to 0.528 for $K = 1.405$.

Third, that both the critical pressure and the acoustic velocity at the smallest cross-section of a nozzle are maintained the same irrespective of any further pressure reduction on the divergent side of the nozzle.

Fourth, that the critical velocity can be exceeded only on the divergent side of the nozzle if the pressure p_2 is reduced much below the above critical pressure.

Fifth, that the maximum mass rate of flow per unit area is reached at the critical velocity of the gas, and this rate is maintained irrespective of the pressure or velocity changes on the divergent side of the nozzle.

Sixth, that an increase of the initial pressure p_1 after the critical limit is reached increases the critical pressure in the smallest section, maintaining the same ratio of p_2/p_1, and while the critical velocity is still the same as the acoustic velocity, yet the increased density gives a larger rate of mass flow in proportion to the increase of p_1 or of p_2, which increases in the same ratio.

The analysis given in the paper is based upon the usual assumption of adiabatic expansion of the gas and the friction losses neglected. It should be emphasized that Figs. 3 and 4, which are extremely illuminating, are in fact solutions of Equation [7] for the range from zero drop to zero pressure. The part that may actually be obtained in a nozzle is only the first half up to the critical point of maximum flow. As the author shows in Fig. 6, it requires a drop of pressure much below the critical pressure in the nozzle before velocities are increased over the acoustic velocity of the fluid.

The writer would like to ask the author to give an explanation of how in any case velocities are obtained as high as twenty times the acoustic velocity of the fluid.

Water-gas manufacturers have for a long time used nozzles above the critical flow for the supply of steam to gas generators, determining the quantity of flow by the so-called Napier's rule, $W = pA/70$.

Some eighteen years ago the writer had a chance to check this rule at one of the large gas stations in Chicago. There a 6-in. live-steam pipe carrying a pressure of 150 lb. supplied the steam to two gas generators. Each generator had a nozzle of the same diameter in the corresponding branch from the main line. An impact tube was inserted in the main line to indicate the flow of the high-pressure steam in the pipe. Running with two gas generators, one at a time, the differential on the impact tube was 20 per cent higher on one of the machines than on the other. This repeated itself invariably. The nozzles were carefully checked; the lines appeared to be approximately the same, except that one was about ten or fifteen feet farther away than the other, but this did not explain the difference in the flow. Could the author tell us what his experience has been in duplicating the maximum flow at practical applications of nozzles?

It is of interest to apply the author's analysis to the case of the square-edged-orifice plate. In that case, of cou se, there is no apparent reason for a critical, or limiting, velocity either at the section of the orifice or at the *vena contracta* because there is no rigid continuity between any of the sections. That is, in the case of the square-edged orifice, the exit velocity may assume a value determined by an expression similar to Equation [7], or at least a value proportional to it.

Following the demonstration of Figs. 3 and 4, there should be a similar set of curves for the *actual* rate of flow through the orifice, because the velocity is free to increase with the drop of pressure, and the density is free to decrease with the final pressure, and to approach zero as a limit when p_2 approaches zero.

From the experiences that have been published on the subject, the opposite is shown to be the case. John L. Hodgson,[5] for instance, has shown actual test data on orifice plates down to the value of $p_2/p_1 = 0.10$, where the mass rate of flow actually increased with the drop of pressure and by extension the curve indicates a maximum rate of flow at $p_2 = 0$.

The pertinent question is how can there be a definite mass flow with a condition of zero density of the fluid. On the other hand, it is just as hard to conceive of a definite maximum velocity of the fluid at a zero rate of mass flow. Mr. Hodgson's experiments leave no doubt that the mass flow was not diminished at the lower pressure limit. We must conclude, therefore, that after the critical velocity, the density in the streamline is not wholly dependent on the pressure in the space surrounding the fluid stream. This should be equally as true for shaped nozzles as it is for square-edged orifices. In other words, Equation [7] does not seem to apply after the critical velocity is reached in the nozzle.

H. S. Bean.[6] This paper is a timely contribution to the literature on fluid flows. As the author has indicated, most engineers have but a hazy idea of the physical relations involved in gas flows at high velocities. It is a subject that might well be given

[4] Mechanical Engineer and Vice-President, Republic Flow Meters Co., Chicago, Ill. Mem. A.S.M.E.

[5] "The Laws of Similarity for Orifice and Nozzle Flows." Trans. A.S.M.E., vol. 51 (1929), paper no. FSP-51-42-103.

[6] Physicist, Bureau of Standards, Washington, D. C. Mem. A.S.M.E.

much more attention by many of our engineering schools. The importance of gas flows at velocities in the region of the acoustic velocity is not limited to problems of turbine and engine design and ballistics, but also extends to the field of gas measurement. In this work the so-called "critical-flow orifice" is being used both as a limiting demand meter and as a reference meter. The subject has also to be considered in some cases in the design of airfoils.

The phenomenon of gas flows at high velocities through nozzles, either expanding or non-expanding nozzles, is by no means so simple as would appear from the author's analysis. However, the several assumptions which were made are necessary for making a simple analysis of the flow. It would be very difficult, if not impossible, to construct equations to represent the actual flow conditions, for they are so complicated that it is doubtful if any one knows exactly what does take place. A view of a jet of gas issuing from a nozzle at a velocity greater than the acoustic velocity will show various bands across the jet. These bands probably indicate regions of relatively higher or lower density.

It is common practice to assume that the static pressure is constant over any right section of a gas stream flowing along a closed channel such as a pipe or nozzle. Recent experiments by Dr. Prandtl and others have shown that this is not the case. To be sure, the variations are generally small and may be neglected in most engineering computations.

In the paper ρ has been used to represent density expressed in absolute units, while γ is used to represent density expressed in engineering units, often called "specific weight." To some readers it might have been clearer to have used one system of units throughout, and thus to have used but one of these symbols. Also, in section III it might have been clearer to some if p_1 were taken as always representing the pressure at the first or upstream section, and p_2 as representing the pressure at the second or downstream section.

J. M. Naiman.[7] The author has clarified the important distinction between the critical rate of mass flow per unit area W/A, and of linear velocity, w. The former is the one which reaches its maximum value in the minimum cross-section of the flow streamlines, i.e., in the *vena contracta* of the streamlines. The latter, on the other hand, merely reaches in the *vena contracta* the "critical" value of "acoustic velocity," which is not at all its maximum value, since the velocity increases beyond the minimum area or *vena contracta* point, i.e., beyond the throat of the nozzle described, if the pressure beyond this point is less than 52.8 per cent of the initial pressure ahead of the nozzle. The only reason why the mass flow per unit area, W/A, does not increase beyond the nozzle throat from its maximum value at the throat or *vena contracta*, even though the gas velocity w increases above "acoustic velocity," is that the rate of decrease in gas density γ is faster than the rate of increase in gas velocity w. This is very aptly brought out by the two curves of Fig. 3, from which one can see why the product of the two, i.e., $w\gamma$, upon which W/A, the mass flow per unit area, depends, actually decreases beyond the *vena contracta*, in spite of increase of the gas velocity beyond acoustic velocity; i.e., beyond the *vena contracta*, W/A decreases, but the increase in area A keeps W constant.

The effect of temperature changes when the gas velocity exceeds "acoustic velocity," as evidenced by the so-called compression shocks, with resulting decrease of the gas velocity from w_1 (which is more than the acoustic velocity, c) to w_2 (which is less than c), with c being the geometric mean between w_1 and w_2, is very interesting, and should be of value in the design of the outlet end of nozzles, in such a way that the outlet pressure is not too low, and yet the velocity beyond the nozzle throat is above acoustic velocity, if the latter is desirable.

Considering the value of the points brought out by the author it would help to popularize the subject if the mathematical development of the basic equations were more concise and less laborious.

For example, the relation between the change in the kinetic and the change in the potential energy of a gas is as well known as the more basic relation between force and acceleration, and half of the first two pages could be saved by starting with the sufficiently basic relation,

$$\frac{w_2^2 - w_1^2}{2g} = \int v dp \quad \ldots\ldots\ldots\ldots\ldots [1]$$

with the remark that this relation omits the negligible factor of gravity, important only in meteorology, and the effect of friction.

Similarly, the demonstration made by the author from the bottom of page 3 to the lower part of page 4, that the velocity in the *vena contracta* (for the case when p/p_1 is equal to or less than 0.528) is equal to the acoustic velocity c at the pressure and temperature of the gas in the *vena contracta*, could be simplified as follows:

The velocity in the *vena contracta* may be calculated from the author's Equation [7] by noting that the pressure ratio for the case under consideration is, as shown at the top of page 3,

$$\frac{p}{p_1} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}}$$

so that the term $\left(\frac{p}{p_1}\right)^{\frac{k-1}{k}}$ in Equation [7] becomes $\left(\frac{2}{k+1}\right)$, giving,

$$w = \sqrt{\frac{2gk}{k-1} RT \left(1 - \frac{2}{k-1}\right)} = \sqrt{\frac{2gk}{k+1} RT} \text{ (ft. per sec.)} \quad \ldots\ldots [2][8]$$

On the other hand, the acoustic velocity at the pressure p and the temperature T in the *vena contracta* is

$$c = \sqrt{\frac{kp}{\rho}} = \sqrt{\frac{kpg}{\gamma}} = \sqrt{kpgv} = \sqrt{kgRT} \quad \ldots\ldots [3]$$

To express this in terms of the initial gas temperature T_1, we note from the gas laws that

$$pv = RT, \quad p_1v_1 = RT_1, \quad \text{and} \quad pv^k = p_1v_1^k$$

from which we may write,

$$\frac{RT}{RT_1} = \frac{pv}{p_1v_1} = \frac{p}{p_1}\left(\frac{p_1}{p}\right)^{\frac{1}{k}} = \left(\frac{p}{p_1}\right)\left(\frac{p}{p_1}\right)^{-\frac{1}{k}} = \left(\frac{p}{p_1}\right)^{1-\frac{1}{k}} = \left(\frac{p}{p_1}\right)^{\frac{k-1}{k}} \quad \ldots\ldots [4]$$

[7] Chicago, Ill. Assoc-Mem. A.S.M.E.

[8] Compare with the value of the maximum velocity, possibly, w_{max} which as shown by the author is $w_{max} = \sqrt{\frac{2gk}{k-1} RT_1}$ (ft. per sec.), or $\sqrt{\frac{k+1}{k-1}} = 2.437$ times greater than the "critical velocity." Thus, for $T_1 = 523$ deg. abs. (63 deg. fahr.), $w_{max} = 2500$ ft. per sec. while $w = 2500/2.437 = 0.410 \times 2500 = 1025$ ft. per sec. only.

But for the case under consideration,

$$\frac{p}{p_1} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}}$$

Therefore Equation [4] may be simplified to

$$RT = RT_1\left(\frac{p}{p_1}\right)^{\frac{k-1}{k}} = RT_1\left(\frac{2}{k+1}\right) \ldots\ldots [4a]$$

and Equation [3] for acoustic velocity in the *vena contracta* becomes

$$c = \sqrt{kgRT} = \sqrt{\frac{2kg}{k+1}RT_1} \ldots\ldots [3a]$$

which, when compared with Equation [2] for the gas velocity w through the *vena contracta*, shows it to be equal to the acoustic velocity c through the nozzle throat; i.e.,

$$w = c \ldots\ldots [5]$$

At this point it is interesting to note the simplified equation for the flow rate through the *vena contracta* in pounds per second, when the pressure ratio p/p_1 is equal to or less than $\left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} = 0.528$. Thus, we have from Equation [2], remembering the adiabatic equation $pv^k = p_1v_1^k$, the basic gas law $p_1v_1 = RT_1$ and the relation $\gamma = \frac{1}{v}$,

$$W = Aw\gamma = A\sqrt{\frac{2gk}{k+1}RT_1}\left(\frac{1}{v}\right) = A\sqrt{\frac{2gk}{k+1}RT_1}\left(\frac{p}{p_1}\right)^{\frac{1}{k}}$$

$$\left(\frac{1}{v_1}\right) = A\sqrt{\frac{2gk}{k+1}RT_1}\left(\frac{2}{k+1}\right)^{\frac{1}{k-1}}\left(\frac{p_1}{RT_1}\right) = \frac{0.5\,Ap_1}{\sqrt{T_1}}$$

(lb. per sec.)..... [6]

where W = air-flow rate, lb. per sec.
A = *vena contracta* area, sq. ft.
p_1 = initial air pressure, lb. per sq. ft. abs., and
T_1 = initial air temperature, deg. fahr. abs.

$$\left(\frac{2}{k+1}\right)^{\frac{1}{k-1}}\sqrt{\frac{2gk}{(k+1)R}} = 0.5318$$

For a gas whose specific gravity is S, since the gas law becomes $p_1v_1S = RT_1$ (where $R = 53.34$), R/S should be substituted for R into the Equation [6], which then becomes

$$W = \frac{0.5318\,Ap_1}{\sqrt{ST_1}} \text{ (lb. per sec.)} \ldots\ldots [6a]$$

A research program is now being carried on under the writer's supervision in the laboratories of one of his clients, which is to determine how the effect of friction modifies the last equation, and results so far secured promise to form the basis of valuable progress in the field of the flow of fluids. The results of these tests will, in due time, be published by the writer.

In Equation [1], it is confusing to use the symbol F in the right-hand member of the equation to represent force, and in the left-hand member to represent cross-sectional area.

Author's Closure

In order to answer the question by Mr. Spitzglass relative to the possibility of velocities as high as twenty times the acoustic, the author would like to refer to occurrences such as detonation. It has been shown by different authors[9] that the velocities of the propagation of the pressure wave as well as the velocities of the gases themselves may enormously exceed the acoustic velocity. In the case of detonation of oxy-hydrogen gas, velocities up to 8600 ft. per sec. can be obtained, while in the case of trinitrotoluol, velocities as high as 18,500 ft. per sec. may occur for such cases. The pressure differences and changes of temperature are so large that some of the assumptions, on which the calculations given in the paper are based, no longer hold true; so that the formulas given there do not hold.

To explain why the differential on the impact tube could be 20 per cent higher on one of the machines than on the other, as observed by Mr. Spitzglass, it would be necessary to have more details, especially with regard to the shape of the pipe lines and the velocities of the steam.

Concerning the application of the formula developed in the paper to flow through a square-edged orifice, the author does not agree with Mr. Spitzglass that there should in this case be no critical or limiting velocity either at the section of the orifice or at the *vena contracta*. First of all, there is only a *vena contracta* when the pressure ratio is larger than the critical ratio, the velocity thus being smaller than the acoustic velocity. For pressure ratios smaller than the critical, there is no *vena contracta* at all. In this case, the pressure decreases from atmospheric pressure, p_1, to a value given by $p' = 0.528\,p_1$ in the section of the orifice, with a corresponding increase of the velocity up to the acoustic velocity. In proceeding outward from this section, a further decrease of the pressure takes place down to a value p_2, accompanied by a corresponding increase of the velocity beyond the acoustic velocity, and forming thereby a diverging flow. The fact that the flow is diverging indicates that the pressure in this diverging part is not the same as that in the surrounding gas. It should always be kept in mind that to pass a certain quantity of gas per unit time the smallest area is required if the gas is flowing at the acoustic velocity, while a larger area is required to pass the same quantity of gas at a velocity exceeding the acoustic velocity.

The author agrees with Mr. Bean that the phenomenon of flow of gases exceeding the acoustic velocity is not so simple as would appear from the analysis given in this paper, should the reader assume that our knowledge about this kind of flow is exhausted by that which is given therein. The author only wished to draw the attention of a larger audience to this interesting and important part of aerodynamics, avoiding any higher mathematics. Mr. Bean says that it would be very difficult, if not impossible, to construct equations to represent the actual flow conditions. His statement is not quite correct, because these equations have been known for a long time:

$$\rho\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z}\right) = -\frac{\partial p}{\partial x} + \mu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right) + \frac{1}{3}\mu\frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right),$$

and two analogous equations for the y and z components.

However, the integration of this system of differential equations, including the fulfilling of the boundary conditions, is very difficult, if not hopeless. Neglecting the viscosity, as is done in the paper, is in many cases justified. The further assumption made in the paper that the flow can be considered as a one-dimensional phenomenon cannot always be maintained.

[9] Berthelot, *Comptes Rendus*, vol. 93 (1881), p. 18. Chapman, *Phil. Mag.*, vol. 47 (1899), p. 90. Becker, R., *Zeit. f. techn. Phys.*, vol. 3 (1922), p. 152, 249; vol. 8 (1922), p. 321. Rüdenberg, R., *Artillerist. Monatsh.* (1916), p. 237.

If we are interested in details of the flow in nozzles, for instance, in the pressure distribution over a cross-section, or in details of compression shocks and pressure waves occurring in air jets at velocities above acoustic velocities, we have to consider the flow as three-dimensional or sometimes as two-dimensional. In the latter case, Prandtl and Steichen succeeded in solving the corresponding differential equations by introducing Legendre transformations.

In this way Prandtl was able to explain and calculate in detail the standing pressure waves that occur in high-velocity air jets. These standing pressure waves, which are described by Mr. Bean as various bands across the jet, are regions of relatively higher or lower density as he supposes, and therefore can easily be made visible by the so-called Schlieren method.

With respect to the static pressure in pipes, it may be stated that this pressure is constant over the cross-section, provided the latter is constant in the direction of flow, but that the static pressure is not constant over the cross-section in diverging or converging pipes.

Referring to the possibility of shortening the paper somewhat by starting with Equation [3] instead of [1] as suggested by Mr. Naiman, the author is of the opinion that by starting with [1] the development becomes clearer for those who are not very familiar with the subject and who need to know why the various assumptions have to be made. This is particularly necessary since the formulas given later hold only if the velocity can be considered as a function of the coordinates only of the time (stationary flow).

The author also does not agree that the way in which Mr. Naiman develops the relation that the maximum velocity in the smallest cross-section is equal to the acoustic velocity, represents a simplification, but rather that it is another way of deriving the same formula. It always depends on what we assume as being known. If we assume, for instance, that the relation $dp/d\rho = c^2$ can be considered as well known,[10] the desired relation can be deduced directly from Equation [10] in connection with Equation [11], thus using only three equations. Mr. Naiman develops an Equation [6] or [6a] for the rate of flow through a nozzle when the pressure ratio is equal to or less than the critical ratio. This expression is only a particular case of the author's Equation [9a], which holds for all pressure ratios and hence also for the critical ratio. In order to show this, by substituting in Equation [9a] $\frac{p}{p_1} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}}$ and considering that $\left(\frac{2}{k+1}\right)^{\frac{k+1}{k-1}} = \left(\frac{2}{k+1}\right)^{\frac{2}{k-1}} \cdot \frac{2}{k+1}$, we obtain directly

$$W = \frac{A p_1}{\sqrt{T_1}} \sqrt{\frac{2}{k+1} \cdot \frac{g}{R} \left(\frac{2}{k+1}\right)^{\frac{2}{k-1}}}$$

which is the same equation as Equation [6a] given by Mr. Naiman. Substituting the values for g, R, and k, we have

$$W = \frac{0.53\, A p_1}{\sqrt{T_1}}$$

[10] This equation simply says that any changes of density caused by changes of pressure are propagated with the acoustic velocity.

On Problems in the Theory of Fluid-Film Lubrication, With an Experimental Method of Solution

By ALBERT KINGSBURY,[1] PHILADELPHIA, PA.

Analytical treatment of problems in perfect film lubrication is in general very difficult; solutions have thus far been obtained only in a few relatively simple cases. The paper describes methods by which fairly accurate solutions of any stated cases may be obtained experimentally, through the analogy between electrical potential and current flow in a conductor and pressure and volume flow in the lubricating film. Electrical measurements are made upon enlarged models of the lubricating films, the models being bodies of conducting fluid contained in wooden boxes having forms determined by theory. Pressures at points in a film having been deduced from the electrical data, graphical or other means of integration are used to determine the total load, the friction, and the quantities of oil flow at the edges of the film. The method is not limited as regards the shape of the film or variation of viscosity within the film. Solutions are given for a number of cases of plane bearing surfaces and journal bearings, showing close agreement with analytical solutions in cases where the latter have been obtained.

I—INTRODUCTORY

MATHEMATICALLY exact application of the theory of lubrication to practical cases is not generally feasible. Even in the simplest cases it involves difficult mathematical procedure, as well as much tedious work in numerical reduction. Until the work of Michell,(3)[2] on rectangular plane surfaces, no solution had been made that included the important feature of flow transverse to the rubbing motion. Recently, Boswall(4) has obtained approximate solutions for fitted partial journal bearings and for the sector-shaped surfaces of pivoted-block thrust bearings. But in order to avoid excessive mathematical difficulties, all the few solutions thus far obtained have been more or less restricted in the character of assumptions of film forms and of variation in temperature and viscosity of lubricant; factors that among others are not accurately known or determinable under working conditions in practice. Rigorous mathematical solutions, taking into account all the known physical actions involved, are as yet not obtainable; and even if such were obtained, they would necessarily be based upon certain ideal conditions, such as mechanical accuracy of the bearing surfaces, and freedom from distortion by pressure, heat, or wear.

On the other hand, the numerous direct experiments on bearings that have been conducted in the past have not led to general formulas for engineering use. Hersey(5) has shown, by dimensional reasoning, the algebraic relations that would enter into such formulas, but the necessary numerical coefficients, to be derived from experiments, are still wanting. Probably the main reason for this lack lies in the uncertainties as to the form and temperatures of the oil film in experimental bearings, leading to discordant results; differences of fit or finish cause great discrepancies. Experience indicates that extended, systematic, and carefully conducted experiments would be required in order to permit of general formulation with approximate accuracy; and even such experiments would require to be conducted in the light of physical theory. In the absence of such experiments, the fundamentally sound existing theory, omitting no major factor, and covering conditions that may be closely approximated in practice, is in itself a valuable guide to practice; and it would be still more valuable if more readily available. The object of the present paper is to present a method of extending the application of theory to bearing problems, by means of experimental solutions of stated cases, with sufficient accuracy for engineering purposes, and covering cases that have not heretofore yielded to mathematical treatment.

The approximate and partly experimental methods now to be described are not limited as regards form of bearing surfaces, or other assumptions such as viscosity variation; and relatively little mathematical work is involved, and that of a simple kind. As compared with the method of direct experiment upon bearings, the present method has the advantage of exact treatment of the film dimensions, and of permitting separate determinations of the effects due to separate actions, such as the effects of shear, of centrifugal action, and of boundary pressures. If the solutions obtained fail to fairly represent actual cases, it is only by reason of inexact or incomplete statement of the problems, not because of limitations of the method.

II—GENERAL DESCRIPTION OF THE EXPERIMENTAL METHOD

The method, described in brief, consists primarily in direct experiment upon large-scale electrically conducting models, each so designed that the space relations of current and voltage are very nearly the same as those of volume flow and pressure in lubricating films of arbitrarily assumed form and viscosity variation. The observations of current and voltage are readily interpreted in terms of volume flow and pressure; then by means of graphical or other approximate methods of integration, it is easy to determine the total pressure or load, its position and direction, the frictional resistance, and the volume and distribution of the oil flow. The scale of the electrical model is made large in the direction of thickness of the oil film, but not correspondingly large, if enlarged at all, in the other dimensions.

It is possible to draw various physical analogies to the conditions of flow and of stress in the lubricating film. Perry (8) remarks that viscous flow, the flow of heat or of electricity in a

Contributed by the Special Research Committee on Lubrication and presented at the Annual Meeting, New York, N. Y., December 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

conductor, stress and strain in an elastic solid, and other physical problems, are all correlated through the "equation of continuity." Heaviside (9) draws an analogy between viscous flow and the flow of electric current in a conductor. Michell (3) has applied the elastic analogy experimentally to the study of lubricating films between plane surfaces; but it does not appear that any of the other possible analogies have been utilized for experimental work in this field. The electric-current analogy offers the greatest possibilities, because of simplicity of the special apparatus, ease of control, and readiness of reasonably accurate measurements.

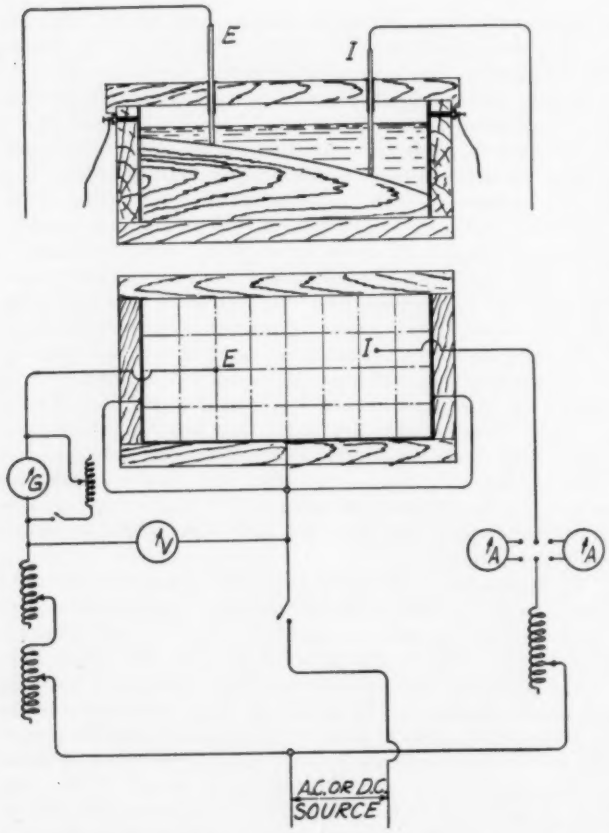

FIG. 1 TYPICAL FORM OF ARRANGEMENT OF TEST MODEL, WITH DIAGRAM OF THE ELECTRICAL INSTRUMENTS AND WIRING

The general arrangement of the model consists of a body of fluid of low electrical conductivity, with free upper surface, contained in a wooden box having the same plan as the developed bearing surface, to any desired scale; the varying depth of the bath is determined by a wooden form fastened in the box, its contours being determined according to the reasoning given in Section III. Metal plates inserted at the sides provide means for establishing potentials corresponding to pressure conditions at the edges of the bearing film. Metal-rod electrodes, inserted vertically to the full depth of the bath at chosen points, furnish means for supplying current, corresponding to volume flow in the oil film, and for measuring voltage, corresponding to pressure in the oil film. Details of some of the constructions will be described later.

The experimental procedure, according to the conditions of the problem, consists either in supplying measured current successively at the centers of small divisional areas of the bath, or of measured voltage at the side plates or of sectional parts thereof, and observing the voltage thereby produced at other points of the bath. The sum of the observed values of voltage at a given vertical in the bath due to all of the separate currents or voltages supplied, when reduced by the method described in Section III, gives the desired value of the pressure in the oil film at the corresponding point.

Fig. 1 shows a typical form of arrangement of test model, with a diagram of the electrical instruments and wiring.

The box and the form are most conveniently made of well-seasoned wood, which has been found serviceable if well coated with an asphalt paint or with a solution of celluloid in acetone. Several other coatings were tried, but none but those mentioned were found to be waterproof. The top edge of the box, made to a plane and set level, forms a datum from which to gage the depth of the bath, measured vertically from the bottom form to the free surface. The projected area is plotted to the desired divisional areas; the wood cover has drilled holes in which close-fitting copper tubes are inserted, for locating and guiding the rod electrodes, at the centers of the divisional areas for the current electrode, and at the corners of the divisional areas for the voltage electrode.

For several reasons, aqueous solutions appear to be the best substances available for the electrical models. As Kohlrausch (6) has pointed out, fluids are the only homogeneous conductors, all solids such as metals being more or less non-homogeneous; and aqueous solutions have true ohmic resistivity, which may readily be varied through a wide range by the use of more or less dissolved chemical. Their specific conductivities are low in all cases; and this is a requisite in the models, in order to permit of the necessary definite control of boundary potentials by means of metal-plate electrodes.

In some of the experiments relating to plane bearing surfaces, the test bath, constituting the model of the lubricating film, was a solution of pure cupric sulphate in distilled water, with a resistivity of about 50 ohm-inch. Copper was used for the side plates and the current and voltage electrodes; and direct current was used, supplied by one or two commercial dry cells. The use of direct current, instead of alternating current as used by Kohlrausch,(6) was due to the relatively great sensitiveness of direct-current instruments, and particularly because there appears to be no quick-reading a.c. voltmeter serviceable for very low ranges (0.002 to 0.005 volt).

The use of direct current in connection with an electrolytic bath for the model has some disadvantages, in that the contact of the electrolyte with the electrodes induces small and variable potentials and currents, independently of the action of the external batteries; and with continued use of the battery currents there are surface changes at the electrodes (polarization), causing surface resistances and counterpotentials that markedly affect the observations. These difficulties are minimized by using a salt of the electrode metal to provide the desired conductivity in the bath; by using a battery current that is barely large enough to make the contact currents of minor importance; by keeping the current flowing only long enough to read the instruments; and by reversing the current for alternate readings of potential at a given point, so that the errors nearly balance out in the summation. A highly important help in reducing the errors consists in frequent withdrawal of the copper parts from the bath and scouring them with emery cloth to remove the dark-colored deposits due to the electrolytic action. A current of the order of one-fourth ampere per square inch of the current electrode has been found suitable; excessive current causes undue local heating of the bath, with consequent local changes of resistance, which are undesirable, since all calculations are based upon uniform resistivity in the bath. With these precautions, check tests for the value of the pressure at a given point generally agree within about 1 per cent.

A more accurate and less troublesome arrangement was used in later experiments. As compared with the direct-current method described above, the changes consisted in the use of alternating current,(6) chromium-plated copper electrodes, and higher resistivity of bath.

The current was taken from the city supply, 110 volts, 60 cycles, and was controlled as required by wound rheostats.

The bath was a dilute solution of potassium dichromate in distilled water, having a resistivity of at least 500 ohm-inch, and in some cases much higher. By thus increasing the resistivity it was possible to raise the minimum measured voltages in the bath to about 0.050–0.060 volt, thus bringing the voltage measurements within the range of available a.c. voltmeters.

The chromium plating of the electrodes greatly reduced the attention required for keeping the surfaces clean. As received from the plating works, the chromium surfaces had been buffed, and apparently had a very thin coating of the stearic acid or other substance used with the abrasive for charging the buffing wheels, so that the bath solution would not wet the chromium, nor would cleaning by ordinary methods secure the necessary wetting. This difficulty was overcome by scouring the surfaces with fine washed emery moistened with a portion of the bath solution, applied with a pad of surgical cotton. This secured immediate and thorough wetting, and the surfaces so cleaned remained in constant condition throughout long series of tests, without evidence of plating, of oxidation, or of polarization. This condition is necessary for accurate results in the experimental work, since surface resistances at the electrodes would result in false indications of voltage at all points in the bath.

The resistivity of the bath solution was determined by direct measurements, using a prism of the fluid of about 6 sq. in. section, contained in a wood box about 24 in. long, with movable plate electrodes, and using the same electrical instruments that were used for the model tests. Resistivities were determined over the range of expected room temperatures, thus obtaining data for corrections for temperature changes that might occur during tests.

Referring to Fig. 1, it will be observed that the potentials were taken by a null method; if the current required to operate the voltmeter were taken from the bath, the distribution of current and of potential in the bath would thereby be altered and thus the true potential would not be read.

The electrical problems involved are closely akin to those of measuring the conductivity of electrolytes. On this subject there is an extensive literature in physical and chemical journals; with very few exceptions, the methods described involve the use of alternating current, and the principles and precautions necessary for precise results are applicable to the present experimental work.

III—THEORY OF THE EXPERIMENTAL METHOD: PRESSURES DUE TO RELATIVE MOTION OF BEARING SURFACES

The differential equation established by Reynolds (1), and now generally used as a basic expression, is

$$\frac{d}{dx}\left(h^3\frac{dp}{dx}\right)+\frac{d}{dz}\left(h^3\frac{dp}{dz}\right)=6\mu\left\{(U_0-U_1)\frac{dh}{dx}+2V_1\right\}\ldots[1]$$

in which

$U_0 - U_1$ is the relative tangential velocity of the surfaces
V_1 is the relative normal velocity of the surfaces
x is parallel to U_0 and U_1
z is at right-angles to x and parallel to both surfaces
h is the film thickness
p is the pressure, above atmospheric or other uniform ambient pressure, and
μ is the coefficient of viscosity, assumed constant by Reynolds.

This equation, derived from the fundamental expressions for stress in a viscous fluid (identical with those for an elastic solid), may be written, by dividing by 12μ,

$$\frac{d}{dx}\left(\frac{h^3}{12\mu}\frac{dp}{dx}\right)+\frac{d}{dz}\left(\frac{h^3}{12\mu}\frac{dp}{dz}\right)=\frac{U_0-U_1}{2}\frac{dh}{dx}+V_1\ldots[2]$$

In this form, the physical meaning of the terms is as follows: Considering as an "element" a volume of the film of unit dimensions in x and z, and of height h (the film thickness), the expression $\left(\frac{h^3}{12\mu}\frac{dp}{dx}\right)$ may readily be shown (2) to be the component of volume of lubricant, per unit time, flowing in the x-direction past the section of unit length in z and of height h, due to the pressure gradient $\frac{dp}{dx}$. The derivative of this quantity with respect to x, that is, the first term of [2], is the difference of the flow past the opposite faces of the element; it is the net volume flowing out from (or into) the element in the x-direction; and this is true whether μ be constant or variable, while [1] is true only if μ is constant. A precisely similar reasoning applies to the second term of [2]; this term expresses the net component rate of volume flow out from (or into) the element in the z-direction. The third term of [2] is the net volume per unit time flowing into (or out from) the element in the x-direction, as determined by a uniform rate of shear over the film thickness h, due to the relative motion of the bearing surfaces in the x-direction, without reference to pressure. The fourth term is the volume-displacement rate due to the relative component of motion normal to the nearly parallel bearing surfaces, also without reference to pressure.

Thus Equation [2] states, in symbols, with reference to a single elementary volume of the film, the equality of the inflow to the outflow; an equality that can exist only if the lubricant is continuous and incompressible, as assumed by Reynolds (1) in deriving Equation [1].

It appears also that if there be any other action than those considered above, by which a volume displacement for the element may be determined independently of pressure effects, a corresponding term may be inserted on the right in [2]; for example, expansion of the fluid by heat, or displacement of volume by centrifugal action. Further, it is important to note that because of the linear relation of pressure and viscous flow, in any solution or integration of [2] with the object of finding an expression for p at any point in terms of the known or assumed volume displacements on the right, it is permissible to find the separate values of p for the separate terms on the right, and the algebraic sum of such values is that due to all the terms on the right, whether the latter be considered together or separately. This is analogous to the addition or superposition of stresses and of strains in the theory of elasticity, the latter theory and that of lubrication being based upon the same fundamental equations. And further, if any or all of the terms on the right be considered as operative at a single element at x_1,y_1, producing there a pressure p_1, then at any other point x_2,y_2 there will be a pressure p_2, less than p_1, and depending for its value upon the ways in which the flow from x_1,y_1 is distributed throughout the film. And if further the terms on the right be operative simultaneously at all the elements, the total pressure at a point x_2,y_2 is the algebraic sum of all the pressures p_2 due to all the elementary volume supplies taken separately. This latter principle is the basis of the present experimental method.

For present purposes, the basic differential equation for the oil film may be written, from [2],

$$\frac{d}{dx}\left(\frac{h^3}{\varphi}\frac{dp}{dx}\right)+\frac{d}{dz}\left(\frac{h^3}{\varphi}\frac{dp}{dz}\right)=12\mu_0 q \quad \ldots\ldots\ldots [3]$$

in which μ_0 is the viscosity at a base point, and φ a non-dimensional function of x and z such that the viscosity at any point is given by $\varphi\mu_0$, and q represents any or all of the terms on the right in [2]. The solution of [3] for p requires that h, φ, and q shall be determinable from the data of the problem, for all parts of the surface, whether or not they can be expressed as continuous functions of the film dimensions and the surface motions; and the boundary values of p are also required data.

In order to establish working equations for the experimental method, we have first to consider that just as viscous flow is proportional to the pressure gradient and inversely as the viscosity, so is current flow proportional to the potential gradient and inversely as the resistivity (Ohm's law). There is, however, this difference: that the viscous flow is proportional to the third power of the film thickness, while the current flow is proportional to the first power only. Thus following the reasoning that has been applied to Equation [2], as applying equally to the electrical conditions, we may at once write the electrical equation analogous to [2], giving the differential relation of current and potential in the model,

$$\frac{d}{dx}\left(\frac{H}{r}\frac{dE}{dx}\right)+\frac{d}{dz}\left(\frac{H}{r}\frac{dE}{dz}\right)=i=(\text{approx.})\ \frac{I}{\alpha} \quad \ldots\ldots [4]$$

in which H is the variable depth of the bath, r is the uniform resistivity, E the potential, i the current supplied per unit area. Like Equation [2], this is an equation of continuity; it is the symbolized statement of the equality of the inflow and the outflow of current, with reference to a single elementary volume of the bath, of unit-area base and of height H. The reason for the expression I/α is that in the experiment it is not generally practicable to deal directly with unit areas; the whole area is divided into an arbitrary number of (preferably equal) areas α, and a current I is supplied at the center of each of these areas successively; thus instead of i we may write I/α, the mean intensity of current for the divisional area, as giving an approximation which is closer as the areas α are smaller and therefore more numerous. Practically, it is desirable to make the number of divisions as small as may be, since for each point where the pressure is to be determined, observations must be taken for each of the divisional areas; but supplying a current I at a point within the area α is not the exact equivalent of the theoretical distributed current i over the same area, and the discrepancy is in general greater as α is greater. Thus a compromise is required, for which rules have not been laid down; but it may be said that in general a very large number of divisions is not required; in some cases a small number, such as eight to twelve, may suffice.

Comparing [3] and [4], it is evident that if we were to make, numerically, $H=\frac{h^3}{\varphi}$ and $\frac{Ir}{\alpha}=12\mu_0 q$ at all points, then a complete experimental solution of [4] for the numerical value of E at any point would give also the numerical value of p at the same point; assuming, of course, that the values of E and p are made the same at all points around the edges. But in the experimental work it is desirable to make H a relatively large dimension, say, of the order of one inch; h may be of the order 10^{-3} inch, hence h^3 is of the order 10^{-9} inch; φ may be of the order unity. Thus we may write $H=K\frac{h^3}{\varphi}$ where K is a constant of the order $10.^9$ Introducing this factor K in [3], we have

$$\frac{d}{dx}\left(K\frac{h^3}{\varphi}\frac{dp}{dx}\right)+\frac{d}{dz}\left(K\frac{h^3}{\varphi}\frac{dp}{dz}\right)=12K\mu_0 q \quad \ldots\ldots [5]$$

Now referring to [4], if we supply any measured current I_1 at a single small divisional part having an area α_1 at x_1,y_1, and measure the potential ΔE_2, thereby produced at a point x_2,y_2, the relationship may be indicated as

$$\Delta E_2=\frac{I_1 r}{\alpha_1}\psi$$

in which ψ is an undetermined function of x_1,z_1,x_2,z_2. Considering [5] in the same way and for the same points, the same value of ψ will apply; hence we may write

$$\Delta p_2=12\,K\mu_0 q_1\psi$$

whence, by elimination of ψ,

$$\Delta p_2=12\,K\mu_0\Delta E_2\frac{q_1\alpha_1}{I_1 r}$$

Thus considering the whole bearing surface, we may write for the pressure at any point, dropping the subscripts for generality,

$$p=\Sigma(\Delta p)=12\,K\mu_0\,\Sigma\left(\frac{\Delta E}{Ir}\,q\alpha\right) \quad \ldots\ldots [6]$$

or, replacing K by its value $\frac{H\varphi}{h^3}$,

$$p=12\,\mu_0\,\Sigma\left(\frac{\Delta E}{Ir}\frac{H\varphi\,q\alpha}{h^3}\right) \quad \ldots\ldots [7]$$

Equations [6] and [7] are the general expressions for the experimental determination of the pressure, in so far as it is produced by the relative motion of the bearing surfaces. If there are, in addition, external actions producing non-uniform pressures in the film, these are most conveniently treated separately, as shown in the following section. In the application of [6] and [7] it is necessary to bear in mind that all the variables on the right relate to the points where the current is supplied, except ΔE, which relates to the points where p is to be determined.

IV—NON-UNIFORM BOUNDARY PRESSURES

If a part of the boundary of the film is at a known pressure p_0 due to external conditions, the remainder of the boundary being at zero pressure, there results a non-uniform pressure field in the film, the pressure Δp at any point depending upon the form and dimensions of the film, but directly proportional to p_0. For the experimental determination of the pressure, the electrical model, proportioned as in III, may be provided with a metal plate at the wall, covering the corresponding part of the boundary of the bath, and kept at a potential E_0, while the remainder of the boundary is held at zero potential; this produces a potential field in the bath exactly similar to the pressure field in the film, and the potential ΔE at any point is directly proportional to E_0. We may then write for the pressure at any point,

$$\Delta p=\frac{\Delta E}{E_0}\,p_0$$

If the pressure p_0 varies from point to point at the edges of the film, the resulting pressure at a point in the film may be found approximately by dividing the wall plate into parts, each representing a part of the film boundary having a mean local

pressure p_0. Dealing with these parts successively as described above, the pressure p at a point in the film is, approximately,

$$p = \Sigma(\Delta p) = \Sigma\left(\frac{\Delta E}{E_0}\, p_0\right)$$

It will be noted that the value of the resistivity of the bath is not involved; the only requisite is that the resistivity be uniform throughout the bath, as in all cases.

The voltages E_0 and ΔE may be measured separately by the use of voltmeters; but since only their ratio is involved, a simpler and more accurate method is to measure their ratios directly by means of a Wheatstone bridge, thus dispensing with all absolute electrical measurements.

V—INDIRECT METHOD

In cases in which h and μ are assumed to be functions of x only, independent of z, a solution for the "infinitely wide" bearing may first be made, resulting in $p_x = f(x)$. This may be done by calculation in the simpler cases, and in any case either by

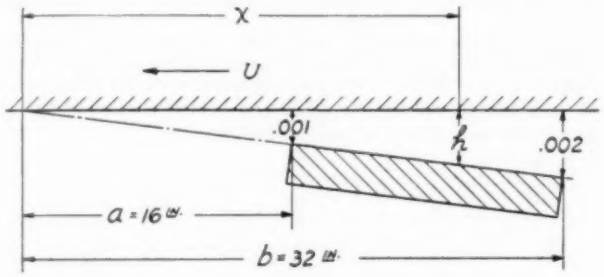

FIG. 2

graphics or by the experimental method of III. Having this solution, the pressures for any finite width may be found by the aid of IV with much less work than by the direct application of III, as follows: Referring to Fig. 3, if the model be treated by the method of III for the case of infinite width, the pressure $p_x = (x)$ exists along the non-conducting side BB as well as elsewhere; if for finite width, the pressure along BB is kept at zero by a conducting plate. We may therefore write in a case of finite width, for any point x, z,

$$p_q = p_x - p_s$$

in which p_q = pressure with side leakage at BB
p_x = pressure without side leakage at BB
p_s = pressure due to pressures $p_0 = p_x = f(x)$ along the side BB, acting alone.

The pressures p_s may be found by method IV with a minimum of time and labor. Thus in the case of the model of Fig. 3, five divisions of the side plate at BB were found fairly sufficient; this required but five observations for each point where the pressure is to be found; while when the method III was applied directly there were 32 observations of voltage and 32 of current for each pressure determination. Obviously the saving by the indirect method is greater as the width of the bearing in the z-direction increases, and as the number of divisions of BB diminishes.

The sole objection to this indirect method is that for narrow bearings, and for points near the boundary in any case, the value of p_q is small compared with p_x, and thus a small experimental error in p_s involves a larger proportionate error in p_q. Nevertheless experience indicates that owing to the superior accuracy of the bridge method of IV, this indirect method is preferable, as regards both simplicity and accuracy, for the cases where it is applicable.

VI—PLANE SURFACES: RECTANGULAR SLIDE BLOCK, OF INFINITE WIDTH AT RIGHT ANGLES TO THE RECTILINEAR MOTION; CONSTANT VISCOSITY; STEADY CONDITIONS

This hypothetical case was chosen primarily as furnishing a first critical test of the experimental method, since the pressures can be calculated independently and exactly.

Fig. 2 shows the assumed dimensions of the bearing block and the oil film, and Fig. 3 the arrangement of the model. The constant K was chosen as 5×10^8; thus the depth of the bath varies from $(0.002)^3 \times 5 \times 10^8 = 4$ in. at the inlet end, to $(0.001)^3 \times 5 \times 10^8 = 0.5$ in. at the outlet end. The metal plates at these ends, connected by wire, serve to determine zero

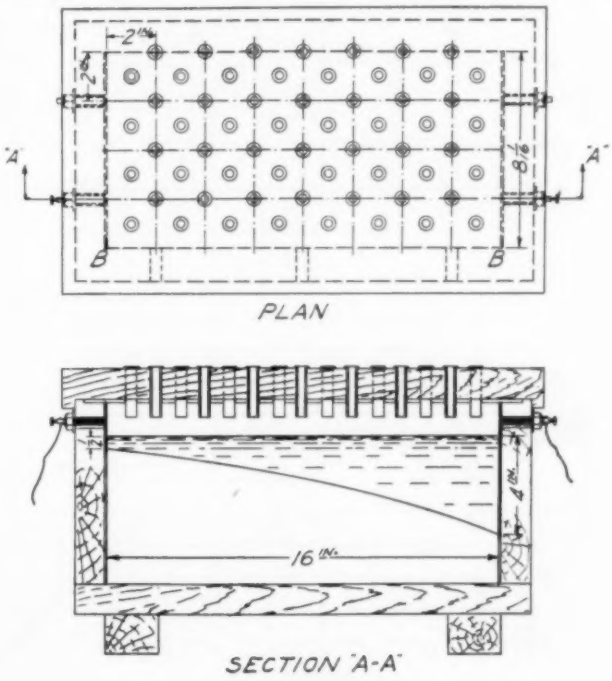

FIG. 3

potential, corresponding to zero pressure; the potentials measured in the bath are differences (+ or —) from the metal-plate potential, just as the pressures in the oil film are differences above or below the external pressure. The bottom form and the sides, being non-conductors, prevent any transverse flow of current. Thus the model represents a section of the oil film in the hypothetical case of infinite width at right angles to the motion.

Applying the method III, the following values are to be substituted in Equation [6] or [7], as required; U being the relative velocity $U_0 - U_1$ of Equations [1] and [2]:

$K = 5 \times 10^8$
r = 49.5 ohm-inch at 50 deg. fahr. with corrections for varying temperature
$q = \frac{U}{2}\frac{dh}{dx} = \frac{U}{32{,}000}$
$\varphi = 1$
α = 2 in. × 2 in. = 4 sq. in.
$h = cx$
$\frac{dh}{dx} = c = \frac{1}{16{,}000}$

Equation [6] thus becomes

$$p = 7.5 \times 10^8 \mu_0 U \Sigma \left(\frac{\Delta E}{Ir}\right) \ldots\ldots\ldots\ldots [8]$$

Equation [7] becomes

$$p = \frac{6\mu_0 U}{c^2} \Sigma \left(\frac{\Delta E}{Ir} \frac{H\alpha}{(x^2)}\right) \ldots\ldots\ldots\ldots [9]$$

Either [8] or [9] may be used for the numerical calculation. There are 32 terms $\frac{\Delta E}{Ir}$ for the pressure summation at each point. Fig. 4 shows the results of a test, made with alternating current. The circled points show the experimental values of p/C and the full curve the theoretical values; the latter being given by the expression, derived by integrating [3] with omission of the second term,

$$p/C = \left[\frac{(x-a)}{(a+b)} \frac{(b-x)}{x^2}\right] \text{ in which } C = \frac{6\mu U}{c^2} \ldots . [10]$$

It will be noted that the experimental results agree very closely with the theory. The pressures shown in Fig. 4 for this simple case relate only to a bearing block of the particular dimensions $a = 16$ in., $b = 32$ in. For any other dimensions with the same general assumptions, the pressures could be calculated from Equation [10]; but in this case, as in others to follow, the specific experimental results are readily convertible to apply to *geometrically similar* bearings, by means of dimensional reasoning.(5) Thus in Equation [9], the factors in $\frac{\mu_0 U}{c^2}$ are independent of the size of the bearing; the group $\frac{H\alpha}{x^2}$ is of zero dimensions; but the group $\frac{\Delta E}{Ir}$ is of dimension L^{-1}. Hence in a bearing of the size $a = 16n$ in., the pressures at similarly located points would be $\frac{1}{n}$ th of those found by the experiment described.

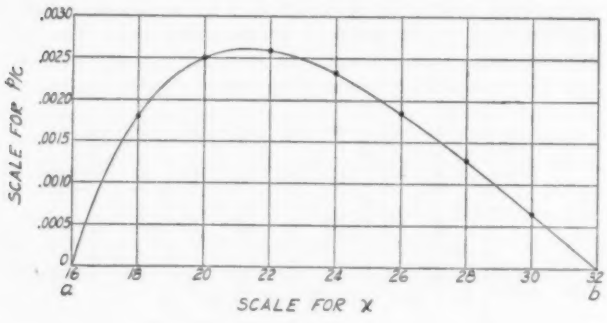

FIG. 4

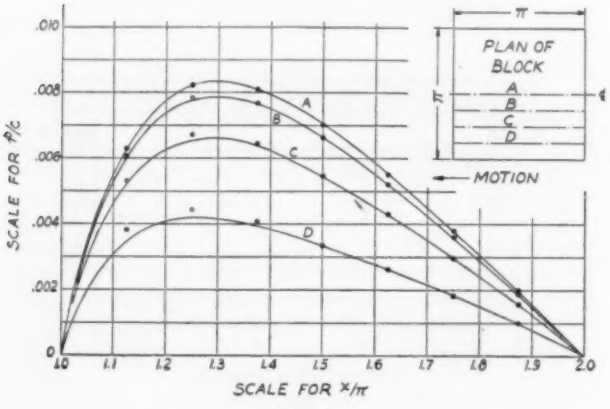

FIG. 5

VII—PLANE SURFACES; RECTILINEAR MOTION; SQUARE SLIDE BLOCK; LEAKAGE AT RIGHT-ANGLES TO THE MOTION; CONSTANT VISCOSITY; STEADY CONDITIONS

This case was chosen as a further test of the applicability of the electrical method, comparison being made with the theoretical results obtained by Michell.(3) As in the preceding case, the conditions are hypothetical, such cases not existing in practice.

The dimensions of the model are shown in Fig. 3. The arrangement differs from that of VI only by the addition of a zero-potential conducting plate at *BB*, corresponding to the condition of leakage along that side of the oil film. The model thus represents one-half of the oil film, either side of the median plane.

The numerical data are the same as in VI, and Equations [8] and [9] and deductions therefrom also apply; the only differences lie in the values $\frac{\Delta E}{Ir}$, and there are, as in the preceding case, $4 \times 8 = 32$ such terms in the summation for the pressure at each point; and for the 28 chosen points, a total of 896 observations each of current and of voltage.

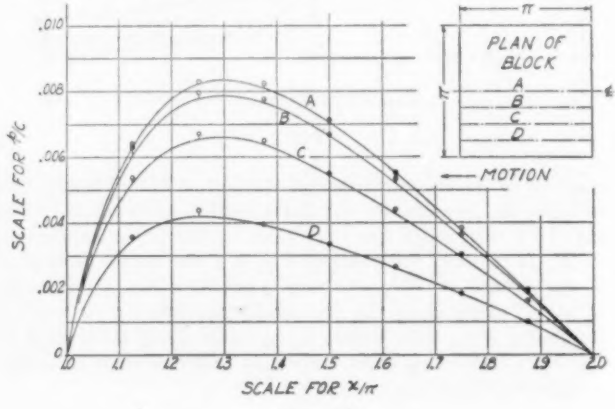

FIG. 5(a)

Fig. 5 shows the comparison, the circled points being the test results by method III, obtained with alternating current; and the full curves, graphical interpolations from the results of Michell's calculations.

In this case, the experimental values average 2.2 per cent higher than the pressures calculated by Michell; thus the agreement of the experiment with the mathematical results is less exact than in VI and in all other cases tested in which no side leakage is involved.

Fig. 5(*a*) shows a further test for this case by the indirect method V. The mean error in this case is 0.9 per cent in excess of Michell's results. A repeat test by method V confirmed the circled points so closely that the differences could not be shown on the diagram.

VIII—PIVOTED-BLOCK THRUST BEARINGS; SECTOR-SHAPED SURFACES; SIDE LEAKAGE; VARIABLE VISCOSITY

Fig. 6 shows the assumed form and dimensions of the pivoted block. The "axis of tilt" is the line of intersection of the extended plane of the block with the surface of the rotating collar,

and the particular choice of this axis is such as to make the oil film geometrically similar along arcs at all radii (a condition not necessarily the best in practice) and the variable thickness at the leading edge twice that at corresponding points at the trailing edge.

The viscosity is assumed to be uniform along any radial line, but varying uniformly with the angular position of the radius, so that at the trailing edge it is one-half that at the leading edge. This assumption is largely arbitrary, in view of the highly complex nature of the conditions of heat equilibrium in the film, and of the meagerness of existing physical data on the subject; yet for conditions of high speed and pressure it is probably closer to the truth than would be, for example, an assumption of constant viscosity.

The data for the specific case, partly shown in Fig. 6, and the substitutions for changing Equations [6] and [7] to polar coordinates are as follows:

$K = 5 \times 10^8$

c = dihedral angle between the bearing surfaces

$h = c\rho \sin\theta$

$\frac{dh}{dx} = c \cos\theta$

$a = b\rho\,\Delta\theta$ (values of ρ being taken at the middle of the widths b)

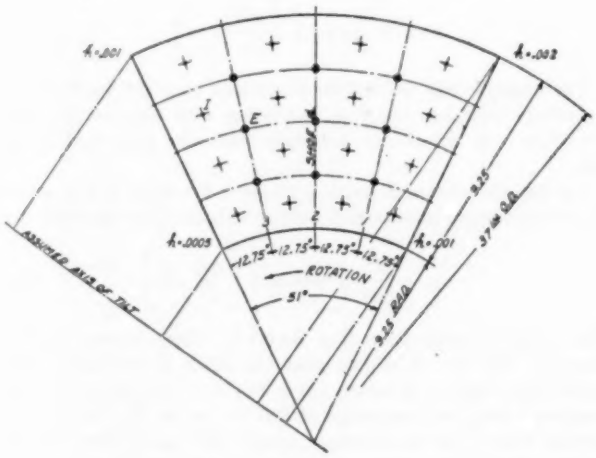

FIG. 6

ω = angular velocity of collar, radians per second

N = angular velocity of collar, revolutions per minute

U = linear speed of collar at any radius $= \omega\rho = \frac{\pi N}{30}\rho$

$q = \frac{U}{2}\frac{dh}{dx} = \frac{\pi}{60} N\rho c \cos\theta$

Equation [6] thus becomes

$$p = \frac{\pi}{5}\mu_0 N c b\,(\Delta\theta) K \Sigma\left[\frac{\Delta E}{Ir}\rho^2\cos\theta\right] \quad \ldots\ldots\ldots [10]$$

Equation [7] becomes

$$p = \frac{\mu_0 N}{c^2}\frac{\pi}{5} b\,(\Delta\theta)\,\Sigma\left[\frac{\Delta E}{Ir}\frac{H\varphi\cos\theta}{\rho\sin^3\theta}\right] \quad \ldots\ldots\ldots [11]$$

Figs. 7 and 8 show the pressure distribution obtained by tests with direct current, for the block of Fig. 6, and the film of maximum thickness 0.002 in., with $N = 100$ revolutions per minute and $\mu_0 = 3.4 \times 10^{-8}$ (inch, lb., sec.) corresponding to about 150 seconds Saybolt.

For extending these experimental values of p to cases of larger or smaller blocks, geometrically similar to the experimental block, it may be noted that in Equation [11] the dimensions of the product $\mu_0 N$ are the same as those of p; namely, $ML^{-1}T^{-2}$, and the remaining factors reduce to zero dimensions. Hence for the same N, μ_0, and c the pressure at any point is independent

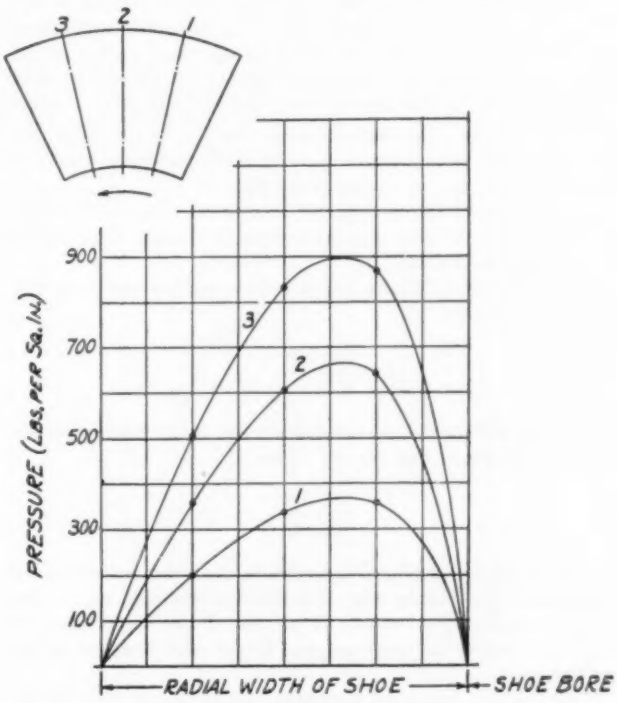

FIG. 7

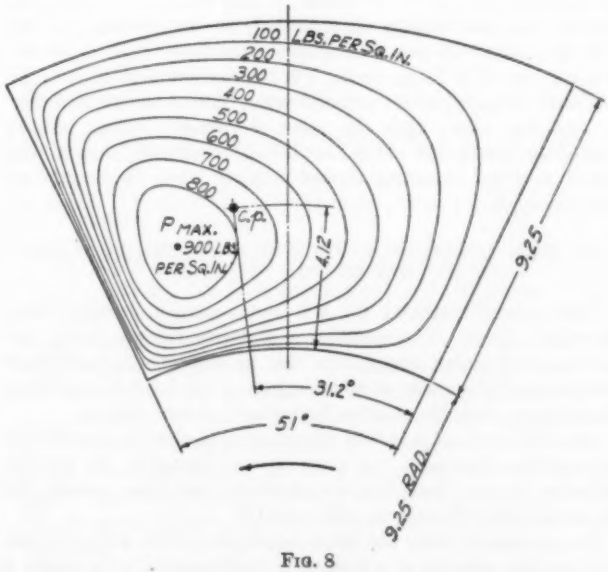

FIG. 8

of the size of the block; but for a given circumferential speed, the pressure is inversely as the size.

The friction torque is determined for the numerical example given above, by means of Reynolds' equation for the shear stress at the collar surface, x being in the direction of the motion.

$$f_s = \frac{\mu U}{h} + \frac{dp}{dx}\frac{h}{2} \quad \ldots\ldots\ldots [12]$$

The values $\frac{dp}{dx} = \frac{dp}{\rho d\theta}$ are found graphically at the selected points, from the pressure curves plotted from the experimental data, and the values of $\mu U/h$ for the same points are readily calculated; then by approximate integration the mean pressure is found to be 352 lb. per sq. in. The friction torque is 508 in-lb., and the power loss 0.805 hp. The torque is equivalent to a friction force of 36.6 lb. acting at the mean radius of the block, corresponding to a mean coefficient of friction of 0.000908. This coefficient agrees closely with the formula $f = 0.00009\sqrt{\text{r.p.m.}}$ derived from tests on large bearings of this form, for the same mean pressure and approximately the same viscosity of the oil at the entrance edge of the film.

The volumes of oil entering and leaving the film, for the same numerical example, were also determined by the aid of the curves of pressure distribution.

The volume of oil flowing per unit time and per unit length of radial edge, is given by

$$\frac{U}{2}h \pm \frac{h^3}{12\mu}\frac{dp}{dx}$$

and for the circular edges, the volume lost is determined by the rate per unit length and per unit time.

$$\frac{h^3}{12\mu}\frac{dp}{d\rho}$$

It was found by graphical integration that the volume of oil entering at the leading edge is approximately 0.98 cu. in. per sec.; of which approximately 27 per cent is lost along the outer arc, 7 per cent at the inner arc, and 66 per cent flows out at the trailing edge.

If all the heat generated were absorbed by the oil, then assuming a specific gravity of 0.91 and a specific heat of 0.45, the mean temperature rise of the oil would be 21.9 deg. cent. Assuming further that the leakage oil is heated, on the average, by one half the maximum rise, the temperature rise of the oil at the trailing edge is 26.5 deg. cent. The original assumption as to the viscosity change implies a temperature rise of about 17.5 deg to 19.5 deg. cent.; thus the assumed viscosity change implies that about one-fourth of the heat is conducted away through the metal, and the remaining three-fourths is taken up directly by the oil supply.

IX—THE PRESSURE EFFECT DUE TO CENTRIFUGAL ACTION IN THE OIL FILM

This was determined for the sector-shaped bearing block described above. The question is of minor interest only; but in view of frequent suggestions that at high speeds centrifugal effects must be considerable in bearings of this kind, it is perhaps desirable to show the relative importance of such effects.

For this purpose, it is first necessary to derive by analysis the appropriate expression for q for use in Equation [6] or [7]; all other factors, including the electrical test data, remain the same as for the Equations [10] and [11].

In accordance with the usual conception, it is assumed that the angular velocity of a lamina of thickness dy, at a height y above the stationary surface, is $\frac{y\omega}{h}$; ω being the angular velocity of the collar, and h the thickness of the film. The density of the oil being m, each such lamina, of volume $\rho d\rho \cdot d\theta dy$ is subject to a "centrifugal force" of the value

$$m\rho^3\omega^2 d\theta \cdot d\rho \cdot \frac{y^2 dy}{h^2}$$

This force is balanced by the difference of the radial components of the shear forces on the upper and lower faces of the element. Applying the established laws of laminar flow, it is readily shown by integration that the volume flowing across a section $h \cdot \rho d\theta$ in unit time is

$$\frac{m\omega^2\rho^2 d\theta h^3}{40\,\mu_0\varphi}$$

Hence the difference of flow past two such sections at an interval of $d\rho$ is

$$\frac{m\omega^2 d\theta}{40\,\mu_0} d_\rho\left(\frac{h^3\rho^2}{\varphi}\right)$$

Substituting for h its value $c\rho \sin\theta$, differentiating, and dividing by $\rho d\rho \cdot d\theta$ to reduce to terms of unit area of bearing surface, we have the desired value

$$q = \frac{m\omega^2 c^2\rho^3 \sin^3\theta}{8\,\mu_0\varphi} = \frac{m\omega^2}{8\,\mu_0}\frac{h^3}{\varphi} \quad \ldots\ldots\ldots\ldots [13]$$

Thus Equations [6] and [7] become, by substitution for q,

$$-p = \frac{3}{2} m\omega^2 K \Sigma\left(\frac{\Delta E}{Ir}\frac{h^3}{\varphi}\alpha\right) \quad \ldots\ldots\ldots\ldots [14]$$

$$-p = \frac{3}{2} m\omega^2 \Sigma\left(\frac{\Delta E}{Ir} H \alpha\right) \quad \ldots\ldots\ldots\ldots [15]$$

The negative sign is used for the reason that the value of q is essentially negative, the flow increasing with the radius; thus the effect is to reduce any pressures otherwise generated in the film.

For the special case in hand, expressing the value of ω in terms of revolutions per minute and with $\alpha = b\rho\Delta\theta$, [15] becomes

$$-p = \frac{\pi^2}{600} N^2 mb\ \Delta\theta \Sigma\left[\frac{\Delta E}{Ir}\rho H\right] \quad \ldots\ldots\ldots [16]$$

The pressure distribution thus found by direct current tests is shown in Fig. 9. It is seen that the effect is very small, the maximum negative pressure being but 0.11 lb. per sq. in., as compared with the maximum of 900 lb. per sq. in. due to tangential shear. At the assumed speed, 100 r.p.m., the ratio is about 1/8000; the ratio would vary directly as the speed, the value of c being held constant; but even at the very high speed of 1000 r.p.m., the ratio would be but 1/800. Thus for all practical purposes, the centrifugal effect is negligible.

X—EFFECTS OF MOMENTUM OF OIL AT FILM ENTRANCE

If the channel through which oil is supplied to the leading edge of the pressure film is of large section compared with the film thickness, the oil adjacent to the moving surface has substantially the same speed as that surface, throughout a layer that is of fairly large thickness compared to the thickness of the film. Hence the oil enters the film at a pressure approximately the same as that at center of a jet of velocity U directed against a fixed plate; and if the bearing block is square-edged, the entry pressure may be assumed to have approximately the value established by experiments with jets directed normally against fixed plates, $p_e = mU^2/2$.

The volume that actually enters the film is small compared to the total jet volume, and its mean velocity of entrance is reduced in general to less than one-half of the jet velocity. Hence the entry pressure is presumably not greatly affected by the flow into the film. In practice, however, the edge of the bearing

block is at least slightly rounded or beveled; and it appears that this should cause the entrance pressure to exceed the above value. Only direct experiment could determine the true entrance pressure; and for want of such tests, the pressure is taken as $mU^2/2$ for present purposes.

The pressure so calculated is not important in the case of moderate speed; but in recent practice, particularly in pivoted-block thrust bearings, the speed in some cases exceeds 200 ft. per sec. At this speed, with oil of specific gravity 0.9, the calculated entry pressure is 242 lb. per sq. in.; this obviously has an appreciable influence upon the pressure distribution in the film, since in high-speed bearings the mean pressure rarely exceeds 500 lb. per sq. in.

In case the oil is supplied under pressure, the electrical method may be used for determining the combined effects of supply pressure and jet pressure, by treating their sum as the initial pressure at the leading edge; or the effects of each upon the film pressure may be determined separately, as may be desired.

For the determination of the film pressures due to any assumed entry pressure, the general Equations [6] and [7] do not apply directly, since the values of q at the several divisional areas, due

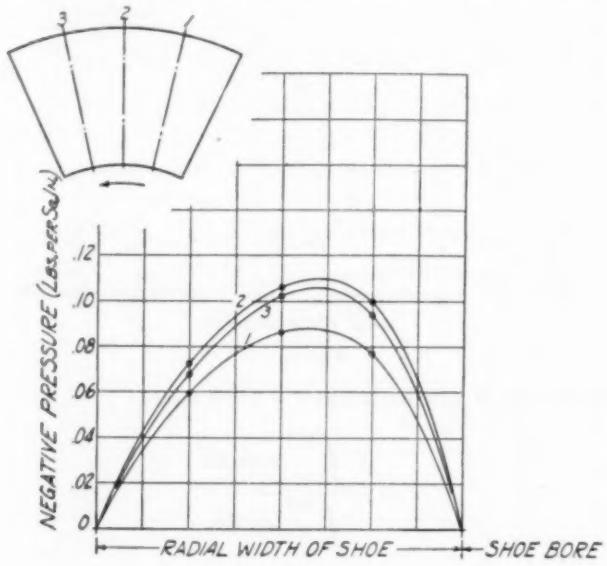

FIG. 9

to the entry pressure, are not determinable in advance. The case is treated on the basis of boundary pressures only.

The simplest case is that in which the entry pressure is uniform along the leading edge, as in journal bearings. The electrical analogue is established according to the principles of IV, by keeping the plate electrode at the leading edge of the bath at a potential E_0 above the nominal zero potential of the other edge plates; the potential E is then observed at any desired point x, y, in the bath. Then p_0 being the assumed jet pressure, and p the resulting pressure at x, y.

$$p = p_0 \frac{E}{E_0} = 1.37 \times 10^{-3} D^2 N^2 m \frac{E}{E_0} \ldots\ldots [17]$$

In the case of non-uniform pressure along the leading edge, as exemplified by the jet pressure in thrust bearings, the electrical arrangement is provided according to method IV, by substituting for the single plate electrode at the leading edge a number of narrow vertical strips, slightly separated from each other and from the side plates. In the test, a voltage E_0 is applied to one of the strips, the remaining strips and plate electrodes being kept at the nominal zero potential. The voltage ΔE is then observed at a point x,y of the bath. The calculated or assumed mean pressure for the position of the strip being p_0, and Δp the resulting pressure in the film at x,y,

$$\Delta p = p_0 \frac{\Delta E}{E_0}$$

All the separate strips being treated similarly, the pressure total at the point x,y is, approximately,

$$p = \Sigma (\Delta p) = \Sigma \left(p_0 \frac{\Delta E}{E_0} \right)$$

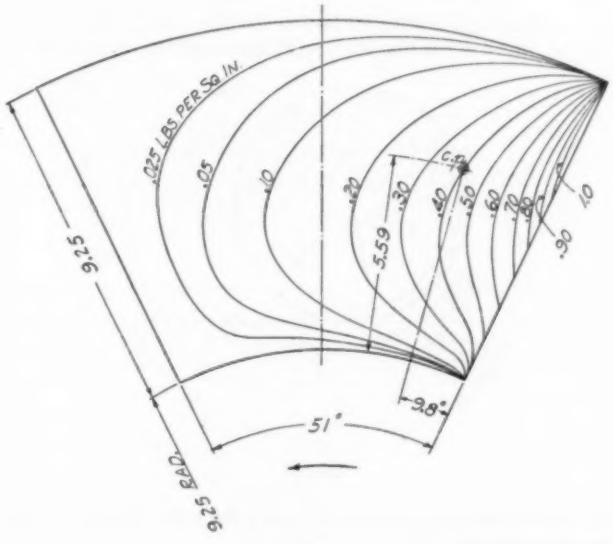

FIG. 10

On the assumption that $p_0 = \frac{mU^2}{2}$, and with ρ the mean distance of a strip from the center of rotation, it follows that

$$p = \frac{\pi^2 N^2 m}{1800} \Sigma \left(\frac{\Delta E \rho^2}{E_0} \right) = 5.49 \times 10^{-3} N^2 m \Sigma \left(\frac{\Delta E \rho^2}{E_0} \right) \ldots [18]$$

Fig. 10 shows the results of this method as applied to the thrust bearing (Fig. 6) with $N = 100$, for which the pressures produced by shear are shown in Figs. 7 and 8. In this case four voltage strips separated $^1/_8$ in. were provided at the leading edge, and direct current was used. A combined pressure diagram could be drawn by direct addition of the shear pressure and the inertia pressure, for a given film form and rotative speed; but this would require a separate combined diagram for each rotative speed, since the inertia pressure varies as the square of the speed, while the shear pressure varies as the first power if the film thickness is held constant, or is constant if the total load is constant.

XI—JOURNAL BEARINGS: CYLINDRICAL SURFACES, AXES PARALLEL. METHOD III

Fig. 11 shows the geometrical notation.

a = radius of journal
$a + \eta$ = radius of bearing
η = radial clearance
c = eccentricity factor

$e = c\eta$ = distance between the axis of the journal and that of the bearing
θ = angle measured from line of centers, in direction of U
ϕ = angle of inclination of journal load
U = linear velocity of journal surface = $\frac{\pi a N}{30}$
N = revolutions per minute
$dx = a d\theta$
z = distance parallel to axes, from middle of width
p = pressure in film at any point θ, z
β = mean value of p in Z-direction at any value of θ
R = mean load per unit width of bearing surface
$h = \eta(1 + c \cos\theta)$ = film thickness
$\frac{dh}{dx} = -\frac{\eta c \sin\theta}{a}$
l = length of bearing surface in the direction of the motion
w = width of bearing surface at right angle to the motion.

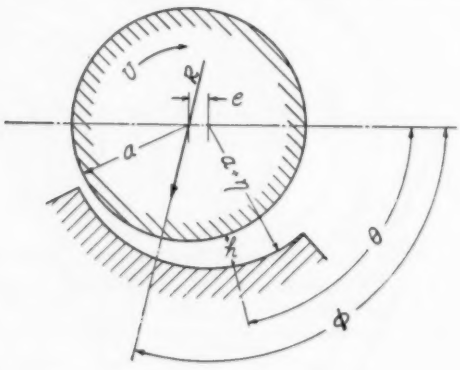

FIG. 11

For substitution in Equation [6] or [7] the value of q for journal bearings thus becomes:

$$q = \frac{U}{2}\frac{dh}{dx} = \frac{\pi}{60} N \eta c \sin\theta$$

Equation [6] becomes:

$$p = \frac{\pi K}{5} N \mu_0 \eta c \Sigma \left(\frac{\Delta E \alpha}{Ir} \sin\theta\right) \ldots\ldots\ldots [19]$$

and [7] becomes:

$$p = \frac{\pi}{5} N \mu_0 \eta c \Sigma \left(\frac{\Delta E}{Ir}\frac{H \varphi \alpha}{h^3} \sin\theta\right) \ldots\ldots\ldots [20]$$

If the values of $\sin\theta$ are taken at the centers of the areas α, Equations [19] and [20] are nearly exact if these areas are relatively small; but more precisely, the value of $\sin\theta$ for each area α should be the mean value; the further, the current should be supplied, not at the center of the area, but at the "center of gravity" of the values of $\sin\theta$ within the area. These latter considerations may be taken into account when the areas α are relatively large, and particularly for any area having a large variation of $\sin\theta$. Thus if the areas are rectangles of sides Δx and Δz, and the variation of h in the distance Δx is Δh, the exact value of $q\alpha$ in [6] is:

$$q\alpha = \frac{U}{2}\frac{\Delta h}{\Delta x} \Delta x \Delta z = \frac{U}{2} \Delta h \Delta z$$

Thus [6] becomes, as the most suitable form for use,

$$p = \frac{\pi}{5} K N a \mu_0 \Sigma \left(\frac{\Delta E}{Ir} \Delta h \Delta z\right) \ldots\ldots\ldots [21]$$

As regards the location of the current electrode within an area $\alpha = \Delta x . \Delta z$: since q varies as dh/dx, the best experimental approach to the theoretical distribution of q is obtained by placing the current electrode at the "center of gravity" of the variable q for the the given area. This center is in the middle of the width Δz, and its position in the x-direction may readily be estimated from a curve $y = dh/dx$. Or passing to the analytic form, if $\Delta x = x_2 - x_1$, then the x-location is given, by the usual method for centers of gravity,

$$\bar{x} = \frac{\int_{x_1}^{x_2} \frac{dh}{dx} x dx}{\int_{x_1}^{x_2} \frac{dh}{dx} dx} \ldots\ldots\ldots [22]$$

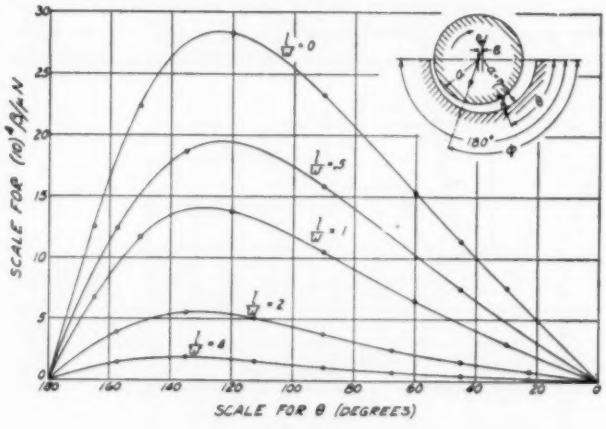

FIG. 12

For example, if Δx extends from $\theta = 0$ to $\theta = \pi/4$,

$$\bar{x} = \frac{a \int_0^{\pi/4} \theta \sin\theta d\theta}{\int_0^{\pi/4} \sin\theta d\theta}$$

$$= \frac{a \left[\sin\theta - \theta\cos\theta\right]_0^{\pi/4}}{\left[\cos\theta\right]_0^{\pi/4}} = 0.518a = 0.66\,\Delta x$$

Thus in this case the current electrode is advanced by $0.16\,\Delta x$ in the direction of decreasing h, beyond the center of figure of the divisional area under consideration. For an area in which Δx extends from $\theta = \pi/4$ to $\theta = \pi/2$, the corresponding correction is much smaller, being but $0.0267\,\Delta x$. The quantity β, which as defined above represents $\int_{z=0}^{z=w/2} \frac{pdz}{w/2}$ at any chosen value of θ, affords a convenient simple basis for comparing visually the load capacities of bearings of a given length l with varying widths w as in Figs. 12 and 15. Further, the curves of β plotted against x or θ, may be used as if β were actually a uniform pressure over the width w, in all calculations for the total load and its direction; for the friction; and for the quantities of oil entering and leaving the film. This is, however, true only with h independent of z, as determined by the assumed condition of parallel axes.

XII—180-DEG. JOURNAL BEARING. METHOD III

Referring to Fig. 12, the dimensions of the models were made to conform to the following bearing data:

a = 3.82 in. (24 in. circumference)
η = 0.001 a = 0.00382 in.
c = 0.4

The viscosity μ was assumed constant.

The test results using alternating current, for five ratios l/w are shown in Fig 12, the circled points being the experimental values of $\beta/\mu N$. For the case of l/w = 0 (infinitely

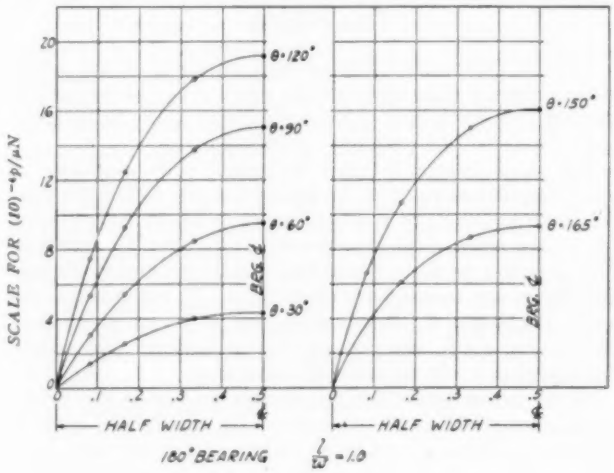

FIG. 13

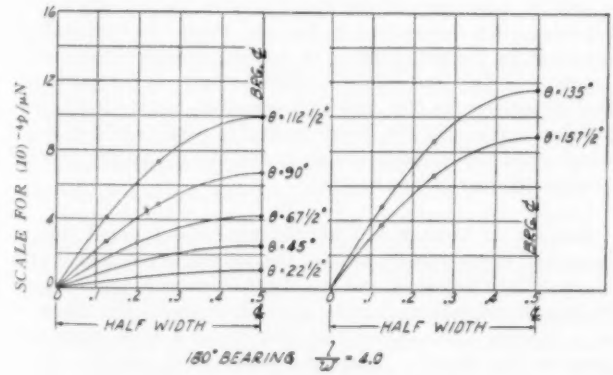

FIG. 14

wide bearing) the curve shows the theoretical values of $\beta/\mu N$, calculated from the equations of Harrison,(10) identical with those of Sommerfeld(7); the experimental results are seen to be very close to the theoretical values. For the remaining values of l/w, the curves are drawn through the experimental points, no theoretical check being available. The curves are drawn with reference to the developed bearing surface.

Fig. 13 shows the experimental values of the pressure p at various values of z and of θ, for the case l/w = 1. Similarly, Fig. 14 shows how p varies with z and with θ for the case l/w = 4. The latter case being a relatively narrow bearing, these transverse pressure curves are very nearly parabolas; this conforms to the hydrodynamical theory, as may readily be shown by making dp/dx = 0 in Equation [1] and integrating the remaining terms.

Fig. 16 shows how the load R is related to the values of l/w, the value of R for the case of no side leakage being taken as unity. The value of R in each case is found by the usual method of resolving the value of β (Fig. 12) with reference to two arbitrary axes, and recombining; the same process yields the direction angle ϕ of the load line. (Figs. 12 and 17.)

Fig. 18 shows the variation of the friction coefficient (tangential resistance at journal surface ÷ load) with variation of l/w.

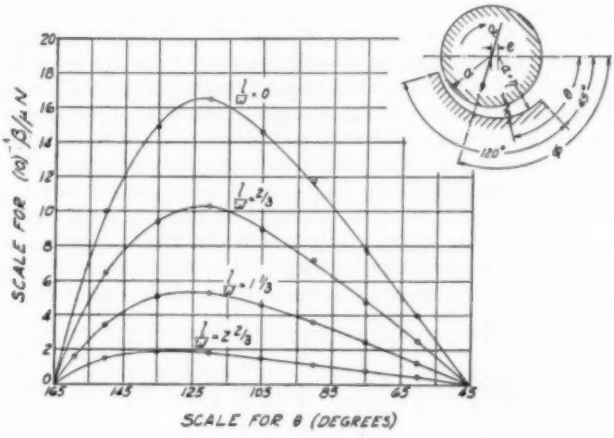

FIG. 15

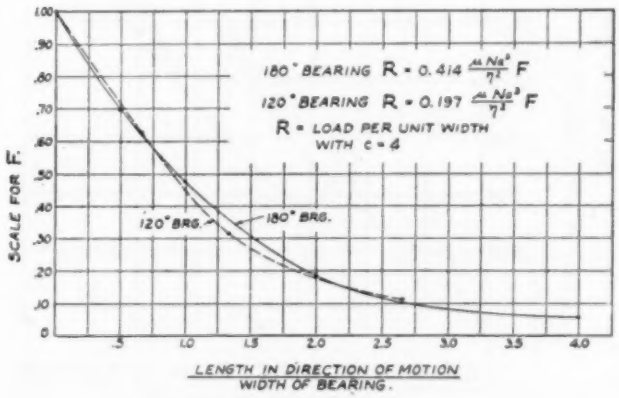

FIG. 16

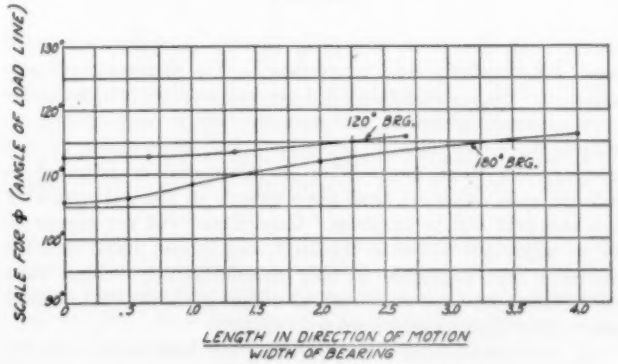

FIG. 17

XIII—120-DEG. BEARING. METHOD III

Fig. 15 shows the assumed arrangement of bearing and journal; the data are otherwise the same as for the 180-deg. bearing. Thus the oil film considered is a part of the same film treated in section XII; it extends from θ = 45° to θ = 165°. The experimental treatment is similar to that described for the 180-deg.

bearing. In Fig. 15, the curve for $l/w = 0$ is derived from the graphical work of Howarth; (11) the circled experimental points show close agreement with the graphical solution. For the remaining values of l/w, the curves are drawn through the experimental values. Fig. 16, 17, and 18 show further derived results, in connection with those for the 180-deg. bearing.

XIV—CONCLUDING REMARKS

The results of the tests of the method indicate a degree of accuracy sufficient for engineering purposes; the experimental results agree very nearly with the theoretical values in all cases where the latter are available, the greatest discrepancy being those shown in Fig. 5 and 5(*a*) where the test results average respectively, 2.2 per cent and 0.9 per cent higher than the values calculated by Michell.

It is probable that a greater degree of precision could be attained by the use of alternating current of high frequency, such as 1000 cycles per second, as used by Kohlrausch(6), and with a vibration galvanometer or a telephone receiver as a null indicator. In the tests described, pointer galvanometers were used, for simplicity and convenience. The direct-current galvanometer has no objectionable features; but the dynamometer-type alternating-current galvanometer, as is well known, is subject to errors due to inductance and capacitance in the circuits, and these must either be eliminated or adjusted to balance each other so that the currents in the galvanometer coil and field will be in phase. Capacitance did not appear to be an important factor in the tests, and it was found that inductance was negligible if only non-inductively wound voltmeters and ammeters were used, as well as in the indirect method where these instruments were not required.

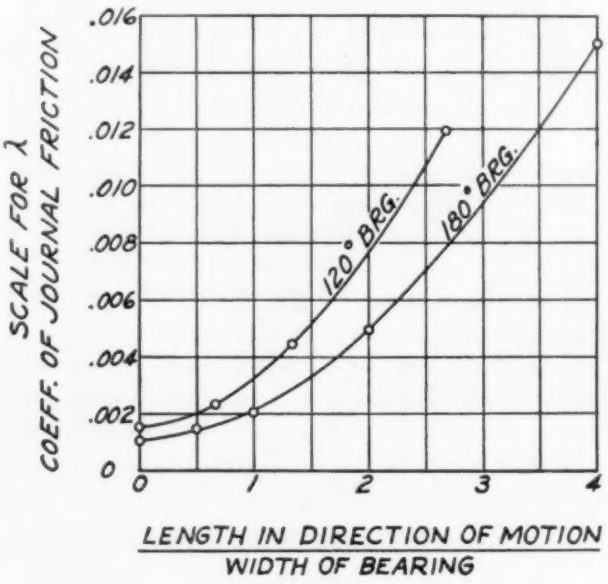

FIG. 18

All the experimental work described has been carried out by Mr. S. J. Needs, including the making of the special apparatus, taking observations, reduction of data, and preparation of the diagrams.

Discussion

A. G. M. MICHELL.[3] The author's experimental method of solving lubrication problems will be welcomed by all workers in the field, and the fullness of the explanations which he has given of its details will be gratefully appreciated.

The correspondence between the results of the experimental and theoretical methods in the cases which the author has published is gratifying, and it is therefore to be hoped that extended use will be made of the experimental method for the investigation of similar problems not amenable to theoretical treatment. By this means comparisons might be made, for instance, between the merits of thrust-bearing pads with various positions of the axis of tilt, and between journal bearings with wholly converging and with partially diverging films.

As the author points out, the experimental (as is also indeed the mathematical) method is based on the principle of additive volume displacements. The limitations of the principle, however, require to be recognized; for instance, in cases where the momentum of the fluid becomes of importance. For this reason it may be suggested that the momentum of the entering fluid is not adequately represented in the case treated in section X of the paper, by the mere addition of an entry pressure to the viscous equations of flow, but that it involves a change in the pattern of flow throughout the film, making it essentially three-dimensional; in other words, that the kinetic energy is possibly not so much transformed into pressure energy in the film as directly into intensified laminar motion and heat.

ADOLPH A. MOLINE.[4] With the present-day trend toward larger and higher-speed machines, the designer is confronted with many difficult problems, and one of the foremost is the bearings. He is searching continuously for methods to predict the operation of a bearing. The author has contributed a very interesting paper on this subject. There are many items, however, which cannot be considered by the author's method and which affect the bearing operation materially, such as changes in viscosity, thermal distortion of the bearing shell, probable misalignment, and finish of the bearing and journal surfaces.

It would be interesting to know the author's opinion as to the minimum oil-film thickness for slow-speed and for high-speed cylindrical bearings; also what he considers a good value for bearing clearance based on the bearing diameter.

Referring to Fig. 18, it would appear that a ratio of bearing length to bearing diameter of about unity would result in the lowest friction coefficient. No doubt, for safe operation, a slow-speed bearing should have a higher ratio of bearing length to diameter than a high-speed bearing, as the end leakage is greater on a short bearing than on a long bearing, which necessarily results in a thinner oil film. What does the author consider as the minimum ratio of bearing length to diameter?

H. A. S. Howarth.[5] The art of making fluid-film bearings has been very long in its development. It started no doubt when the first hot box occurred in the wheeled war chariot of some prehistoric king. Clay or fat may have been applied to cure the trouble. The bearing parts were surely of wood.

It has taken uncountable centuries to carry the art down to us, through the adoption of metal axles and bearings and the use of animal oils as lubricants until the high-speed machine age was reached.

It is not so long ago that Morin's friction coefficients were the sole dependence of machine designers. He would turn in his grave if he should hear of the low coefficients we encounter today.

Fluid-film bearings, with no metallic contact, were scarcely dreamed of until discovered accidentally by Tower in 1883. Physicist Reynolds was so intrigued by Tower's discovery that he set out to bring physical theory to bear upon the problem. In 1886 Reynolds presented to the small world about him the hydrodynamical analysis of bearing lubrication.

Reynolds' work was abstruse and few were interested. Because modern publicity did not come to its rescue it lay for half a generation buried in the Philosophical Transactions.

In the meantime Mr. Kingsbury, before graduation from Cornell in 1889, had acquired from Professor Thurston an interest in bearings that has followed him to this day. Mr. Kingsbury's most important early published work was that describing his experiments on the air-lubricated journal bearing, in the course of which he was led to several of the conclusions which Reynolds had reached by analytical mathematics.

Before the publication of his experiments Mr. Kingsbury learned of Reynolds' analysis and proceeded to study it thoroughly. He must have been gratified to see how closely each confirmed the other.

Thus fortified by his experimental and mathematical knowledge of the art, Mr. Kingsbury in 1898 made the first construction and tests of the thrust bearing that is now known by his name. But it was his other work in experimental engineering that led to his giving up his teaching of applied mechanics at Worcester in 1901 to devote his time to engineering for the Westinghouse companies.

Once embarked in the business world Mr. Kingsbury stayed therein, and since 1914 he has been concerned solely with the development of his thrust-bearing business. His interest in bearing problems has continued keen, and it was but natural that he should have been selected as chairman of the Lubrication Research Committee of this Society.

Recognizing the importance of the mathematical analysis of Reynolds, Mr. Kingsbury has continually urged engineers to master it. This has led to the further development of the art by others. But no amount of urging will give others the mental capacity to clear away the intricate problems which Reynolds himself had left unsolved.

Although much valuable work has been done by others since Reynolds' time, it has remained for Mr. Kingsbury himself to add the finishing touches to the analytical study of the lubricating film. He has now, figuratively speaking, placed the capitals on the columns, so that construction may now proceed upon a temple dedicated to fluid-film bearings.

L. J. Bradford.[6] The author has outlined an experimental method for determining the pressures existing in the oil film of a bearing and of evaluating the effect of each of the various factors which contribute to this pressure. He has shown that the values obtained by this method agree remarkably well with the theoretical values obtained by applying the equations of Reynolds and Michell to the cases dealt with. There is, however, one other step that should be taken before this method can be accepted with complete confidence. The agreement between the pressures actually developed in the oil film of a bearing and those predicted by the application of the hydrodynamic theory should be demonstrated.

Some years ago Mr. Kingsbury designed and built a machine for investigating the film pressures in a journal bearing $2^1/_2$ in. in diameter and 5 in. long. The essential parts of this machine were a cylindrical sleeve bearing without grooves, lubricated by oil supplied under pressure of 9 or 10 lb. per sq. in. supplied to one end of the bearing. Holes were drilled through the shell of this bearing and connected to pressure gages, thus permitting the pressure in the oil film at the point where the holes entered the bearing to be determined. By rotating the bearing, traverses covering the entire 360 deg. could be made.

Mr. Kingsbury generously loaned this machine to the Pennsylvania State College, and work with it has been going forward for the last two years. Fig. 19 shows a typical curve of pressure found at the center of the bearing, together with a theoretical curve plotted from Harrison's equation, using the theoretical eccentricity. It will be noted that the positive pressure begins on the "on" side at right angles to the direction of the load, and in this case extends for about 140 deg. in the direction of rotation, then drops to a negative pressure of a maximum of about 4 or 5 in. of mercury, then after about 10 deg. rises to a value of about atmospheric, and continues at that value for the remainder of the circumference.

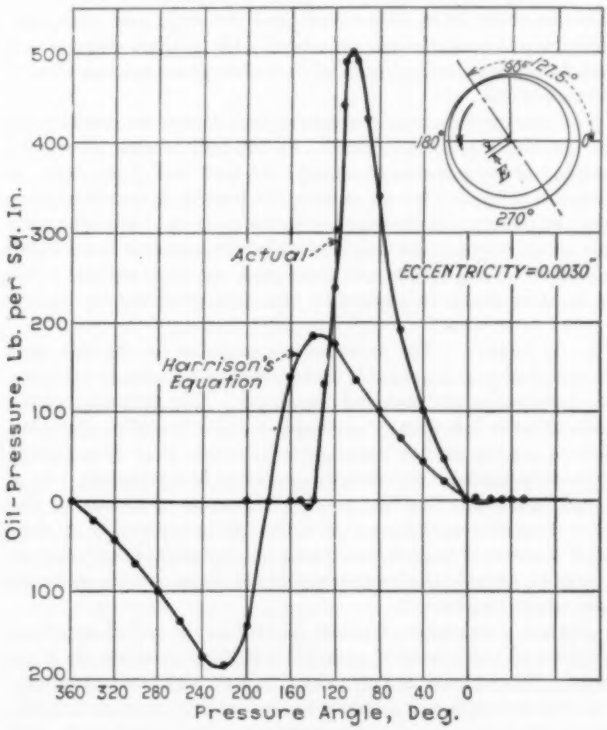

Fig. 19 Typical Curve of Pressure at Center of Bearing (Load = 200 lb. per sq. in. projected area; speed 500 r.p.m.; temperature, 107.5 deg. fahr.)

The pressure distribution actually found differs considerably from that predicted by the theory. This can be ascribed to four causes:

1 Zero absolute pressure is approximately 15 lb. per sq. in.

[5] Vice-President and General Manager, Kingsbury Machine Works, Philadelphia, Pa. Mem. A.S.M.E.

[6] Professor of Machine Design, Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

below atmospheric, and therefore the very low pressures called for by theory are impossible of attainment.

2 The oil is supplied at one end only, and is therefore non-symmetrical with respect to the bearing.

3 There is considerable in-leakage of air at the outlet end of the bearing in the region of negative pressures.

4 Oil carries a considerable quantity of air, both in solution and in suspension. This air is liberated at pressures below atmospheric and serves to break the vacuum that would otherwise be formed. This is shown by the pressure's attaining a negative value of 4 or 5 in. of mercury and then rising to about atmospheric after an interval of only about 10 deg.

All of these factors interrupt the continuity of the oil film, which is a condition essential to the theory.

An effort was made to stop the in-leakage of air by sealing the end of the bearing with a stuffing box so that the space between the journal and bearing would be submerged in oil. Observations made after this was done showed that the eccentricity was decreased about 10 per cent, the line of centers moved in the direction of rotation about 12 deg., the negative pressure's was raised to about 15 in. of mercury, and the angle over which the pressure was positive was increased. All of these changes are such as to bring the experimental curve into closer agreement with the theoretical.

The bearing has been redesigned with a view to profiting by the experience we have gained. In the new bearing oil will be supplied under pressure to a groove at each end of the bearing. This will be equivalent to running the bearing in an atmosphere equal in pressure to that carried in the grooves. We hope with this arrangement to be able to develop the negative loop, which is at present impossible, and thus bring the experimental curve much more nearly in agreement with that predicted by theory.

L. A. Terry.[7] The paper makes available for the first time an electrical analogy suitable for experimental studies of problems of considerable mathematical complexity. The generality of the method, since it is equally applicable to other branches of applied physics, as the author has suggested, makes it of considerable value to individuals not directly interested in lubrication. Thus it will be recalled that the problem of torsion of a shaft of circular cross-section and variable radius can be reduced to an electrical problem of finding the current and potential distribution in a strip of variable thickness much in the same manner as in the lubrication problem.

There are a number of points relative to the technique of application of the described experimental method which are of interest. The pressure at any point x_1, z_1 is obtained experimentally from the summation of pressure due to point (or, more accurately, small-volume) sources at chosen places in the model bath, with current corresponding to the volume flow in the oil film. It is therefore necessary to take a very large number of readings to obtain the pressure distribution for any model. It appears that a much more convenient method would be to cause currents to flow at all points at once in such a way as to fulfil the conditions of the right-hand side of Equation [5], and thereby permit a single set of observations to suffice for the complete determination of the pressure. The currents could be properly adjusted by having a large amount of resistance external to the bath so that any changes in the bath potential at various points during the adjustment of the proper current values would not appreciably affect the flow from an electrode. It would be appreciated if the author would indicate any additional complications this might involve.

Usually one desires to know the total load which can be carried by a bearing and the friction torque or loss. Therefore a very useful addition to the model would be apparatus which would make possible the direct observation of these two quantities.

The principle of superposition has been used freely throughout the paper, and the separate effects of the pressures due to centrifugal action and momentum have been discussed and shown to be, by themselves, negligible. In general, superposition must be used with a good deal of caution due to non-linear characteristics of the complete differential equation. In Section X of the paper, attention has been given to the effects of momentum of the fluid as a whole at a chamfer, in which case the method of superposition seems justifiable. However if the effect of the inertia forces inside the film itself at the chamfer is to be considered, then pressure variations in the y direction must be included in Equation [5], and it is also no longer linear. Likewise the complete equations defining the motion when variable viscosity is considered are non-linear. By considering these effects in a much different manner from that of the present paper, H. Brillié[8] has shown that the resulting forces are indeed far from negligible.

One of the most fundamental requirements for the study of lubrication by experimental models is the necessity of knowing the dimensions of the oil film. The bearing surfaces bounding the film are quite accurately known, within limits of course of manufacturing tolerances. But usually if the relative position of the surfaces is determined analytically, then one has, in more or less convenient form, the additional data required for obtaining the pressure. The relative position can be obtained from the experimental method of solution by trial and error, but may involve a large amount of experimentation. This appears to be a very serious limitation on the general applicability of the developed method of solution.

It is to be noted that the author has compared the results obtained from the experimental method with values calculated on the basis of the classical theory, and therefore not necessarily those obtained in actual bearings. The agreement shown in the paper between the two is noteworthy.

Robert O. Boswall.[9] The author's electrical method of dealing with fluid-film lubrication problems is of particular interest in view of the complicated mathematical and arithmetical processes required to obtain even approximate solutions when the effect of side leakage, viscosity changes, and other relevant phenomena are taken into account.

That the method is capable of giving accurate results is obvious from the close comparison it gives the Michell's data, but the writer regrets that the position adopted for the axis of tilt in the case of the sector-shaped pads does not enable a direct comparison to be drawn between the results obtained by the electrical method and those obtained by mathematical processes and given in his book.

The author's apparatus should be of special use in connection with journal bearings which do not readily lend themselves to mathematical treatment on account of additional complications resulting from surface curvature.

In Fig. 12, which refers to pressure conditions for a bearing subtending an arc of 180 deg., the line of centers is shown in a horizontal position, and the direction of the resultant film pressure obviously points to the necessity of eccentric loading. It would be interesting to know how decrease in viscosity would affect the pressure conditions and whether such a bearing could

[7] A.-C. Engineering Department, General Electric Company, Schenectady, N. Y.

[9] College of Technology, Manchester, England.

be centrally loaded, i.e., whether the effect of reasonable changes in the viscosity would enable the line of action of the resultant film pressure to pass through the geometrical center of the brass. There is another point—how does the line of centers get into the horizontal position shown?

When the journal is at rest, the line of centers will be coincident with the line of action of the load, and it is presumed that as the journal commences to rotate and the speed increases, the line of centers will swing round until it assumes a position such as that indicated in Fig. 12.

This point is mentioned as the writer has always experienced difficulty in obtaining perfect film conditions with journal bearings having arcs exceeding about 120 deg., and he has been under the impression that this difficulty can be attributed to the fact that in the early stages of the motion, when the line of centers will only have swung round through a small angle, a relatively large extent of film at the outlet end will be divergent. This leads to the production of negative pressures which reduce the effective length of the film and interfere with the proper motion of the line of centers.

With an arc of 120 deg. this divergence will not be so extensive, and the formation of negative pressures is not likely to have such a serious effect.

With the apparatus described it should be possible not only to determine the motion of the journal center for both central and eccentric loading conditions, but also to ascertain the extent of the negative pressures produced at each stage of the motion. It might be assumed that the viscosity was halved as the lubricant passed between the surfaces, and it would be necessary, of course, to use, say, three eccentricity positions for each position of the line of centers, and then interpolate to obtain the same position for the resultant film pressure in each case.

It must be borne in mind that the apparatus will presumably indicate negative pressures in excess of those actually possible in practice and that there such conditions are indicated the continuity of the film may be expected to break down.

The momentum effect discussed in section X may possibly be of importance as the author suggests, but it would be interesting to know why this should be regarded as a jet effect since at first sight it would appear to be rather a question of viscous flow along a channel with the bearing block as an obstruction and the film opening as a narrow orifice.

In conclusion, the writer would like to take this opportunity of congratulating the author for a very valuable and interesting paper which should do much to stimulate interest in this important and difficult branch of engineering science.

M. Stone.[10] The subject of this paper is one of considerable interest to the engineering profession, and possibly of particular interest to the writer. This latter is because of his active engagement in the application and operation of the author's bearings and because the type of solution that he has resorted to duplicates the solution of a parallel problem[11] that the writer has worked with in the past—the torsion of prismatical bars.

The present high-pressure thrust bearing had its origin in America and Europe practically simultaneously—by the author here and by Mr. Michell abroad. Whereas the author came upon the idea from a physical or experimental point of view (the writer thinks this is true), Michell arrived at the same conclusion from an entirely mathematical approach. By solving the flow and pressure distribution over a rectangular plate, under certain idealized, simple boundary assumptions, Michell came accurately upon the idea of a pivoted surface that is allowed to assume the position of least friction.

However, as the bearing has been finally evolved, Michell's solution is not accurate enough to determine pressure, temperature, and flow distributions, although it did point the way quite definitely to the ideal type of bearing. The indefinite conditions of viscosity and temperature, side leakage, influx and efflux of oil, segmental shape of the present bearing shoe, and the like are obstacles in the way of a purely analytical solution. However, as far as the purely mathematical difficulties are concerned, the author's solution can be said to be satisfactory, but there still remains the indefiniteness of certain boundary conditions which vitiate his solution as well as the purely mathematical one. However, with certain assumed conditions, the author, Mr. Kingsbury, is able to obtain solutions that present insurmountable mathematical difficulties.

Even analytically, it was shown by Michell that the ideal location of the pivot was at the center of pressure of the bearing segment as determined for its optimum position (see Fig. 8, for instance). However, due to practical considerations, which mainly revolve about the hydrodynamical conditions at the leading edge, and are influenced very much by the form of the bevel or rounding of the edge, the center of pressure may actually be located behind the symmetry axis of the segment, instead of ahead. (This is shown in Figs. 8 and 10.) So that, practically, one does not know exactly where to place the pivot, i.e., from the analysis alone. However, for purposes of using a segment in bearings that may operate in either direction, we have always located the pivot on the symmetry axis, practically at the center of gravity of the plate. Tests that have been made here and in Europe do not reveal any change of bearing efficiency by such a change; in fact, it is quite conceivable that such a position is better than the theoretical one for many conditions of operation.

One of the most important problems that still remains unsatisfactory in the operation of these thrust bearings concerns the prediction of bearing temperatures. This involves an accurate knowledge of how and where the heat is generated over the bearing surface, the effect of equalization of temperature through heat conduction in the shoe itself, and dissipation of heat through the coolers, by conduction, etc. At present, the Westinghouse Company is conducting a series of experiments on several field installations of such thrust bearings for large waterwheel generators, and also in the testing department, with the solution of this problem in view. The best idea of heat generation must follow from such a solution as Mr. Kingsbury has carried out.

Concerning the solution itself, when the hydrodynamic differential equation:

$$\frac{d}{dx}\left(\frac{h^3}{12\mu}\frac{dp}{dx}\right) + \frac{d}{dz}\left(\frac{h^3}{12\mu}\frac{dp}{dz}\right) = \frac{U_0 - U_1}{2}\frac{dh}{dx} + V_1 \quad [23]$$

is analyzed physically for a given position of the pressure plate, we obtain a modified Poisson's partial differential equation with a variable right-hand number:

$$\frac{\partial}{\partial x}\left(f_1\frac{\partial \phi}{\partial x}\right) + \frac{\partial}{\partial z}\left(f_1\frac{\partial \phi}{\partial z}\right) = f_2(x,z) \quad [24]$$

where

$\phi(x,z)$ = scalar potential function
$f_1(x,z)$ = variable-flow resistance
$f_2(x,z)$ = strength of sources or sinks.

The left-hand side of the equation is really the divergence of the flow. The right-hand side represents the density distribution of sources or sinks of the flow medium.

[10] Mechanical Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; at present on special investigations in Europe.

[11] "The General Torsion Problem, Solution by Electric Flow Analogy," M. Stone. Third International Congress of Applied Mechanics, Stockholm, August, 1930.

Electrically this means that flow takes place in a two-dimensional plate of geometrical contour similar to the bearing segment, and with variable conductivity, obtained by varying the thickness of the plate. The right-hand side of the equation represents the current density supplied or taken away from the plate. The next important conditions to impose are the boundary conditions, where electric potential is the analogue of pressure. The problem is simple where the function ϕ is zero, but in the case of the effects of oil at the entrance, the boundary pressure must be assumed before the problem becomes soluble.

This same type of problem has been treated in exactly the same way as the author has done, in the previously-referred-to article. For the case of torsion, the general equation can be written:

$$\frac{\partial^2 P}{\partial x^2} + \frac{\partial^2 P}{\partial y^2} = \nabla^2 P = -2cG \quad [25]$$

In the same sense, the left-hand side is the divergence, and $-2cG$ is the flow-intensity distribution. The boundary conditions are P = constant. This equation can be solved directly, in the same manner as Mr. Kingsbury has done, but there always is the necessity of having to supply current at distinct points, which leads to inaccuracy. Equation [25] was thus transferred to an equation of this type:

$$\frac{\partial}{\partial x}\left(f_1 \frac{\partial \phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(f_1 \frac{\partial \phi}{\partial y}\right) = 0 \quad [26]$$

This allows a solution of the problem *without* the necessity of supplying current as Mr. Kingsbury has done. This presents a much simpler and experimentally more desirable procedure. As far as the experimental procedure is concerned, the writer agrees that the electric flow through an electrolyte method (using a.c., however) is probably the easiest and most accurate. A very comprehensive treatment, however, is given of practically all such methods known, by B. Hague,[12] which article should be consulted by any one interested in carrying out such solutions.

Author's Closure

The suggestion is made by Mr. Michell and by Mr. Terry that there may be appreciable pressure and flow effects from accelerations *within the film*. We have at this time neither an adequate theoretical treatment of this question nor any direct experimental data; but approximate calculations indicate that even at the highest speeds occurring in practice, the pressure effects due to accelerations within the film are negligible for practical purposes. The only case thus far solved is that of radial acceleration in thrust bearings, for which an approximate treatment is given in Section IX. The results there given may be reduced to the following formula, applicable to films of any size geometrically similar to Fig. 6, independent of the film thickness and of the viscosity:

$$-p = 1.64 \times 10^{-4} v^2 \text{ (approx.)}$$

in which $-p$ is the mean centrifugal pressure in pounds per square inch, and v is the rim speed in feet per second. Taking v as 200 ft. per sec., $-p$ is 6.6 lb. per sq. in. The mean working pressure for such a bearing would be about 500 lb. per sq. in.; thus it would be affected but 1.3 per cent by the centrifugal action in this case of very great speed. All other internal accelerations appear to be of relatively less effect, as far as can be estimated by approximate calculation. It therefore seems that a fair approximation is obtained by taking the internal pressure effects of local boundary pressures as directly additive, as was done in Section X.

Mr. Moline refers to the vexatious facts that viscosity changes with temperature, and bearing parts are distorted by heat and by pressure. The methods given in the paper are nevertheless applicable, requiring only that the models be made to conform to any assumed conditions, however bad they may be; the main difficulty lies in the infinite variety of conditions, both bad and good.

A categorical statement regarding permissible film thicknesses is not possible. Bearings under test, with great unit pressure and very high speed, may operate satisfactorily with a film thickness which no reasonable estimate would make as great as 10^{-4} in.; but this is far removed from the limitations imposed by the wear that occurs when starting and stopping under load, and by the presence of solid particles in the oil. The current practice of basing bearing areas and loads upon unit pressures is the readiest method of recognizing these latter limitations. In thrust-bearing practice approximate calculations from loads, speeds, and friction indicate minimum film thicknesses ranging from 0.0008 in. to 0.002 in., the smaller value being for low speed and high pressure, the larger value for very high speed and moderate pressure. There is very little exact information on film thicknesses in journal bearings in practice, and on film forms and friction losses from which the thickness might be deduced by calculation.

Theoretical considerations of journal bearings, including side leakage, indicate that if the width of the bearing be fixed at any value not exceeding one and one-half diameters, the bearing-arc length should be approximately equal to the width, for a minimum of power loss by friction; but if the arc length be fixed there is no limit for the increase of the width except that imposed by distortion of the bearing parts by heat and pressure, however this distortion may be assumed to necessitate increasing the minimum film thickness.

Professor Bradford's diagram shows an effective film of only 140 deg. in the complete bearing; this is similar to the condition described by Mr. Boswall as regards the incidence of zero or negative pressures, and other experimenters have found like results. Professor Bradford's further experimental results will be awaited with interest; but the Harrison curve could be approximated experimentally only by absolutely tight sealing of the sides of the film, with an oil supply at not less than atmospheric pressure at the minimum-pressure point.

Negative pressures depend in large part upon the side leakage and the eccentricity ratio. If the minimum film thickness is small compared with the radial clearance, the effective film occupies but a small angle, and the pressure falls to zero at a short distance beyond the point of nearest approach. The conditions shown in Fig. 12 do require unsymmetrical loading, as noted by Mr. Boswall; for an assumed uniform viscosity, the load line cuts the brass about 16 deg. beyond the center, if the width of the bearing is great; reducing the width increases this divergence, as shown in Fig. 17; but on the other hand, increase of temperature of the oil as it passes through has the opposite effect. Practically nothing is known as to temperature range in the film; one cannot be assured that the film temperature is given by the temperature of the metal near the surface. The load would be nearly central in Fig. 12 if we could, for example, assume that the viscosity varied as the cube of the film thickness, but this would imply a viscosity change of 12.6 to 1 in the film, which is far beyond credibility. The conditions in Fig. 12 are substantially those required for a minimum coefficient of friction with a given minimum film thickness; if the load be made central, the minimum film thickness being the same, the load must be reduced about 10 per cent, while at the same time the power

[12] B. Hague, "Experimental Methods of Determining the Distribution of Electric and Magnetic Fields," *Electrician*, Feb., 1929.

loss increases about 12 per cent, and negative pressure is probable near the off-end of the brass. If with central load the minimum film thickness be still further reduced, the negative pressure area extends. This may account in principle for the facts noted by Mr. Boswall, it being inferred that he was working with central loads.

APM-53-6

Stresses in Retaining and Centering Rings for Turbine-Generator Rotors

By R. PATTERSON[1] and D. H. HARMS[2]

In this paper the authors deal theoretically with the distribution of stresses throughout the system of parts enclosing the rotor coil ends of a turbine generator.

This system of parts consists of a disk of uniform cross-section, a cylinder, and a part of the shaft. These parts are fastened together by means of fairly heavy shrink fits and therefore, in the development of formulas for the stresses, the effect of this shrinkage, as well as that of rotation, must be considered.

Since these parts must remain integral for the design considered, the importance of being able to predetermine the speeds at which the various parts may become free is apparent. Therefore formulas were developed for these speeds subject to the boundary conditions which were set up.

An example is given for which the distribution of stresses for two cases is plotted. These two cases are, respectively, for the generator at standstill and at operating speed.

A summary of the significant results is given at the beginning, and a discussion of the main points of interest at the close of the paper.

DESIGNERS of turbine generators are constantly confronted with the demand for increased output and consequently larger units. This increase in size necessarily calls for a more complete analysis of the mechanical problems involved. A great deal of progress has been made in this direction, but a number of features still remain under discussion. One of these, for which the authors will endeavor to develop a solution in the present paper, is that of the distribution of stresses in the rings enclosing the rotor-coil ends and that portion of the shaft beneath the centering ring. In addition to the stresses, it is also important to be able to predetermine the speeds at which the various members of the system become loose from each other.

R. Patterson

D. H. Harms

There are several designs for holding in place the rotor-coil ends of turbine generators, each of which has its advocates and all of which apparently perform satisfactorily. It is not the authors' intention to discuss in the present paper the merits of the various designs, the only one which they analyze being shown in Fig. 1.

The rings referred to are the centering ring and the retaining ring. The centering ring is shrunk on the shaft beyond the rotor coils and provides a fit for one end of the retaining ring, which in turn must carry the centrifugal force of the coil ends when the generator is in operation.

In order to obtain a practical solution for this problem the retaining and centering rings and that portion of the shaft which encloses the coil ends must be considered as a system of parts dependent upon each other rather than as individual parts. Since these parts are fastened together by shrinkage, the solution must have regard to the combination of stresses due to shrinkage and rotation.

Centrifugal forces of the order of 12,000,000 lb. are common values for the retaining-ring and coil ends. These tremendous forces alone, not considering the heavy shrink fits, necessitate high working stresses, and therefore, in order to be assured of adequate factors of safety for known materials, we must know more accurately than ever the stress distribution.

The authors believe, without wishing to raise any controversy, that this is the first time a complete analysis of the problem as set forth has been published, and also that it is one of considerable practical importance to the designers of turbine generators.

Summary of Significant Results

Referring to Fig. 1, the tangential stress in the retaining ring has its maximum value at the fit between the retaining and centering rings.

A change in the thickness of the centering ring does not materially alter this stress.

It is also apparent from the graphs given later that the fatigue range is small.

The bending stress in the retaining ring reaches an appreciable value at zero speed, while the shearing stresses are very small.

With a heavy shrink fit the retaining ring at zero speed may contract to a smaller diameter for approximately one-half its length from the free end than it had in the unstressed state.

The tangential stress in the centering ring is a maximum at the fit between the centering ring and shaft, and this maximum occurs at the operating speed.

The predominating stresses are tangential, with the exception,

[1] Mr. Patterson was born in Rensselaer, N. Y., Aug. 8, 1896. He entered the blueprint department of the General Electric Co. as an apprentice draftsman in 1916. Enlisting in the United States Navy in 1917 he served in the aviation branch for the duration of the war. He returned to the General Electric Co. and was employed in the drafting section of the turbine-engineering department; at present is in charge of mechanical calculation pertaining to turbine-generator design.

[2] Mr. Harms was born in Aachen, Germany, Dec. 29, 1897. After serving in the German Navy during the World War he was graduated, receiving an E.E. degree from an institute of technology in 1921. He entered the testing department of the General Electric Co., Dec. 1, 1925. From Sept. 26, 1927, to May 31, 1930, he was employed in the turbine-generator engineering department, after which he left the General Electric Co. to return to Germany. He was employed by the Bergmann Co. in Germany and at present is working in Russia.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

perhaps, of the radial compression stress in the centering ring, due to shrinkage alone.

The stresses in the shaft at its joint with the centering ring are small, at the operating speed, but the tangential stress at the bore for zero speed may reach an appreciable value.

The following assumptions will be made in order to avoid complications in the solution:

1 The retaining and centering rings are of uniform cross-section
2 The centrifugal force due to the coil ends is uniformly distributed over the retaining ring in the axial as well as in the peripheral direction
3 The length of the shaft has no effect upon the deformation due to shrinkage
4 The axial stresses in the centering ring and the radial stresses in the retaining ring are negligible
5 No force can be transmitted between the parts of the coils resting in the rotor slots and those lying underneath the retaining ring.

Considering first the shaft and centering ring, let u be the

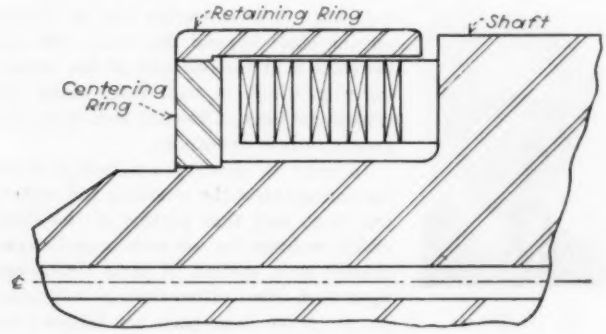

FIG. 1

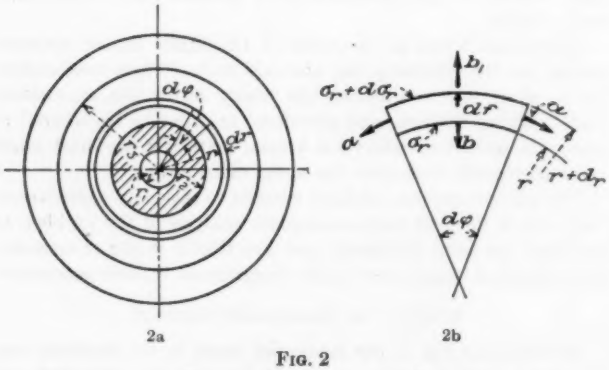

FIG. 2

radial displacement of a point r distant from the center, so that r becomes $r + u$.

The radial elongation is then

$$\epsilon_r = \frac{du}{dr} \quad [1]$$

and the tangential elongation becomes:

$$\epsilon_t = \frac{u}{r} \quad [2]$$

The radial displacement u is to be considered positive if the original radius is increased. We shall furthermore call all forces positive which tend to increase the original radius.

The relation between stress and strain from the theory of elasticity can be written as follows:

$$\epsilon_r = \frac{1}{E}\left(\sigma_r - \frac{1}{m}\sigma_t\right) \quad [3]$$

and

$$\epsilon_t = \frac{1}{E}\left(\sigma_t - \frac{1}{m}\sigma_r\right) \quad [4]$$

where σ_r and σ_t are the radial and tangential stresses, respectively, $1/m$ is Poisson's ratio, and E denotes the modulus of elasticity.

Since all the force shown in Fig. 2 (b) must be in equilibrium, we can write the following equation:

$$b_1 - b + df = ad\varphi \quad [5]$$

where

$$b_1 = (\sigma_r + d\sigma_r)(r + dr)d\varphi \quad [6]$$

$$b = \sigma_r r d\varphi \quad [7]$$

$$a = \sigma_t dr \quad [8]$$

and

$$df = rd\varphi dr \frac{\gamma}{g}\frac{(2\pi rN)^2}{3600r} \quad [9]$$

In Equation [9] γ represents the weight of the material per unit volume, g is the intensity of the earth's field, and N the number of revolutions per minute.

Substituting Equations [6]–[9] in Equation [5] and remembering that $drd\varphi$ is negligible (being a differential of the second order), we obtain:

$$\sigma_r dr d\varphi + d\sigma_r r d\varphi + r^2 \frac{\gamma 4\pi^2 N^2}{3600g} dr d\varphi = \sigma_t dr d\varphi \quad [10]$$

From [3] and [4] we obtain directly:

$$\sigma_r = \frac{mE}{(m^2-1)}(m\epsilon_r + \epsilon_t) \quad [11]$$

and

$$\sigma_t = \frac{mE}{(m^2-1)}(m\epsilon_t + \epsilon_r) \quad [12]$$

Substituting the values for ϵ_r and ϵ_t from Equations [1] and [2] in [11] and [12] gives:

$$\sigma_r = \frac{mE}{(m^2-1)}\left(m\frac{du}{dr} + \frac{u}{r}\right) \quad [13]$$

and

$$\sigma_t = \frac{mE}{(m^2-1)}\left(m\frac{u}{r} + \frac{du}{dr}\right) \quad [14]$$

Differentiating Equation [13],

$$d\sigma_r = \frac{mE}{(m^2-1)}\left(m\frac{d^2u}{dr} + \frac{rdu - udr}{r^2}\right) \quad [15]$$

Calling

$$\frac{\gamma 4\pi^2 N^2}{3600g} \cdot \frac{(m^2-1)}{m^2 E} = q \quad [15a]$$

then, by substituting Equations [13], [14], and [15] in [10], the following differential equation is obtained:

$$r^2\frac{d^2u}{dr^2} + r\frac{du}{dr} - u = -qr^3 \quad [16]$$

the solution of which is

$$u = Ar + \frac{B}{r} - q\frac{r^3}{8} \quad \ldots\ldots\ldots\ldots\ldots [17]$$

This equation gives the elongation in terms of the radius, and calling u_1 and u_2 the elongations of the shaft and centering ring, respectively, we have

$$u_1 = A_1 r + \frac{B_1}{r} - q\frac{r^3}{8} \quad \ldots\ldots\ldots\ldots\ldots [18]$$

and

$$u_2 = A_2 r + \frac{B_2}{r} - q\frac{r^3}{8} \quad \ldots\ldots\ldots\ldots\ldots [19]$$

In the equations that follow, the subscript 1 will always refer to the shaft, 2 to the centering ring, and 3 to the retaining ring.

We shall now investigate the stresses in the retaining ring, a cross-section of which is shown in Fig. 3. Since the difference

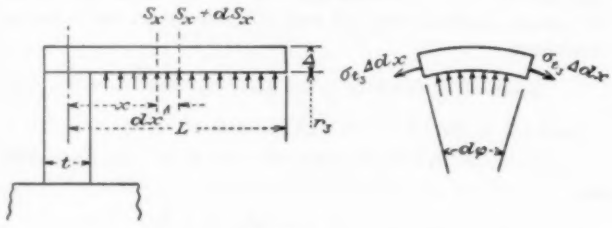

FIG. 3

between the outer and inner radius of this ring is small, we can consider it as a thin ring.

Considering the forces on a ring element $\Delta r_3 d\varphi dx$, we have at the distance x a shearing force S_x and at the distance $x + dx$ the shearing force $S_x + dS_x$. These forces act in the radial direction. In the tangential direction there is a force of $\sigma_{t3} \Delta dx$ acting on both surfaces. The resultant of these two forces is $\Delta\sigma_{t3} d\varphi dx$ acting in the radial direction. Calling the centrifugal force per unit volume due to the ring and its coil load P, we have one more radial force, which is $P \Delta r_3 d\varphi dx$. P is approximately given by the following relation:

$$P = \frac{(W_r + W_c)}{2\pi r_3 L \Delta g} \cdot \frac{4\pi^2 r_3^2 N^2}{3600\, r_3} = \frac{(W_r + W_c)}{L \Delta g} \pi \frac{N^2}{1800} \ldots [20]$$

where W_r = total weight of the retaining ring, lb.
W_c = total weight of the coil load, lb.
L = length of the retaining ring, inches
Δ = thickness of the retaining ring, inches
N = revolutions per minute
g = gravitation constant, inch $\times$ sec.$^{-2}$

Since all the forces on the ring element must be in equilibrium against translational motion, the following equation holds:

$$S_{x+dx} - S_x + P \Delta r_3 d\varphi dx - \sigma_{t3} \Delta d\varphi dx = 0 \ldots\ldots [21]$$

or

$$\frac{dS_x}{dx} + P \Delta r_3 d\varphi - \sigma_{t3} \Delta d\varphi = 0 \ldots\ldots\ldots\ldots [22]$$

Another condition of equilibrium is that the moments on the ring element must vanish. Referring to Fig. 3 and calling counterclockwise moments positive, we obtain, by taking moments about point x,

$$S_{(x+dx)}\, dx + M_{(x+dx)} - M_x + P \Delta r_3 d\varphi \frac{(dx)^2}{2} - \Delta\sigma_{t3} d\varphi \frac{(dx)^2}{2} = 0 \ldots\ldots [23]$$

Neglecting differentials of a higher order, [23] may be reduced to

$$S_x = -\frac{dM_x}{dx} \quad \ldots\ldots\ldots\ldots\ldots\ldots [24]$$

Differentiating [24] and substituting it in [22] gives

$$\frac{d^2 M_x}{dx^2} = P \Delta r_3 d\varphi - \sigma_{t3} \Delta d\varphi \ldots\ldots\ldots\ldots [25]$$

We may now express the value of $\frac{d^2 M_x}{dx^2}$ by the following equation:

$$\frac{d^2 M_x}{dx^2} = \frac{E}{\left(1 - \frac{1}{m^2}\right)} I \frac{d^4 u_3}{dx^4} \quad \ldots\ldots\ldots\ldots [26]$$

It is necessary to use $\frac{E}{1 - \frac{1}{m^2}}$ instead of E because no lateral extension or contraction of the ring element under consideration is possible. The value of I for the ring element becomes

$$I = \frac{\Delta^3 r_3 d\varphi}{12} \quad \ldots\ldots\ldots\ldots\ldots [27]$$

We can also express σ_{t3} in Equation [25] in terms of the elongation u_3:

$$\sigma_{t3} = u_3 \frac{E}{r_3} \quad \ldots\ldots\ldots\ldots\ldots [28]$$

Substituting Equations [26], [27], and [28] in [25], we obtain the differential equation of the retaining ring in the following form:

$$\frac{d^4 u_3}{dx^4} = -u \frac{\left(1 - \frac{1}{m^2}\right) 12}{\Delta^2 r_3^2} + \frac{12}{\Delta^2 r_3^2}\left(1 - \frac{1}{m^2}\right) u_{30} \ldots [29]$$

where u_{30} represents the elongation the retaining ring would have if it were rotating freely at N revolutions per minute. The actual value of this elongation is:

$$u_{30} = \frac{P r_3^2}{E} \quad \ldots\ldots\ldots\ldots\ldots [30]$$

The solution of Equation [29] is:

$$u_3 = \beta_1 \cos \lambda x \cosh \lambda x + \beta_2 \sin \lambda x \sinh \lambda x + \beta_3 \cos \lambda x \sinh \lambda x + \beta_4 \sin \lambda x \cosh \lambda x + u_{30} \ldots [31]$$

λ is determined from the equation:

$$\lambda = \frac{\sqrt[4]{3\left(1 - \frac{1}{m^2}\right)}}{\sqrt{\Delta r_3}} \quad \ldots\ldots\ldots\ldots [32]$$

β_1, β_2, β_3, and β_4 are constants of integration to be determined from the boundary conditions. That [31] is a correct solution of [29] may easily be verified by carrying out the differentiations indicated in [29].

Boundary Conditions

Thus far we have derived the differential equations for the extensions of the shaft, centering-ring and retaining-ring radii. We shall now consider the boundary conditions which have to be imposed upon these equations in order to determine the

constants. Altogether we must have eight conditions, since there are eight constants to be evaluated.

Consider first the boundary conditions of the retaining ring. It is necessary that the moment as well as the shear force must vanish at $x = L$. This condition gives the two equations:

$$\frac{d^2u_3}{dx^2_{(x=L)}} = \frac{d^3u_3}{dx^3_{(x=L)}} = 0 \quad [33]$$

Another condition is that the bending moment at $x = 0$ has to vanish. In actual practice this is not true since the finite width of the centering ring causes a small moment at this point. With our assumptions, however, we may write

$$\frac{d^2u_3}{dx^2_{(x=0)}} = 0 \quad [34]$$

A fourth condition to be fulfilled is that the reaction at the end of the retaining ring has to be equal to the radial pressure

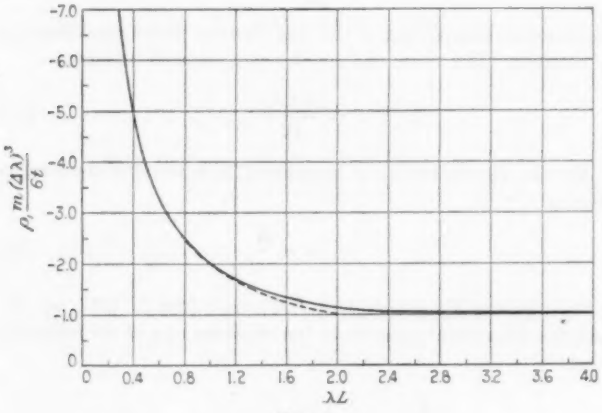

FIG. 4

on the outer periphery of the centering ring. The reaction of a retaining-ring segment of the peripheral length $r_3 d\varphi$ is:

$$S_{(x=0)} = -\frac{E\,\Delta^3 r_3 d\varphi}{12\left(1-\frac{1}{m^2}\right)} \cdot \frac{d^3u_3}{dx^3} \quad [35]$$

Since we have defined a shearing force as positive if acting upward, and a radial stress as negative when compressive, we must have:

$$S_{(x=0)} = \sigma_{r2\,(r=r_3)}\, t r_3 d\varphi \quad [36]$$

By equating [35] with [36],

$$\frac{d^3u_3}{dx^3_{(x=0)}} = -\sigma_{r2\,(r=r_3)} \frac{12\,t\left(1-\frac{1}{m^2}\right)}{E\,\Delta^3} \quad [37]$$

The fifth condition is that the algebraic sum of the extensions of the retaining ring and centering ring at the junction have to be equal to the shrink allowance. The same is true for the centering ring and shaft, giving us the sixth condition. Calling the allowances based on the radii δ_2 and δ_1, respectively, we get the following equations:

$$u_{3\,(x=0)\,(r=r_3)} - u_{2\,(r=r_3)} = \delta_2 \quad [38]$$

and

$$u_{2\,(r=r_3)} - u_{1\,(r=r_3)} = \delta_1 \quad [39]$$

The seventh condition is that the radial stresses of the centering ring and shaft have to be equal to each other at $r = r_3$. Expressing this by an equation,

$$\sigma_{r2\,(r=r_3)} = \sigma_{r1\,(r=r_3)} \quad [40]$$

As the last condition we can state that the radial stress at the bore of the shaft has to vanish. Hence

$$\sigma_{r1\,(r=r_1)} = 0 \quad [41]$$

We have thus stated the eight conditions which are necessary and sufficient for determining the eight constants of integration.

Differentiating [31] twice as indicated by [33], we immediately find that $\beta_2 = 0$. Likewise carrying out the triple differentiation as also indicated in [33] and [37], we obtain the following equations:

$$\beta_1 \tan \lambda L \tanh \lambda L + \beta_3 \tan \lambda L - \beta_4 \tanh \lambda L = 0 \quad [42]$$

$$\beta_1 [\tanh \lambda L + \tan \lambda L] + \beta_3 [\tan \lambda L \tanh \lambda L + 1] + \beta_4 [\tan \lambda L \tanh \lambda L - 1] = 0 \quad [43]$$

and

$$\beta_4 - \beta_3 = \frac{-\sigma_{r2}\, 6t\left(1-\frac{1}{m^2}\right)}{E(\Delta\lambda)_3} \quad [44]$$

Treating these equations simultaneously we obtain:

$$\beta_1 = \sigma_{r2} \frac{6t\left(1-\frac{1}{m^2}\right)}{E(\Delta\lambda)^3} \left[\frac{\sinh 2\lambda L - \sin 2\lambda L}{2 - [\cos 2\lambda L + \cosh 2\lambda L]}\right] \quad [45]$$

$$\beta_3 = -\sigma_{r2} \frac{6t\left(1-\frac{1}{m^2}\right)}{E(\Delta\lambda)^3} \left[\frac{\sinh^2 \lambda L}{\sin^2 \lambda L - \sinh^2 \lambda L}\right] \quad [46]$$

and

$$\beta_4 = -\sigma_{r2} \frac{6t\left(1-\frac{1}{m^2}\right)}{E(\Delta\lambda)^3} \left[\frac{\sin^2 \lambda L}{\sin^2 \lambda L - \sinh^2 \lambda L}\right] \quad [47]$$

Now call

$$\frac{6t}{m(\Delta\lambda)^3}\left[\frac{\sinh 2\lambda L - \sin 2\lambda L}{2 - [\cos 2\lambda L + \cosh 2\lambda L]}\right] = \rho_1$$

or

$$\rho_1 \frac{m(\Delta\lambda)^3}{6t} = \left[\frac{\sinh 2\lambda L - \sin 2\lambda L}{2 - [\cos 2\lambda L + \cosh 2\lambda L]}\right] \quad [48]$$

Equation [48] is plotted on Fig. 4, and we find that for large values of (λL) the trigonometric functions and the constant value 2 may be neglected as compared with the hyperbolic functions, giving

$$\rho_1 \frac{m(\Delta\lambda)^3}{6t} = -1 \text{ (for } \lambda L > 2.2) \quad [48a]$$

For small values we may develop all the functions contained in the foregoing expression into a series, and by neglecting the higher powers obtain the following:

$$\rho_1 \frac{m(\Delta\lambda)^3}{6t} = -\frac{2}{\lambda L} \text{ (for } \lambda L < 1.5)$$

Also call

$$\frac{6t}{m(\Delta\lambda)^3}\left[\frac{\sinh^2 \lambda L}{\sin^2 \lambda L - \sinh^2 \lambda L}\right] = \rho_3$$

or

$$\rho_3 \frac{m(\Delta\lambda)^3}{6t} = \frac{\sinh^2 \lambda L}{\sin^2 \lambda L - \sinh^2 \lambda L} \quad \ldots\ldots\ldots [49]$$

This equation is plotted on Fig. 5, and we find for large and small values of λL, respectively, the following values:

$$\rho_3 \frac{m(\Delta\lambda)^3}{6t} = -1 \text{ (for } \lambda L > 2.2)$$

$$\rho_3 \frac{m(\Delta\lambda)^3}{6t} = -\frac{1.5}{(\lambda L)^2} \text{ (for } \lambda L < 1.5)$$

Likewise call

$$\frac{6t}{m(\Delta\lambda)^3}\left[\frac{\sin^2 \lambda L}{\sin^2 \lambda L - \sinh^2 \lambda L}\right] = \rho_4$$

or

$$\rho_4 \frac{m(\Delta\lambda)^3}{6t} = \frac{\sin^2 \lambda L}{\sin^2 \lambda L - \sinh^2 \lambda L} \quad \ldots\ldots\ldots [50]$$

Equation [50] is plotted on Fig. 6, and we find for large and small values of λL, respectively, the following values:

$$\rho_4 \frac{m(\Delta\lambda)^3}{6t} = 0 \text{ (for } \lambda L > 2.2)$$

$$\rho_4 \frac{m(\Delta\lambda)^3}{6t} = -\frac{1.5}{(\lambda L)^2} \text{ (for } \lambda L < 1.5)$$

For intermediate values of (λL), Equations [48], [49], and [50] must be used.

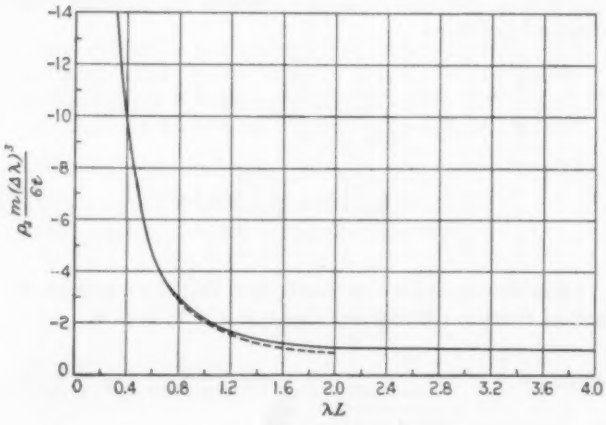

FIG. 5

The present design of turbine generators with which this paper deals has a value of (λL) greater than 2.2. Therefore the constants β_1, β_2, β_3, and β_4 can be written as follows:

$$\beta_1 = -\underset{(r=r_3)}{\sigma_{r2}} \cdot \frac{(m^2-1)}{m^2} \cdot \frac{6t}{E(\Delta\lambda)^3} \quad \ldots\ldots\ldots [51]$$

$$\beta_2 = 0 \quad \ldots\ldots\ldots [52]$$

$$\beta_3 = \underset{(r=r_3)}{\sigma_{r2}} \cdot \frac{(m^2-1)}{m^2} \cdot \frac{6t}{E(\Delta\lambda)^3} \quad \ldots\ldots\ldots [53]$$

$$\beta_4 = 0 \quad \ldots\ldots\ldots [54]$$

There are still four constants to be determined, namely, A_1, B_1, A_2, and B_2. Substituting Equations [18] and [19] in [13] and [14], we are able to write the radial and tangential stresses of the shaft and centering ring as follows:

$$\sigma_{r1} = \frac{mE}{(m^2-1)}\left[A_1(m+1) + \frac{B_1}{r^2}(1-m) - q\frac{r^2}{8}(3m+1)\right] \quad \ldots\ldots [55]$$

$$\sigma_{t1} = \frac{mE}{(m^2-1)}\left[A_1(m+1) + \frac{B_1}{r^2}(m-1) - q\frac{r^2}{8}(m+3)\right] \quad \ldots\ldots [55a]$$

$$\sigma_{r2} = \frac{mE}{(m^2-1)}\left[A_2(m+1) + \frac{B_2}{r^2}(1-m) - q\frac{r^2}{8}(3m+1)\right] \quad \ldots\ldots [56]$$

$$\sigma_{t2} = \frac{mE}{(m^2-1)}\left[A_2(m+1) + \frac{B_2}{r^2}(m-1) - q\frac{r^2}{8}(m+3)\right] \quad \ldots\ldots [56a]$$

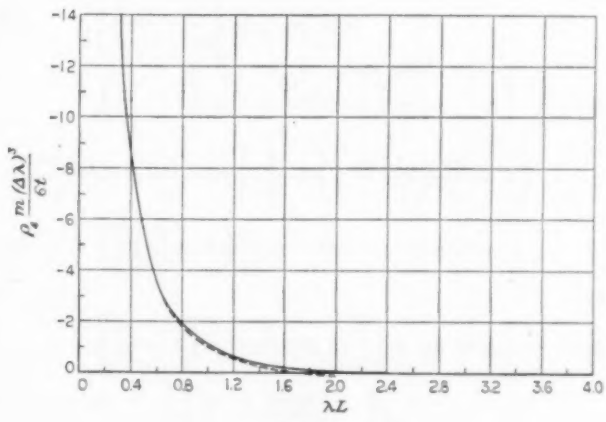

FIG. 6

Now from the boundary conditions which have already been given we can write the following:

For $u_4 - u_2 = \delta_2$ at $x = 0$ and $r = r_3$,

$$\beta_1 + u_{30} - A_2 r_3 - \frac{B_2}{r_3} + q\frac{r_3^3}{8} - \delta_2 = 0 \quad \ldots\ldots [57]$$

and for $u_2 - u_1 = \delta_1$ at $r = r_2$,

$$A_2 r_2 + \frac{B_2}{r_2} - A_1 r_2 - \frac{B_1}{r_2} - \delta_1 = 0 \quad \ldots\ldots [58]$$

Also for $\sigma_{r2} = \sigma_{r1}$ at $r = r_2$,

$$A_2(m+1) + \frac{B_2}{r_2^2}(1-m) - A_1(m+1) - \frac{B_1}{r_2^2}(1-m) = 0 \quad [59]$$

and for $\sigma_{r1} = 0$ at $r = r_1$,

$$A_1(m+1) + \frac{B_1}{r_1^2}(1-m) - q\frac{r_1^2}{8}(3m+1) = 0 \quad [60]$$

We also know that $\sigma_{r2} = \frac{1}{\rho_1}\beta_1$ at $r = r_3$, consequently

$$\frac{\beta_1}{\rho_1} = \frac{B_2}{r_3^2}(1-m) + A_2(m+1) - q\frac{r_3^2}{8}(3m+1) \quad [61]$$

From the foregoing equations the constants A_1, A_2, B_1, and B_2 are found to be as follows:

$$A_1 = \frac{(m-1)}{(m+1)} \cdot \frac{1}{\psi} \left\{ \delta_2 - u_{30} + q\frac{r_3^2}{8}\left[\rho_1\left(1-\frac{r_1^4}{r_3^4}\right)(3m+1) - r_3\left(1+\frac{r_1^4}{r_3^4}\cdot\frac{3m+1}{m-1}\right)\right] + \frac{\delta_1}{2m}\left[m\frac{r_3^2+r_2^2}{r_2r_3} - \frac{r_3^2-r_2^2}{r_2r_3} - (m^2-1)\frac{\rho_1}{r_2}\left(1-\frac{r_2^2}{r_3^2}\right)\right]\right\} \quad [62]$$

where

$$\psi = \rho_1(m-1)\left(1-\frac{r_1^2}{r_3^2}\right) - r_3\left(\frac{m-1}{m+1}+\frac{r_1^2}{r_3^2}\right)$$

$$A_2 = \left(\frac{m-1}{m+1}\right)\cdot\frac{1}{\psi}\left\{\delta_2 - u_{30} + q\frac{r_3^2}{8}\left[\rho_1\left(1-\frac{r_1^4}{r_3^4}\right)(3m+1) - r_3\left(1+\frac{r_1^4}{r_3^4}\frac{3m+1}{m-1}\right)\right] + \delta_1\frac{(m+1)}{2m}\left[\frac{r_2}{r_3}\left(1-\frac{r_1^2}{r_2^2}\right) + \frac{\rho_1}{r_2}(m-1)\left(\frac{r_2^2}{r_3^2}-\frac{r_1^2}{r_3^2}\right)\right]\right\} \quad [63]$$

$$B_1 = \frac{r_1^2}{\psi}\left\{\delta_2 - u_{30} + \frac{q}{8}\left[r_3^2(3m+1)\rho_1\left(1-\frac{r_1^2}{r_3^2}\right) - r_3^3\left(1-\frac{3m+1}{m+1}\cdot\frac{r_1^2}{r_3^2}\right)\right] + \frac{\delta_1}{2m}\left[m\frac{r_3^2+r_2^2}{r_2r_3} - \frac{r_3^2-r_2^2}{r_2r_3} - (m^2-1)\frac{\rho_1}{r_2}\left(1-\frac{r_2^2}{r_3^2}\right)\right]\right\} \quad [64]$$

and

$$B_2 = \frac{r_1^2}{\psi}\left\{\delta_2 - u_{30} + \frac{q}{8}\left[r_3^2(3m+1)\rho_1\left(1-\frac{r_1^2}{r_3^2}\right) - r_3^3\left(1-\frac{3m+1}{m+1}\cdot\frac{r_1^2}{r_3^2}\right)\right] - \delta_1\frac{(m-1)}{2m}\left[1-\frac{r_1^2}{r_2^2}\right]\frac{r_2}{r_1^2}\left[r_3-\rho_1(m+1)\right]\right\} \quad [65]$$

For the large turbine generators which are considered here, the value for (λL) exceeds 2.2, and therefore we can use the simplified value for ρ_1 as found in Equation [48a]. Also the ratio $(r_1/r_3)^2$ is very small compared with unity. Therefore the foregoing constants can be written as follows:

$$A_1 = \left(\frac{m-1}{m+1}\right)\frac{1}{\chi}\left\{u_{30} - \delta_2 + q\frac{r_3^2}{8}\left[\frac{6t}{(\Delta\lambda)^3}\frac{(3m+1)}{m} + r_3\right] - \frac{\delta_1 r_3}{2mr_2}\left[m\left(1+\frac{r_2^2}{r_3^2}\right) - \left(1-\frac{r_2^2}{r_3^2}\right) + \frac{6t}{r_3(\Delta\lambda)^3}\frac{(m^2-1)}{m}\right]\right\} \quad [66]$$

where

$$\chi = (m-1)\left[\frac{6t}{m(\Delta\lambda)^3} + \frac{r_3}{m+1}\right]$$

$$A_2 = \left(\frac{m-1}{m+1}\right)\cdot\frac{1}{\chi}\left\{u_{30} - \delta_2 + q\frac{r_3^2}{8}\left[\frac{6t}{(\Delta\lambda)^3}\frac{(3m+1)}{m} + r_3\right] - \frac{\delta_1(m+1)}{2mr_3}\left[r_2\left(1-\frac{r_1^2}{r_3^2}\right) - \frac{6t}{(\Delta\lambda)^3}\frac{(m-1)}{mr_3^2}\left(1-\frac{r_1^2}{r_3^2}\right)r_3^2\right]\right\} \quad [67]$$

$$B_1 = \frac{r_1^2}{\chi}\left\{u_{30} - \delta_2 + q\frac{r_3^2}{8}\left[\frac{6t}{(\Delta\lambda)^3}\frac{(3m+1)}{m} + r_3\right] - \frac{\delta_1 r_3}{2mr_2}\left[m\left(1+\frac{r_2^2}{r_3^2}\right) - \left(1-\frac{r_2^2}{r_3^2}\right) + \frac{6t}{r_3(\Delta\lambda)^3}\frac{(m^2-1)}{m}\left(1-\frac{r_2^2}{r_3^2}\right)\right]\right\} \quad [68]$$

and

$$B_2 = \frac{r_1^2}{\chi}\left\{u_{30} - \delta_2 + q\frac{r_3^2}{8}\left[\frac{6t}{(\Delta\lambda)^3}\frac{(3m+1)}{m} + r_3\right] + \delta_1\frac{(m-1)}{2m}\left[1-\frac{r_1^2}{r_2^2}\right]\frac{r_2}{r_1^2}\left[r_3 + \frac{6t}{(\Delta\lambda)^3}\frac{(m+1)}{m}\right]\right\} \quad [69]$$

The relations between [66], [67], [68], and [69] are shown by the following three equations:

$$\left.\begin{aligned} A_2 - A_1 &= \frac{\delta_1(m-1)}{2mr_2} \\ B_2 - B_1 &= \delta_1 r_2\frac{(m+1)}{2m} \\ A_1 &= q\frac{r_1^2(3m+1)}{8(m+1)} + \frac{B_1(m-1)}{r_1^2(m+1)} \end{aligned}\right\} \quad [69a]$$

The radical elongation of the retaining ring can now be written as follows:

$$u_3 = u_{30} - \underset{(r=r_3)}{\sigma_{r2}}\frac{6t}{E(\Delta\lambda)^3}\left(1-\frac{1}{m^2}\right)\cos\lambda x e^{-\lambda x} \quad [70]$$

Remembering that $\sigma_{t3} = u_3\frac{E}{r_3}$ and substituting Equations [67] and [69] in [70], the tangential stress in the retaining ring is obtained as follows:

$$\sigma_{t3} = \frac{E}{r_3}\left\{u_{30} + \frac{1}{1+\frac{r_3m(\Delta\lambda)^3}{6t(m+1)}}\left[\delta_2 - u_{30} + q\frac{r_3^3}{4}\frac{m}{(m+1)} + \delta_1\frac{r_2}{r_3}\left(1-\frac{r_1^2}{r_2^2}\right)\right]\cos\lambda x e^{-\lambda x}\right\} \quad [71]$$

From this equation it is readily seen that the maximum tangential stress in the retaining ring is at $x = 0$; that is,

$$\sigma_{t3(\max)} = \frac{E}{r_3}\frac{1}{1+\frac{r_3m(\Delta\lambda)^3}{6t(m+1)}}\left\{\delta_2 + u_{30}\frac{r_3m(\Delta\lambda)^3}{6t(m+1)} + q\frac{r_3^3}{4}\frac{m}{(m+1)} + \delta_1\frac{r_2}{r_3}\left(1-\frac{r_1^2}{r_2^2}\right)\right\} \quad [72]$$

The preceding equations have dealt with the effects due to rotation and shrinkage combined. Now considering the turbine generator at rest, we are left with only the shrinkage effects.

The radial and tangential stresses due to shrinkage alone can readily be written by putting the terms q and u_{30} equal to zero.

Equations [71] and [72] are then, respectively,

$$\underset{(N=0)}{\sigma_{t3}} = \frac{E}{r_3}\frac{1}{1+\frac{r_3m(\Delta\lambda)^3}{6t(m+1)}}\left[\delta_2 + \delta_1\frac{r_2}{r_3}\left(1-\frac{r_1^2}{r_2^2}\right)\right]\cos\lambda x e^{-\lambda x} \quad [73]$$

and

$$\underset{\substack{(x=0\\N=0)}}{\sigma_{t3}} = \frac{E}{r_3} \cdot \frac{1}{1 + \dfrac{r_3 m(\Delta\lambda)^2}{6t(m+1)}} \left[\delta_2 + \delta_1 \frac{r_2}{r_3} \left(1 - \frac{r_1^2}{r_2^2} \right) \right] \ldots [74]$$

However, the stresses in the retaining ring are almost exclusively tangential, due to the heavy shrink fit provided at one end, and the ring takes what has been termed as an "hourglass" shape at standstill. As a result of this, we have a bending and shearing stress which will now be developed, although they are both of much smaller magnitude than the tangential stress.

The bending moment is

$$M_x = \frac{E}{\left(1 - \dfrac{1}{m^2}\right)} I \frac{d^2 u_3}{dx^2} \ldots\ldots\ldots\ldots [75]$$

Therefore the bending stress in the outer fiber is:

$$\sigma_B = \frac{E}{\left(1 - \dfrac{1}{m^2}\right)} \cdot \frac{\Delta}{2} \cdot \frac{d^2 u_3}{dx^2} \ldots\ldots\ldots\ldots [76]$$

Differentiating Equation [31] twice, remembering that β_2 and β_4 are equal to zero, and substituting for β_1 and β_3 their values from [51] and [53], gives

$$\sigma_B = \frac{6tEm}{(\Delta^2\lambda)(m-1)\left[r_3 + \dfrac{6t\,(m+1)}{(\Delta\lambda)^2 m} \right]} \left\{ \delta_2 - u_{30} + q \frac{r_3^3}{4} \frac{m}{(m+1)} + \delta_1 \frac{r_2}{r_3} \left(1 - \frac{r_1^2}{r_2^2} \right) \right\} \sin \lambda x e^{-\lambda x} \ldots\ldots [77]$$

By differentiation, it can be shown that the function $\sin \lambda x e^{-\lambda x}$ has its maximum (for positive values of x) at $\lambda x = \pi/4$. Hence the maximum bending stress occurs at $x = \pi/4\lambda$.

We see from the Equation [77] that since u_{30} is for practical cases always considerably larger than $q \dfrac{r_3^3}{4} \dfrac{m}{(m+1)}$, the bending stress under rotation is always smaller than at rest.

From Equation [24] we know that the shearing force is

$$S_x = -\frac{dM_x}{dx} = -\frac{E}{\left(1 - \dfrac{1}{m^2}\right)} I \frac{d^3 u_3}{dx^3} \ldots\ldots\ldots [78]$$

Hence the average shearing stress becomes

$$\sigma_{s(\text{AVE.})} = -\frac{E}{\left(1 - \dfrac{1}{m^2}\right)} \frac{\Delta^2}{12} \frac{d^3 u_3}{dx^3} \ldots\ldots\ldots\ldots [79]$$

Differentiating Equation [31] three times, remembering that β_2 and β_4 are equal to zero and also that β_3 is equal to β_1, and substituting their values in Equation [79], gives the average shearing stress as follows:

$$\sigma_{s(\text{AVE.})} = -\underset{(r=r_3)}{\sigma_{r2}} \frac{t}{\Delta} e^{-\lambda x} \sqrt{2} \sin \left(\lambda x - \frac{\pi}{4} \right) \ldots\ldots [80]$$

The function $\sqrt{2}\, e^{-\lambda x} \sin \left(\lambda x - \dfrac{\pi}{4} \right)$ has its maximum value (for positive values of x) at $x = 0$ and becomes equal to -1. Then

$$\sigma_{s(\text{AVE.})} = \frac{-mEt}{(m-1)\Delta \left[r_3 + \dfrac{6t(m+1)}{(\Delta\lambda)^2 m} \right]} \left\{ \delta_2 - u_{30} + q \frac{r_3^3}{4} \frac{m}{(m+1)} + \delta_1 \frac{r_2}{r_3} \left(1 - \frac{r_1^2}{r_2^2} \right) \right\} \sqrt{2}\, e^{-\lambda x} \sin \left(\frac{\pi}{4} - \lambda x \right) \ldots\ldots [81]$$

We have already mentioned the importance of being able to predetermine the speeds at which the various members of the system become loose from each other. This will enable us to provide proper allowances, dependent upon the entire system, instead of on merely adjacent parts.

The speed N_3 at which the retaining ring becomes free from the centering ring can be determined by substituting Equations [63] and [65] in [56], by making $\sigma_{r2} = 0$ for $r = r_3$, and remembering that u_{30} and q depend upon the speed N as indicated by Equations [15a], [20], and [30]. Then, calling m (for steel) $= 3.33$ and solving for N_3,

$$N_3 = \frac{10^5}{r_3} \sqrt{\frac{\delta_2^1 + \delta_1^1 \left(\dfrac{r_2^2 - r_1^2}{r_3^2} \right)}{9.48\gamma^1 - 0.47}} \ldots\ldots\ldots [82]$$

where

$$\delta_2^1 = \frac{1000\delta_2}{r_3} = \text{allowance in mils per inch of diameter}$$

$$\delta_1^1 = \frac{1000\delta_1}{r_2} = \text{allowance in mils per inch of diameter}$$

and

$$\gamma^1 = \frac{W_r + W_c}{2\pi r_3 L \Delta} = \gamma \left(1 + \frac{W_c}{W_r} \right) (\gamma = 0.283)$$

Equation [82] gives the correct value, provided the centering ring has not yet started to separate from the shaft. For such a condition, the value would have to be modified to the extent that Equation [39] is fulfilled.

The speed N_2 at which the centering ring becomes free from the shaft can be determined by setting σr_2 at $r = r_2$ in Equation [56] equal to zero, and substituting Equations [63] and [65] in [56].

Solving for N_2, we obtain

$$N_2 = \frac{10^5}{r_3} \sqrt{\frac{\delta_2^1 + \delta_1^1 \left[0.65 \dfrac{r_2^2}{r_3^2} + 0.35 + 2.73 \dfrac{t}{(\Delta\lambda)^2 r_3} \left(1 - \dfrac{r_2^2}{r_3^2} \right) \right]}{9.48\gamma^1 + 0.305 \left[1 + \dfrac{20t}{r_3(\Delta\lambda)^2} \left(1 - \dfrac{r_2^2}{r_3^2} \right) - 2.53 \dfrac{r_2^2}{r_3^2} \right]}} \ldots [83]$$

It must be remembered here that limitations apply to Equation [83] similar to those already explained for Equation [82].

Numerical Example

Calling

$r_1 = 2.5$ $L = 18.0$ $N = 1800$ $\delta_1 = 0.005$ $\delta_1^1 = 0.385$
$r_2 = 13.0$ $\Delta = 1.75$ $W_r = 1400$ $\delta_2 = 0.040$ $\delta_2^1 = 1.667$
$r_3 = 24$ $t = 2.5$ $W_c = 1500$

the following values are obtained:

$u_{30} = 0.02576$ $\chi = 263.943$ $A_1 = 0.0000102$ $B_2 = 0.04236$
$q = 0.79056 \times 10^{-6}$ $(\Delta\lambda)^3 = 0.0418$ $A_2 = 0.000145$
$\lambda = 0.1983$ $\gamma^1 = 0.585$ $B_1 = 0.00010$

The stresses are plotted in Figs. 7 and 8.

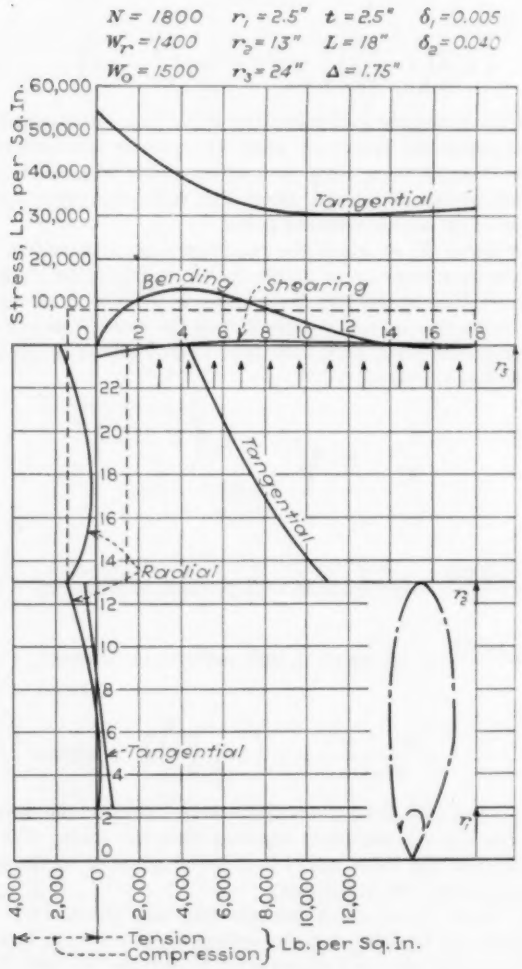

FIG. 7 EXAMPLE A
(N = 1800; Wr = 1400; W_c = 1500; r_1 = 2.5 in.; r_2 = 13 in.; r_3 = 24 in.; t = 2.5 in; L = 18 in.; Δ = 1.75 in.; δ_1 = 0.005; δ_2 = 0.040.)

DISCUSSION OF THE RESULTS

Considering first the tangential stresses in the retaining ring, we may learn from Equations [71] and [72] the following interesting facts:

σ_{t3} has its maximum value at ($x = 0$) and for large values of x it approaches the value which would be obtained if the ring were rotating freely. The tangential stress at any distance x is given by the sum of the latter value and a superimposed stress which varies as a damped trigonometric function as we proceed in the x-direction. This superimposed stress consists of four terms, two of which are proportional to the shrink allowances between the centering ring and shaft and between the retaining and centering rings. The third term depends upon the centrifugal force exerted by the centering ring, which is indicated by the factor qr_3^3, and the fourth term is proportional to u_{30} (the elongation of the retaining ring if it were rotating freely). In calculating an example it will be found that the value of δ_2 contributes the largest amount to the maximum tangential stress in the retaining ring. Any change that may be made in the thickness t of the centering ring does not materially alter this stress.

We shall note at this place that from Equation [72] it might appear that the maximum tangential stress in the retaining ring would reach a finite value for an infinitely thin ring. It is to be remembered, however, that for such thin rings the approximations no longer apply. The value of λx in Equation [71] for this instance is indeterminate, so that the expression $\cos \lambda x \varepsilon^{-\lambda x}$ is no longer unity for $x = 0$. For small distances of x, Equation [71] already gives the value $\sigma_{t3} = \infty$, as it has to be for infinitely thin rings.

The tangential stresses in the retaining ring at standstill are given by Equations [73] and [74]. By inspection, we learn that the tangential stress at zero speed becomes zero for large values of x, as was naturally to be expected. The maximum stress, which depends only on the shrink allowances δ_1 and δ_2, occurs at $x = 0$.

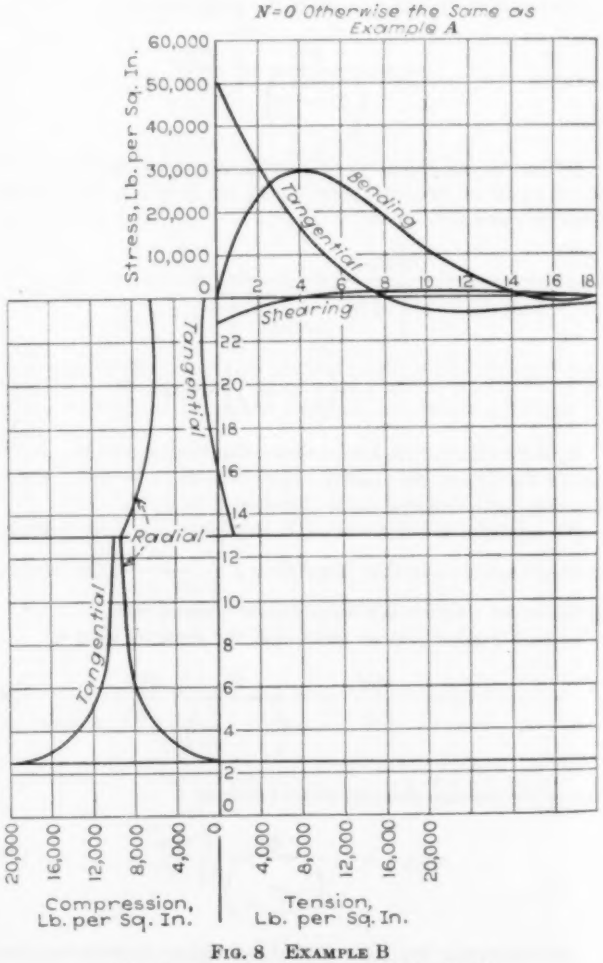

FIG. 8 EXAMPLE B
(N = 0; other values as in Example A, Fig. 7.)

Examples *A* and *B*, showing the stresses at normal and zero speeds, are plotted on Figs. 7 and 8, respectively. Comparing these examples, it is found that the maximum tangential stress in the retaining ring has a fatigue range of less than 10 per cent of the maximum stress at zero speed. It is also apparent that the shrink allowance affects only about one-half of the retaining ring. At standstill, rings of this class actually contract to a smaller diameter than they have in the unstressed state.

The maximum bending stress in the retaining ring occurs at $x = \pi/4\lambda$, and is considerably larger at zero speed than at normal speed. At this point the bending causes compression in the outer and tension in the inner fibers of the ring.

In order to get a true conception of the total stresses in the outer and inner fibers of the ring we must use the following well-known relation:

$$\left.\begin{aligned} \sigma &= \sigma_t - \frac{1}{m}\sigma_B \\ \text{or} \\ \sigma &= \sigma_B - \frac{1}{m}\sigma_t \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [84]$$

the equation to use being the one which gives the largest value for σ. In Equation [84] tensile stresses have to be considered as positive and compressive stresses as negative. From that equation we learn that the reduced stresses in the outer fiber are larger, and in the inner fiber are smaller, than the tangential stress σ_t.

The average shear stress, whose magnitude is always small, has its maximum value at $x = 0$, and decreases to zero for large values of x. The shear stress is parabolically distributed over the cross-section and is zero at the inner and outer fibers.

The tangential and radial stresses in the shaft and centering ring may be calculated from Equations [55], [55a], [56], and [56a], respectively, where the constants A_1, B_1, A_2, and B_2 have a definite relation to each other as indicated by Equation [69a]. It is therefore only necessary to calculate B_2 from [69], when the remaining three constants may be obtained from their relations in [69a].

From the example given, the tangential stress in the centering ring at zero speed has a positive value at the bore, passes through zero, and becomes negative at the retaining-ring fit. The position of this curve with respect to its ordinate is largely determined by the shrink allowances δ_1 and δ_2. A slight decrease of the allowance δ_2 would put the entire ring in tension as it is at the normal speed. The radial stress at the bore of the centering ring is negative at zero speed, decreases with increasing velocity, and becomes of course zero when the separating speed is reached. Beyond this speed the equations developed here no longer apply because the boundary conditions which have been used for the determination of the integration constants change.

The tangential stress in the shaft at normal speed is negative at the shrink fit and positive at the bore, while at standstill it is negative throughout. The radial stresses in this portion of the system are of course zero at the bore. At normal speed this stress is positive for small and negative for large values of r. At zero speed the radial stress in the shaft is negative, and increases from zero to a maximum at the shrink fit.

Equation [82] gives the separating speed between the retaining and centering rings. It is to be noted that this speed is independent of the thickness and length of the retaining rings, as is to be expected.

From Equation [83] the separating speed between the centering ring and shaft may be calculated. In this case we learn that the dimensions of the retaining ring have quite an influence upon the separating speed. By choosing definite values of N_2 and N_3 it would also be possible to solve for the shrink allowances $\delta_1{}^1$ and $\delta_2{}^1$. One would then find that by increasing N_2 with a constant value for N_3 the shrink allowance $\delta_2{}^1$ between the retaining ring and the centering ring could be reduced, which would in turn reduce the maximum tangential stress in the retaining ring. It must be remembered, however, that this would at the same time increase the tangential stress in the centering ring.

Discussion

C. Richard Soderberg.[3] The authors have presented an interesting discussion of a problem which is of utmost importance to the designers of large, high-speed turbine generators. After reviewing the paper somewhat hastily the writer wishes to comment on the following points:

In treating the deformation of the retaining ring, the well-known theory of a beam on an elastic foundation may be used directly, obviating most of the complicated mathematics of the paper. Considering an element of unit circumferential extension of the ring, the differential equation for the radial deformation is easily found to be

$$\frac{EI}{1 - \dfrac{1}{m^2}}\frac{d^4u_3}{dx^4} + ku_3 = 0 \quad \ldots\ldots\ldots\ldots [85]$$

where $EI/(1 - 1/m^2)$ is the flexural rigidity of the element and k is the modulus of the foundation. For a thin ring of mean radius r_m and thickness Δ, k is easily shown to be

$$k = E\frac{\Delta}{r_m{}^2} \quad \ldots\ldots\ldots\ldots [86]$$

The solution of the differential equation [85] for all possible types of boundary conditions is already available[4] in the engineering literature. The constant term in the differential equation [29] is easily disposed of by a linear change in the variable u_3. Obviously, this criticism concerns only the method of arriving at the results; it does not in any way detract from the value of the final results obtained by the authors.

There is another aspect of the retaining-ring problem which is not mentioned by the authors, but which is of great importance in constructions somewhat different from the one illustrated in Fig. 1. This is the bending reactions transmitted by the centering ring and the retaining ring in those cases where the latter is shrunk on both the rotor body and the centering ring. This construction has been used by several foreign and American firms, and troubles due to movements on the shrink fits have been encountered in several instances. The reason for these troubles is that the bending moment on the rotor is almost wholly taken up by the very stiff ring structure. The arrangement shown in Fig. 1 would certainly obviate this trouble, but other satisfactory ones have also been proposed and are in use.[5] Fig. 9 shows a construction which is sponsored by the company with which the writer is associated. The retaining ring is shrunk on at A and B, but the "centering ring" is entirely free from the shaft. This permits the passage of a maximum of cooling air at C under the centering ring, and obviates all bending reactions. This construction has proved to be very satisfactory.

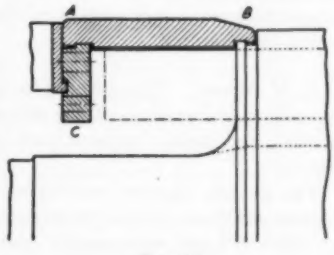

Fig. 9[6]

The writer must confess to a certain disappointment at the

complete absence of any discussion on the important subject of working stresses in turbo retaining rings. No exaggeration is involved in the statement that these working stresses frequently influence the size of the entire machine. In general, these working stresses were established before the knowledge regarding the actual distribution of the stresses was very complete, and every new contribution to the subject brings the actual maximum stress closer and closer to the yield point of the material. In Fig. 7 of the paper the maximum and mean tangential stresses of the retaining ring at 1800 r.p.m. are given as approximately 54,000 and 36,000 lb. per sq. in., respectively. The corresponding figures for 20 per cent overspeed would be considerably greater. Any one who is familiar with the design of large turbine generators will see nothing extraordinary in these figures, but it would be interesting, nevertheless, to have the authors' comments on this important question.

S. TIMOSHENKO.[7] This paper contains a solution of a very important practical problem. It seems to the writer that the solution can be simplified very much by using the well-known theory of bending of bars on an elastic foundation, together with the numerical tables of functions entering in this theory and which have been calculated by A. Zimmermann in "Die Berechnung des Eisenbahn Oberbaues," Berlin, 1888. (See also Hayashi, "Theorie des Trägers auf elastischer Unterlage," Berlin, 1921.)

In designing a retaining ring it is desirable to begin with the determination of the overspeed at which the ring will become loose. At this speed of separation there are no forces acting between the retaining and the centering rings, and there is no difficulty in calculating, by known formulas, the expansion of both rings under the action of centrifugal forces. Knowing the difference between the radial expansions of the two rings, the reactive forces between the rings necessary to remove this difference can easily be calculated by using the tables for beams on an elastic foundation. This manner of calculation will give in a very simple manner a comparison of the stresses of various initial shrink-fit pressures.

A. M. WAHL.[8] The authors have given a very complete and comprehensive analysis of the stress distribution in a very important and highly stressed part of modern turbine-generator rotors.

The general theories underlying the calculation include the well-known theory of a bar on an elastic foundation, first developed by Winkler,[9] and subsequently elaborated on by Zimmerman,[10] Hayashi, Wieghardt, Timoshenko, and others. This theory was applied by Cook[11] to the calculation of a pipe reinforced by steel rings, a case which is essentially the same as that of a retaining ring shrunk on to the centering ring. In addition, the authors apply the well-known theory of deformations of thick rings, often referred to as the Lamé theory. Nevertheless, although the underlying theory is well known, they deserve much credit for bringing the whole solution together in a unified form and determining the integration constants in such a way as to facilitate practical application of the formulas.

The writer wonders whether or not the solutions found in the literature for the various components of the retaining-ring assembly could not be superimposed, using the principle of superposition, and in this manner a solution could be arrived at without the necessity of carrying out the various integrations as was done in the paper. Possibly this might be a fairly simple method of attack.

In order to determine the true factor of safety, it is necessary to combine the various stresses (radial, tangential, and axial) according to certain theories of strength. It should be noted that the authors use the maximum-strain theory for this purpose. The practice of the Westinghouse Company is to use the maximum-shear theory. The use of the latter will give a somewhat more conservative design: i.e., the equivalent stresses as figured will be greater than will be the case if the maximum-strain theory is used. Furthermore, recent tests by Nadai, Lode, Ros, and Eichinger, and others seem to indicate that for ductile materials the maximum "energy-of-distortion" theory is more nearly in agreement with the truth than the maximum-shear theory as far as yielding of the material is concerned. Nevertheless it was also found that the maximum-shear theory is not far from the truth and is on the safe side. For this and other reasons the writer believes that the maximum-shear theory is more consistent for practical use where ductile materials are involved than is the maximum-strain theory used by the authors. It should be noted that for the example considered by the authors where one principal stress is much greater than the others, the difference between the two theories will not be great. There are other cases, however, where a much more pronounced difference will exist.

M. STONE.[12] The authors have presented a clear and accurate solution of the mechanical action of an important element of the turbine-generator. They are probably correct in stating that this is the first time that such an analysis has been published.

However, for some five years now, such a solution as the authors published has been used at the Westinghouse Co., with variations that have to do with the slightly different mechanical construction employed. The problem there has usually been one in which the retaining ring was (1) either shrunk on on both ends—on the centering rings and on the rotor, or (2) the same as (1), with the centering ring free—i.e., not shrunk on the shaft.

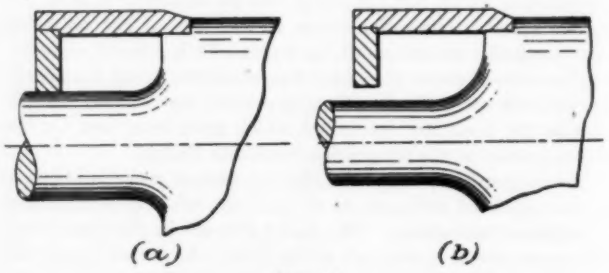

FIG. 10

Referring to Fig. 10, in case (*a*) we have made measurements on the form of the shrunk-on retaining ring—which takes on an "hour-glass" shape, in which the diameter in the middle was considerably less than the original machined diameter. This fact, it is understood, was predetermined analytically and agrees with the authors' statement on page 8.

The authors have gone to some length in developing the fundamental formulas [17] and [29]—which, however, may be taken directly from Timoshenko and Lessells' book,[13] when it is realized that the retaining ring is virtually *a beam on an elastic foundation*.

The general solution of this fourth-degree equation may be expressed through the trigonometrical functions, as Dr. Timoshenko has done, or by hyperbolic functions, as the authors have

done. In our own work, we have prepared tables of evaluated functions—from which any arbitrary boundary conditions may be satisfied.

A remark must be made which has to do with the actual importance of such a solution as the authors have published. Since it is at once appreciated that the highest stresses are the tangential stresses existing in the retaining ring, where it is shrunk on the centering ring or the rotor, it is only necessary to calculate this simple stress due to the shrink fit. If further cognizance is taken of the proper remark of the authors, "that a change in the thickness of the centering ring does not materially alter the stress," then, within the same limits of approximation, these simple stresses are close enough to the maximum to render unnecessary the more involved calculations. (Compare 50,000 and 54,000 lb. per sq. in. in the paper.) The speed at which the retaining ring will lose contact with the centering ring or the rotor body is just as simply calculated, so that in actual designing, only these latter calculations need be made.

Authors' Closure

The authors wish to thank those taking part in the discussion for their just and constructive criticism. One of the points brought out was that the theory of a beam on an elastic foundation, as first developed by Winkler in 1867 and so ably presented by Dr. S. Timoshenko in his recent book on elasticity, could have been applied, once it was realized that the retaining ring is virtually a beam on an elastic foundation. This is obviously true—after one has reviewed the two methods, and the authors are gratified to find that the results obtained by their method, which to them was original, are corroborated by those obtained by using other methods.

Mr. Soderberg mentioned another aspect of the retaining-ring problem; that is, that of considering the free end of the retaining ring as shown in Fig. 1 shrunk upon the rotor body, thereby forming a rigid extension to the rotor body at each end. This type of design was not mentioned in the paper, since the company with which one of the authors is still associated discontinued the design mentioned about eight years ago. The design then sponsored was the one shown in Fig. 1, which performs satisfactorily and eliminates the possibility of any movement at the shrink fits, as pointed out by Mr. Soderberg.

The absence of consideration of working stresses in the paper was not due to any underestimation of their importance, but rather to the fact that the authors had no thought that this question would enter into the discussion. It is generally accepted that the choice of proper working stresses depends not only upon the practical designer and his particular design, along with the results of the theory of elasticity, but also upon the metallurgist and the materials used. Modern practice has accumulated much empirical data on the basis of previous experience, and it is the opinion of the authors that the employment of such information, in conjunction with the results of qualitative analysis, will lead to a sound policy in the selection of proper working stresses.

Mr. Soderberg's statement that the maximum stress of 54,000 lb. per sq. in. shown in Fig. 7, and the mean stress which he estimates at 36,000 lb. per sq. in., would be considerably greater at 20 per cent overspeed, might possibly be misinterpreted. While the lower stresses do increase considerably with overspeed, it was pointed out in the paper that the maximum stress in the retaining ring is due chiefly to the shrink fit, and rises from 50,000 lb. per sq. in. at zero speed, to 54,000 at 100 per cent speed. At 20 per cent overspeed this maximum stress would rise only something like 2 per cent, which would be barely considerable. The other stresses of course never exceed the maximum, and remain less until an overspeed is reached that will break the contact between the retaining and centering rings.

Dr. Timoshenko's statement that it is desirable to start with the separating speeds in designing retaining rings, is very well put. It is only in this way that proper shrink fits can be determined that will insure satisfactory operation. His suggestion of calculating independently, by known formuals, the expansion of both rings due to centrifugal force, and of adjusting their differences to obtain the reactive forces between the rings, was in practice while the knowledge of the actual distribution of stresses was yet incomplete.

Mr. Wahl prefers the maximum-shear theory for determining the true factor of safety rather than the maximum-strain theory, as used by the authors, although he points out that the difference between the results obtained by the two theories will not be very great in this particular problem. Several well-known theories have been advanced from time to time, all of which are of an empirical nature. The authors chose the maximum-strain theory for the reason that of the different theories, one is nearest to reality for brittle metals, and another for very ductile metals, while metals intermediate in ductile qualities may be looked upon as following an intermediate empirical formula which may be devised to suit any individual case. From the notable experiments carried out by Cook and Robertson[14] on thick cylinders, it is possible to conclude that the maximum-strain theory overestimates the true elastic strength for very ductile metals, while the maximum-shear theory underestimates it by about 25 per cent.

Mr. Stone's discussion is essentially covered by the authors' replies to Mr. Soderberg. Mr. Stone also points out, however, that it is only necessary to calculate the maximum stresses for every day practice, which is a simple matter, and with which the authors agree.

Determination of Stresses in Rotating Disks of Conical Profile[1]

By F. C. RUSHING,[2] EAST PITTSBURGH, PA.

In this paper a determination is made of the accuracy of stress-distribution curves obtained by the application of Donath's "Sum and Difference Curves" to rotating disks of conical profiles.

ROTATING disks of conical profiles (Fig. 1) are used rather extensively on account of their economy in the use of material and the facility with which they are produced. A rotating disk in which the stress is equally distributed is relatively thick near the axis and thin at the rim; the variation in the thickness of such a disk is not constant, however, and it is difficult to machine the sides to the exact shape. Since a conical profile approximates the profile necessary for equal stress distribution, and since a disk with straight sides is easily machined, such a disk is commonly used.

In calculating the stresses in conical disks, use is made of approximate methods whose accuracies have never been determined. One of the most extensively used approximate methods is an application of Donath's "Sum and Difference Curves."[3]

Fortunately, an exact method of calculating stresses in conical-profiled disks has been published by Mr. H. M. Martin.[4] The chief purpose of the present paper is to determine, with the use of Mr. Martin's exact method, the accuracy of the results obtained by the approximate application of Donath's "Sum and Difference Curves" to disks of conical profiles. In accomplishing this purpose, it is deemed desirable to include here a brief description of the derivation of each method, together with an example of its application; followed by a comparison of results obtained by the application of the two methods to a wide variety of shapes and sizes of conical disks.

[1] The material presented in this paper was used in a thesis by the author for an M.S. degree from the University of Pittsburgh.

[2] Westinghouse Electric & Manufacturing Co. Mr. Rushing was born in 1906 in Runge, Texas, where he lived until he entered the University of Texas in 1924. He received a B.S. degree from this university in 1928, and became an employee of the Westinghouse Elec. & Mfg. Co. shortly thereafter. As an employee of this company, he was permitted to take the design training course, which enabled him to attend the University of Michigan during the Summer session of 1929 and to receive also some graduate credit from the University of Pittsburgh. He received an M.S. degree from the University of Pittsburgh in 1930. At the present time he is in the design section of the Industrial Motor Engineering Department of the Westinghouse Company.

NOTATION

- x = radial distance from the axis
- y = thickness of the disk at the distance x
- σ_r = radial stress in pounds per square inch
- σ_t = tangential stress in pounds per square inch
- μ = mass density of material of the disk
- ω = angular velocity of rotation
- $\frac{1}{\nu}$ = Poisson's ratio
- ξ = radial displacement at the end of radius x
- R = radius at which extended sides would meet
- D = $2R$
- Y = thickness at center if sides were extended to center
- N = revolutions per minute
- z = x/R
- P = $(1 - z)\sigma_r$
- Q = $(1 - z)\sigma_t$
- u = ωx
- S = $\sigma_t + \sigma_r$
- D = $\sigma_t - \sigma_r$
- T = stress that would be produced in ring at radius R due to the centrifugal force of the ring.

MARTIN'S EXACT METHOD

Mr. Martin, in his paper, derived a differential equation covering the stress distribution in a rotating disk of conical profile. This derivation can be accomplished by applying the principle of equilibrium and the theory of elasticity to a particle in the disk. Applying the principle of equilibrium to a particle in a disk gives

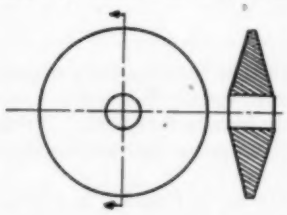

FIG. 1 DISK OF CONICAL PROFILE

$$\frac{d(xy\sigma_r)}{dx} - y\sigma_t + \mu\omega^2 x^2 y = 0. \quad [1]$$

Applying the theory of elasticity to a particle in a disk gives the following pair of relations:

$$\left.\begin{aligned} \sigma_r &= \frac{E}{1-\nu^2}\left(\frac{d\xi}{dx} + \nu\frac{\xi}{x}\right) \\ \sigma_t &= \frac{E}{1-\nu^2}\left(\nu\frac{d\xi}{dx} + \frac{\xi}{x}\right) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [2]$$

The following compatability equation can be obtained by eliminating ξ in Equation [2]:

$$\frac{d\sigma_t}{dx} - \nu\frac{d\sigma_r}{dx} = (1+\nu)\frac{\sigma_r - \sigma_t}{x} \quad \ldots\ldots\ldots\ldots [3]$$

By combining Equations [1] and [3], eliminating σ_t between them, and by making the following changes in coordinates, namely,

$$x = Rz$$
$$y = Y(1 - z)$$

$$P = \sigma_r(1-z), \text{ and}$$
$$Q = \sigma_t(1-z),$$

the following differential equation is obtained:[5]

$$z(1-z)\frac{d^2P}{dz^2} + (3-2z)\frac{dP}{dz} + (1-\nu)P + (3+\nu)\,Tz(1-z)^2 = 0 \ldots [4]$$

In deriving this differential equation, the following useful relations were found:

$$Q = P + z\frac{dP}{dz} + \mu\omega^2R^2(1-z)$$

$$T = 2 \times 10^{-6}D^2N^2$$

A complete solution of Equation [4] gives

$$P = P_1 + P_2 + P_3$$

where P_3 is the particular solution and

$$P_1 = A\left(1 - \frac{0.7}{3}z - \frac{0.7}{3}\frac{1.3}{8}z^2 - \frac{0.7}{3}\frac{1.3}{8}\frac{5.3}{15}z^3 - - - - - -\right)$$

$$P_2 = B(1-z)^2\left[1 + \frac{5.3}{3}(1-z) + \frac{5.3}{3}\frac{11.3}{8}(1-z)^2 + \frac{5.3}{3}\frac{11.3}{8}\frac{19.3}{15}(1-z)^3 + + + + + \right]$$

$$P_3 = T(0.13525 - 0.03156z - 0.34263z^2 + 0.23894z^3)$$

A and B being constants of integration.

Referring now to the change made in the coordinates, note that

$$\sigma_r = \frac{P_1 + P_2 + P_3}{(1-z)}$$

$$\sigma_t = \frac{Q_1 + Q_2 + Q_3}{(1-z)}$$

The use of this method is simplified by reducing the functions of z contained in P and Q to numerical form. This step is possible and practical since z varies only from zero to unity. Table 1 is the result of the introduction of numerical quantities in these functions.

Furthermore, since each of the terms in P and Q is divided by $(1-z)$, this division can be made in Table 1, and Table 2 is established.

In order to fully explain the use of this method, it is applied to a specific example (Fig. 2).

Calculating the radius at which the extended sides will meet gives

$$R = 32.5 \text{ in.}$$

$$z_{hub} = \frac{5}{32.5} = 0.1538$$

$$z_{rim} = \frac{21.5}{32.5} = 0.6616$$

By graphical interpolation the following values for Table 2 are obtained for the boundary values of z:

z	p_1	q_1	p_2	q_2	p_3	q_3
0.1538	0.174	0.1743	1.632	1.568	—27.150	35.000
0.6616	0.120	0.1525	3.490	2.608	— 0.747	3.407

[5] An error appeared in Mr. Martin's paper as published. In the last term of Equation [4], the factor $(3+\nu)$ was written and used as $(3-\nu)$.

[1] Values of p_2, q_2, p_3, q_3 taken from Martin's paper.

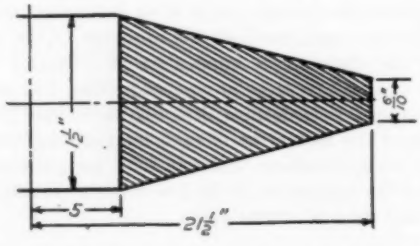

FIG. 2 EXAMPLE OF USE OF MARTIN'S METHOD
(Material of disk, steel; rim load, 8850 lb. per sq. in.; hub load, —710 lb. per sq. in.; speed, 3000 r.p.m.)

Substituting in the expression for T gives

$$T = 2 \times 10^{-6} \times 65^2 \times 3000^2 = 76{,}040$$

Since, according to the solution of the differential equation,

$$\sigma_r = Tp_1 + Ap_2 + Bp_3$$

and since the radial stresses on the rim and the hub are known, together with the above computed values of Table 2 for the rim and the hub,

$$8850 = 76{,}040 \times 0.12 + 3.490A + (-0.747)B$$
$$-710 = 76{,}040 \times 0.174 + 1.632A + (-27.15)B$$

Solving the two equations for A and B gives

$$A = 29.9 \qquad \text{and} \qquad B = 528$$

Having found A and B from known boundary conditions, the stresses can be found for any radius in the disk. Consider

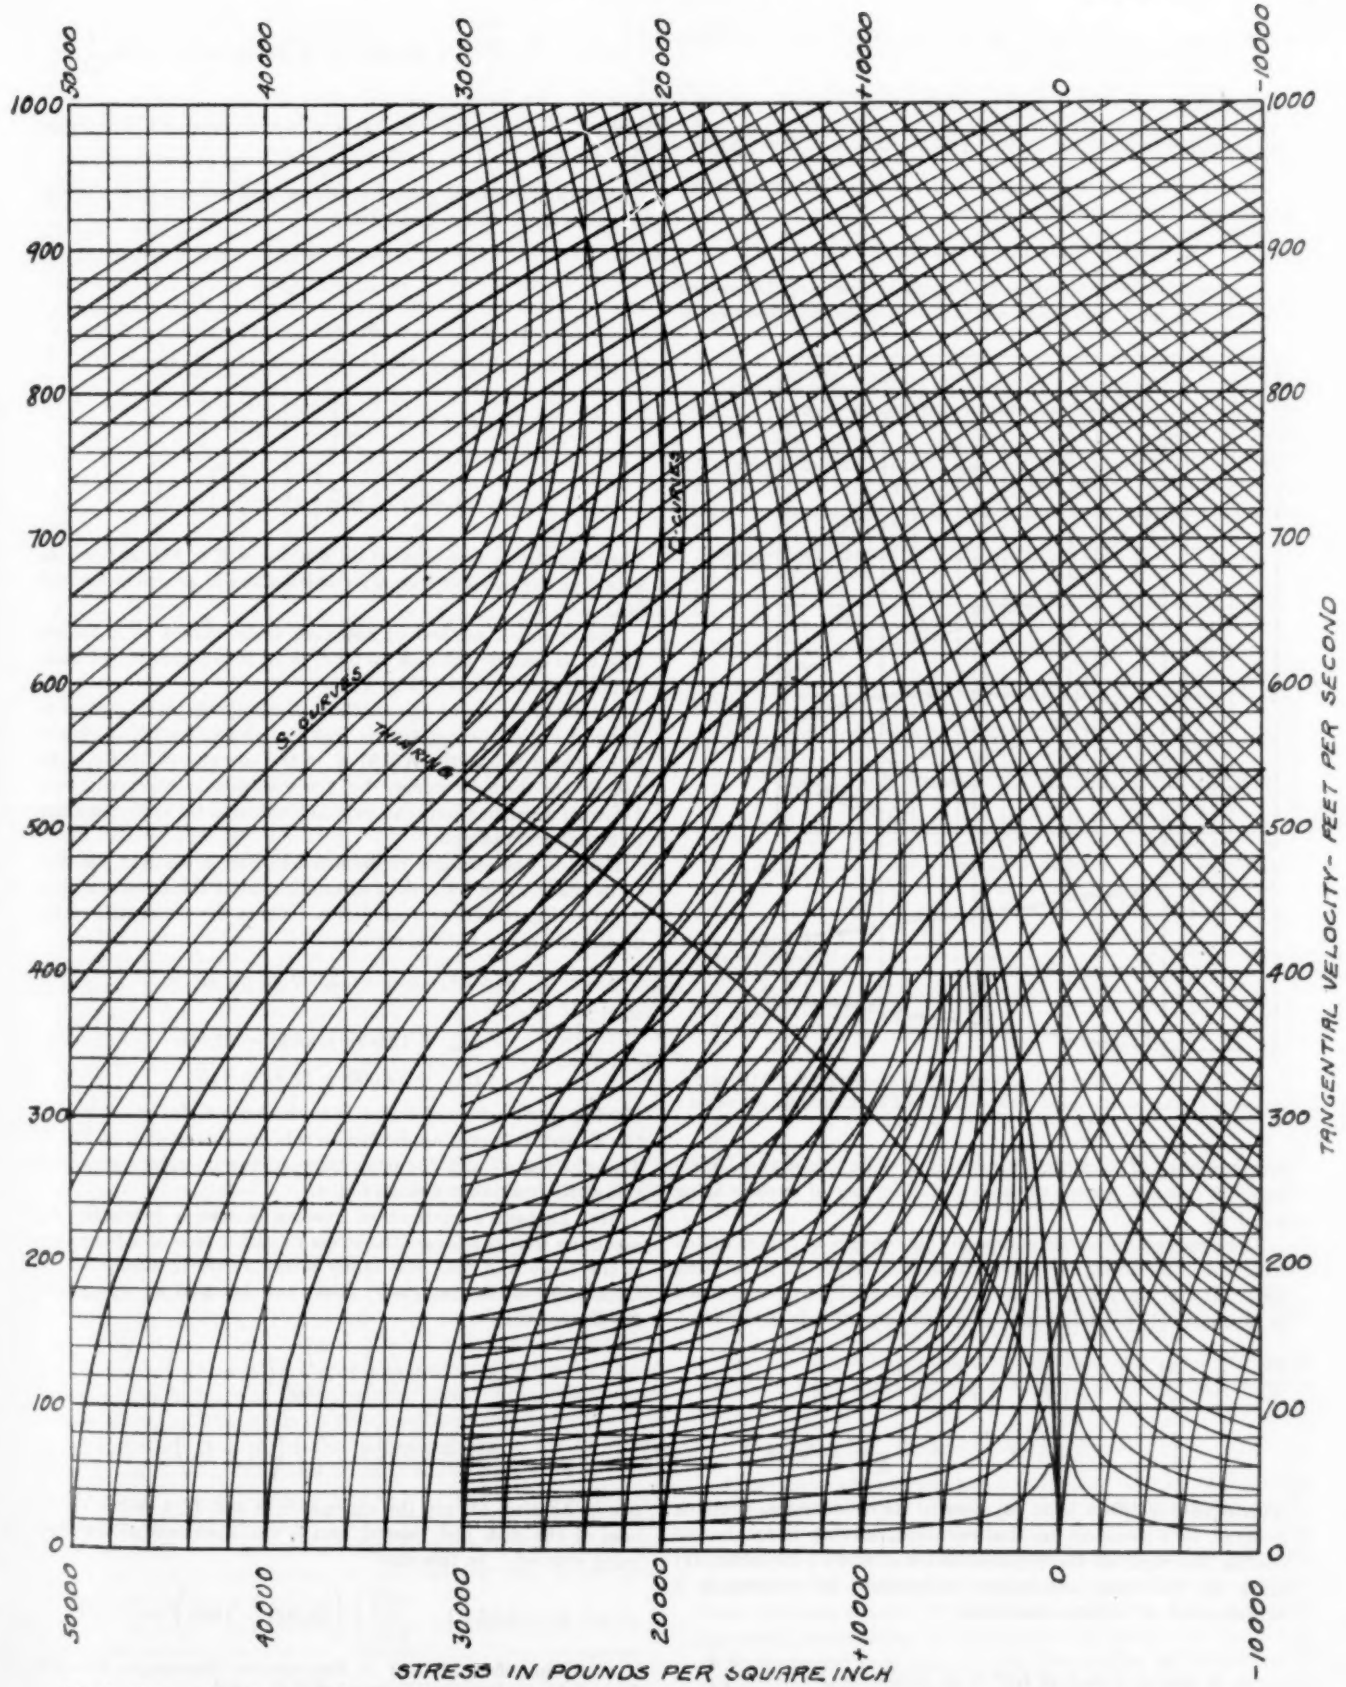

FIG. 3 DONATH'S "SUM AND DIFFERENCE" CURVES OF TANGENTIAL AND RADIAL STRESSES FOR PARALLEL-SIDED ELASTIC STEEL DISKS

a case when $z = 0.2$; then x the radius $= 32.5 \times 0.2 = 6^1/_2$ in., and at $6^1/_2$ in. the stresses are:

$$\sigma_r = 76{,}040 \times 0.1795 + 29.9 \times 1.707 - 528 \times 15.54 = 5{,}500$$

$$\sigma_t = 76{,}040 \times 0.1833 + 29.9 \times 1.617 + 528 \times 21.9 = 25{,}600$$

The complete stress-distribution curves found in this manner are the exact stress curves in Fig. 8.

Donath's "Sum and Difference Curves"

An approximate application of Donath's "Sum and Difference Curves" has been a popular method of determining stresses in

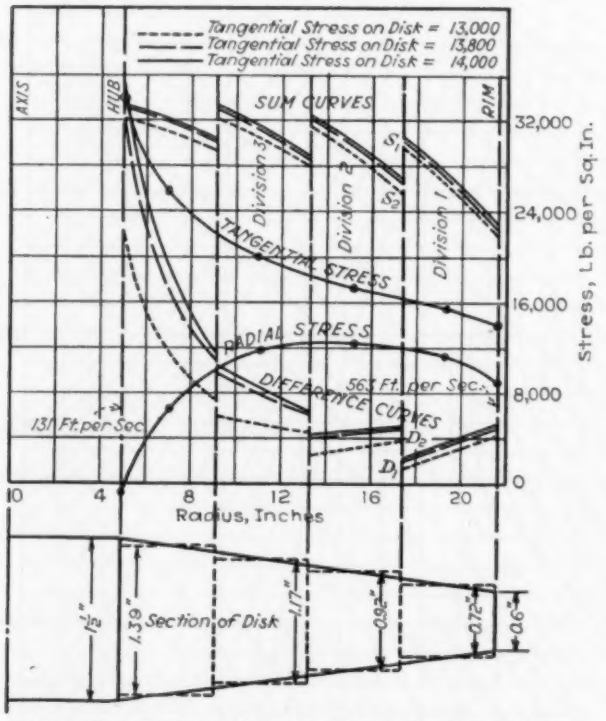

Fig. 4 Use of Donath Curves—"Equal-Division" Method
(Material of disk, steel; speed, 3000 r.p.m.; rim load, 8850 lb. per sq. in.; hub load, —710 lb. per sq. in.)

rotating disks of variable cross-section. The "Sum and Difference" in this case means the sum and difference of stresses along a radius.

The sum and difference curves in this case are of course linked with the differential equation covering stresses in a rotating disk. If the values of σ_t and σ_r, Equation [2], are introduced in Equation [1] the following differential equation is obtained:

$$\frac{d^2\xi}{dx^2} + \left[\frac{d(\log_e y)}{dx} + \frac{1}{x}\right]\frac{d\xi}{dx} + \left[\frac{\nu}{x}\frac{d(\log_e y)}{dx} - \frac{1}{x^2}\right]\xi + \frac{(1-\nu)}{E}\mu\omega^2x^2 = 0 \ldots . [5]$$

This equation differs from [4] only in its coordinates. Setting y equal to a constant in this equation, solving it for ξ, and placing the result in the expressions for σ_t and σ_r, Equation [2] gives the following well-known expressions for stresses in a rotating disk of uniform thickness:

$$\sigma_r = \frac{E}{1-\nu^2}\left[(3+\nu)\,Kx^2 + (1+\nu)b_1 - (1-\nu)b_2\frac{1}{x^2}\right]$$

$$\sigma_t = \frac{E}{1-\nu^2}\left[(1+3\nu)\,Kx^2 + (1+\nu)b_1 + (1-\nu)b_2\frac{1}{x^2}\right]$$

where $K = \dfrac{(1-\nu^2)\mu\omega^2}{8E}$, and b_1 and b_2 are constants of integration.

Donath discovered that by adding and subtracting the expressions for σ_t and σ_r and letting

$$S = \sigma_t + \sigma_r$$

$$D = \sigma_t - \sigma_r$$

$$u = \omega x$$

the following relatively simple functions were obtained:

$$S = (1+\nu)\frac{\mu}{2}\left[-u^2 + K_1\right]$$

$$D = (1-\nu)\frac{\mu}{4}\left[u^2 + \frac{K_2}{u^2}\right]$$

These functions were plotted for a series of K's, Fig. 3, covering a field of stresses and speeds in which disks in practical use will fall.

The common method of applying these curves to a conical disk is to assume the disk to be divided into a number of disks of uniform thicknesses (Fig. 4).

A simplification of the method of applying these curves to disks of variable cross-section was introduced by Mr. Driessen in his paper before the A.S.M.E. in the summer of 1928.[6] The use of the Donath curves by the common method with the Driessen simplifications can best be explained by applying them to a practical example.

Refer to the example represented in Fig. 4, assume the disk to be made up of four disks of uniform axial thicknesses and of equal radial thicknesses as shown. Since the tangential stress on the rim is not known, assume

$$\sigma_t \text{ for the rim} = 13{,}000 \text{ lb. per sq. in.}$$

then

$$S_{\text{rim}} = 13{,}000 + 8850 = 21{,}850$$

$$D_{\text{rim}} = 13{,}000 - 8850 = 4150$$

Having these values of S and D at the known rim speed locates the S- and D-curves applicable to this imaginary disk in Fig. 3. Transfer the S- and D-curves between the boundary speeds of this outer imaginary disk to Fig. 4.

Mr. Driessen's method of passing across a boundary by assuming that the tangential stress on either side of a boundary is the same and that the radial stress varies inversely as the thicknesses of the imaginary disks can be used at this point. He showed that

$$\Delta S = -0.65\left(1 - \frac{t_1}{t_2}\right)\left(S_1 - D_1\right)$$

$$\Delta D = 0.35\left(1 - \frac{t_1}{t_2}\right)\left(S_1 - D_1\right)$$

where ΔS and ΔD are the changes in S and D, t_1 is the thickness of the disk just passed, and t_2 the thickness of the disk being entered. In this case

$$\Delta S = -0.65\left(1 - \frac{0.72}{0.92}\right)\left(29{,}500 - 1500\right) = -3970$$

[6] "A Simplified Method of Determining Stresses in Rotating Disks," M. G. Driessen, Trans. A.S.M.E., 1928.

$$\Delta D = 0.35\left(1 - \frac{0.72}{0.92}\right)\left(29{,}500 - 1500\right) = 2140$$

Adding these increments to S_1 and D_1 gives S_2 and D_2, which are known values of S and D on the outer boundary of Division 2.

Following this procedure in crossing each of the imaginary disks, the S- and D-curves can be established across the entire radius of the disk. It happens in this case that the radial stress indicated at the hub by these curves is 5100, while the actual radial stress is known to be —710; this difference is an indication that the wrong tangential stress was assumed for the rim.

Assume another tangential stress of 13,800 for the rim, and establish the second set of S- and D-curves as are indicated in

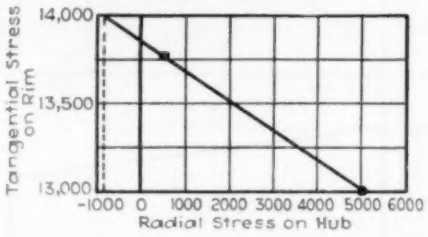

FIG. 5 RELATION BETWEEN RADIAL AND TANGENTIAL STRESSES ON HUB

Fig. 4. At the hub, this set of curves indicates a radial hub stress of 500, which is also incorrect.

At this point in the process, another one of Mr. Driessen's simplifications can be used. He showed that there was a direct relation between the radial stress on one boundary and the tangential stress on the opposite boundary. In this case the two assumed tangential rim stresses with their consequent radial hub stresses can be plotted as in Fig. 5. On this graph the tangential stress on the rim which will give a radial stress of —710 on the hub is indicated to be 14,000.

With this new value of tangential stress on the rim, the third set of S- and D-curves in Fig. 4 can be established.

Since the midpoint between the boundaries of each of the divisions is of the same thickness as the actual disk at that point, the values of S and D indicated at such points are assumed to be most accurate. Through these points the stress-distribution curves, Fig. 4, are established.

The stress-distribution curves obtained in this manner, as well as others obtained by using two and eight divisions of the disk, have been transferred to Fig. 8 where their relative accuracies can be obtained by comparing them to the exact stress-distribution curves.

ONE-EQUIVALENT-DISK METHOD

Some experimentation with the application of Donath's curves has shown that there are other satisfactory methods of applying them. One of the methods involves the assuming of one equivalent disk of uniform thickness equal to the hub thickness of the conical disk for the conical disk. Also, it is assumed that the radial rim stress on this imaginary disk is equal to the radial rim stress of the conical disk decreased in a ratio of rim thickness to hub thickness of the conical disk. To this new disk apply Donath's curves just as they would be applied to a disk of uniform thickness. The stresses indicated by these curves at the hub and at the midpoint between the rim and the hub and the known stresses on the rim are used to construct the stress-distribution curves.

For a better explanation of this equivalent-disk method, consider an example (Fig. 6). Assume

σ_t for the rim = 13,000

then

$$S_{\text{rim}} = \sigma_t + \sigma_r = 13{,}000 + 8850 = 21{,}850$$

$$D_{\text{rim}} = \sigma_t - \sigma_r = 13{,}000 - 8850 = 4150$$

Reducing the rim radial stress in a ratio of rim thickness to hub thickness gives the change in S and D by Mr. Driessen's method as

$$\Delta S = -0.65\left(21{,}850 - 4150\right)\left(1 - \frac{0.6}{1.5}\right) = -6900$$

$$\Delta D = 0.35\left(21{,}850 - 4150\right)\left(1 - \frac{0.6}{1.5}\right) = 3700$$

so $S_1 = 14{,}950$ and $D_1 = 7850$.

Locating these values of S and D on the Donath curve sheet at the rim speed establishes two curves which, when followed to the hub speed and transferred to Fig. 6, prove to be the correct ones since the indicated radial hub stress is the same as the actual hub stress. (σ_t for the rim was chosen correctly just by chance, otherwise other assumptions would have had

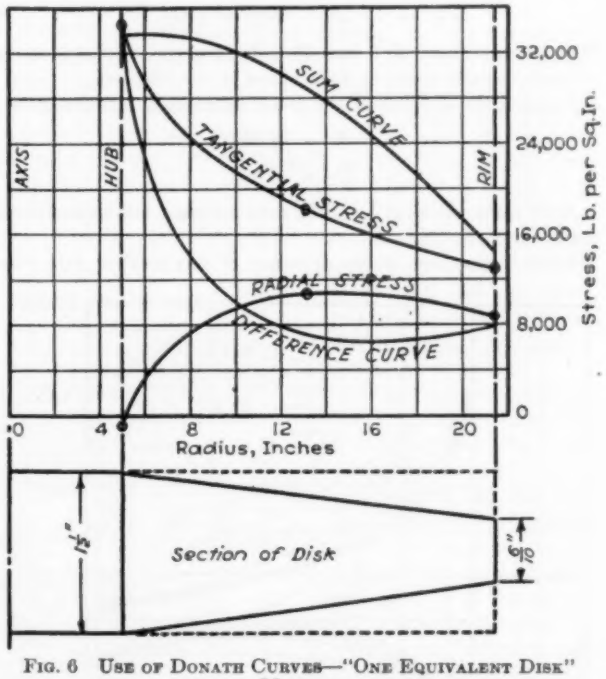

FIG. 6 USE OF DONATH CURVES—"ONE EQUIVALENT DISK" METHOD

(Material of disk, steel; speed, 3000 r.p.m.; rim load, 8850 lb. per sq. in.; hub load, —710 lb. per sq. in.)

to be made and Mr. Driessen's simplification would have been used if the second assumption had been incorrect.)

Refer to Fig. 8 for a comparison of the accuracy of this method with the exact stress curves and with the other approximate curves.

TWO-DIVISION METHOD

Experiment also shows that, by dividing the disk in the neighborhood of three-quarters of the distance from the hub to the rim, very satisfactory results can be obtained. With this method the S- and D-curves are established across the outer imaginary disk just as if the outer imaginary disk were of uniform thickness equal to the thickness of the rim. The boundary is crossed by assuming the indicated radial stress at the boundary to be decreased in a ratio of rim thickness to hub thickness of the conical disk. With the new values of S and D thus ob-

tained the curves are established across the inner imaginary disk. The values of stress indicated at the rim and hub and at midpoint between the division and hub are taken as points through which to construct the stress-distribution curves.

For a better explanation of the use of this method, apply it to an example (Fig. 7).

The radius of the division which has been found to give the best results can be calculated from the following formula:

$$X = \sqrt{\frac{\frac{b^4}{4} + \frac{a^4}{12} - \frac{ab^3}{3}}{\frac{b^2}{2} + \frac{a^2}{2} - ab}}$$

where b = rim radius, and
a = hub radius

Assume

$$\sigma_t \text{ for the rim} = 13{,}250$$

then

$$S_{\text{rim}} = 13{,}250 + 8850 = 22{,}100$$

$$D_{\text{rim}} = 13{,}250 - 8850 = 4400$$

With these values of S and D, establish the S- and D-curves between the rim speed and the speed at the division.

Crossing the division by the use of Driessen's formulas gives

$$S_2 = 17{,}500$$

$$D_2 = 6{,}000$$

With these values of S and D, the curves are established across the inner part of the disk.

For a comparison of the accuracy of this method with other methods, refer to Fig. 8. Note that the three points obtained for the tangential-stress curve fall upon the exact tangential-stress-distribution curve.

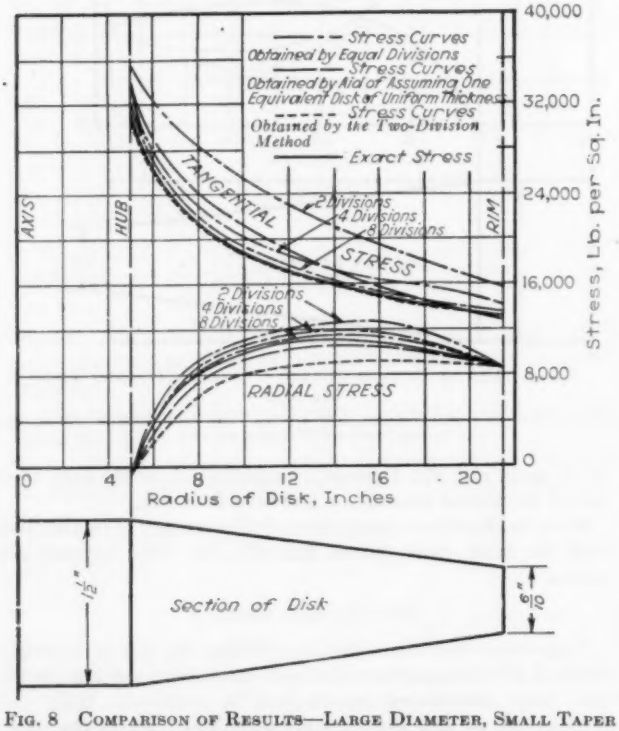

FIG. 8 COMPARISON OF RESULTS—LARGE DIAMETER, SMALL TAPER

APPLICATION TO A VARIETY OF DISKS

Figs. 8, 9, 10, 11, and 12 show the comparisons of the results obtained by the various methods on a variety of disks. The variations in the examples included are the diameters and tapers. From study of these examples, the most accurate approximate method can be selected for general use.

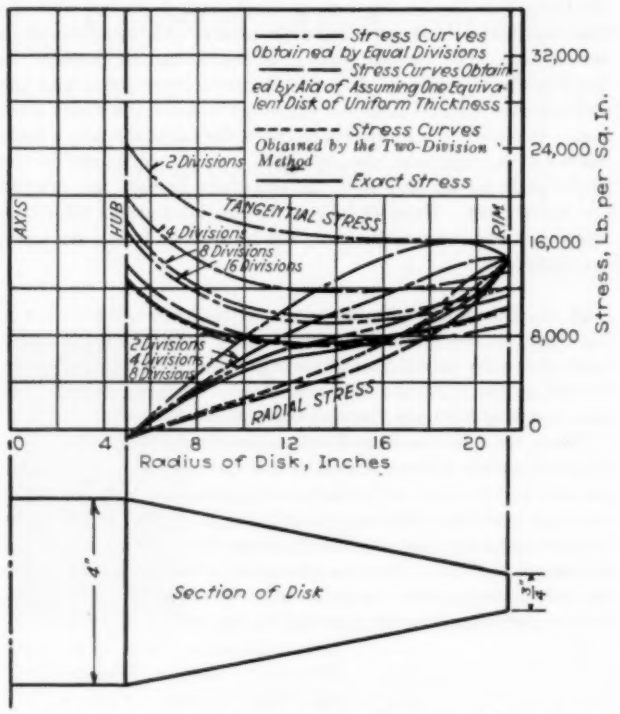

FIG. 10 COMPARISON OF RESULTS—LARGE DIAMETER, LARGE TAPER
(Material of disk, steel; speed, 1500 r.p.m.; rim load, 15,000 lb. per sq. in.; hub load, —500 lb. per sq. in.)

RESULTS

One feature about the stress curves obtained by the equal-division method is that they are in all cases higher than the exact stress curves. The reason for this higher stress indication is apparent since, in any one of the imaginary disks used, Fig. 4, there is assumed to be some material added and some material dropped along the radius, the added material being at a larger radius than the corresponding dropped piece of material. Since the effect of material varies as the square of its radius, this added material more than compensates for the dropped material.

In the comparisons of results, the relative accuracies obtained by two, four, and eight divisions of the disk can be seen. One important feature of the stress distributions obtained in this manner is that the accuracy increases at a rapidly decreasing rate as the number of equal divisions increases. For this reason, four equal divisions give as good results as eight. In one case where there was a high rim load and large taper, eight equal divisions gave an appreciable increase in accuracy over four divisions; however, sixteen divisions were very little better than eight in that case.

The stress-distribution curves obtained by the equivalent-disk method are satisfactory except in a case where the disk has a large taper and is running at a high speed. This method, Fig. 6, assumes a disk with more material at the rim, but the midpoint between the two boundaries is the point at which the additional material will compensate for the lower radial stress at the rim. As can be seen in the comparison of results, this method gives good results in most cases; and the error is fortunately on the safe side. The reason it does not give satisfactory results for a disk of large taper and high speed is that the added material becomes more effective as the speed increases.

The "two-division" method is a successful method of assuming a decreased radial load at some point in the disk and adding material to compensate for it at some certain point. Having this method work satisfactorily on the variety of examples included in this paper is an indication that it will give good results in all cases.

The practical value of Mr. Driessen's "Simplified Method of Determining Stresses in Rotating Disks" has been determined in solving the examples included in this paper. It would seem on first sight that his method of determining a correct value of tangential stress to assume on the rim, after having assumed two values unsuccessfully, would be of great value in the use of Donath's curves. However, after having used these curves

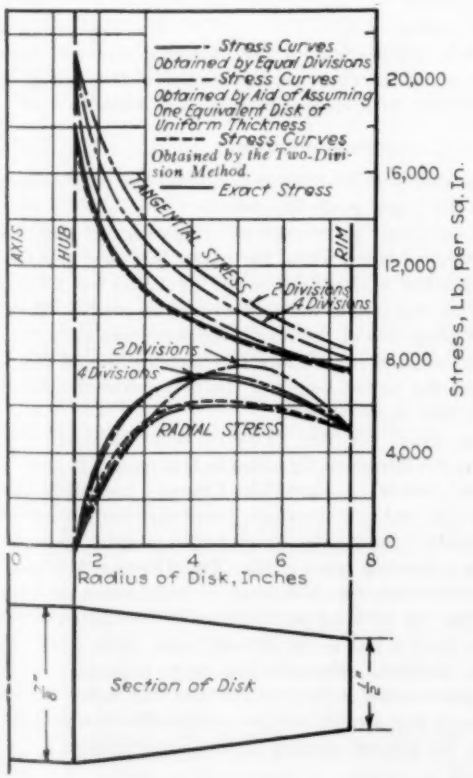

FIG. 11 COMPARISON OF RESULTS—SMALL DIAMETER, SMALL TAPER
(Material of disk, steel; speed, 5000 r.p.m.; rim load, 5000 lb. per sq. in.; hub load, —500 lb. per sq. in.)

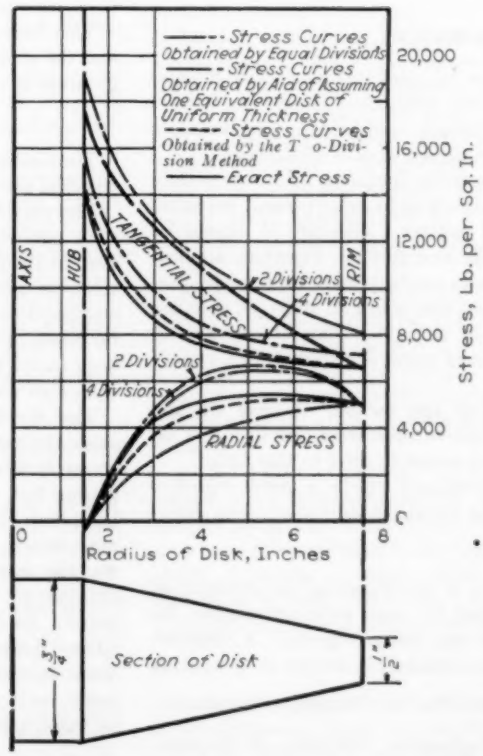

FIG. 12 COMPARISON OF RESULTS—SMALL DIAMETER, LARGE TAPER
(Material of disk, steel; speed, 6000 r.p.m.; rim load, 5000 lb. per sq. in.; hub load, —500 lb. per sq. in.)

for a number of disks, the author has found that a person with some experience in their use can determine mentally the correct stress to assume. Due to the limited field which the published S- and D-curves cover, a person will usually have to assume several stresses before he can establish curves which will not run off the curve sheet before they reach the hub speed; and by the time he has found a tangential rim stress which will not cause the D-curve to run off the sheet before reaching the hub speed, he is able to determine mentally the correct stress value to assume.

This condition is caused by the nature of the difference curves. The value of D on the hub is affected greatly by a small change in the tangential stress on the rim, while the value of S on the hub under similar conditions is affected but a comparatively small amount. The value of Mr. Driessen's method would be increased by an increase in the field which the published S- and D-curves cover.

Mr. Driessen's formulas for use in crossing a boundary between two imaginary disks of uniform thicknesses are of great value, as these simple expressions eliminate the necessity of computing an extensive table for that purpose.

Conclusions and Recommendations

1 In applying the Donath curves by equal divisions along the radius of a disk, four equal divisions of the disk will be found to give satisfactory results.

2 By the method of assuming one equivalent disk of uniform thickness for a conical disk, results of satisfactory accuracy can be obtained for all disks except in cases where the speed is high and the taper large.

3 By the two-division method proposed in this paper, accurate results can always be obtained.

Discussion

A. L. Kimball.[7] The writer has read this paper with interest as one with some familiarity with methods of computing stresses in revolving turbine disks, though not having that intimate knowledge that comes from continued work in disk design.

The value of this paper consists primarily in an up-to-date review of the subject such as cannot be found in present literature without dipping into several sources. Although it cannot be said to contain a fundamentally new method, ingenious application of the Donath and Driessen methods have been made, particularly in separating a conical disk into two steps, as specified by the formula at the top of page 96. This should greatly shorten the labor of calculation of stress distribution in a variety of shapes of conical disks.

Apparently the equations at the bottom of page 94 and the top of page 95 refer to a different disk from that of Fig. 4, although the discussion following seems to refer to this figure.

The paper is clearly presented, and will be a useful reference to have at hand when brushing up on the subject of stress determination in revolving disks.

S. Timoshenko.[8] The idea of investigating the accuracy of the well-known Donath method by using an exact solution for disks of conical profile seems a very interesting one. A considerable amount of work has been done by the author in comparing the Donath method, using various numbers of divisions, with the exact method. It is very desirable to give this comparison in percentages. For certain cases it appears that an increase in the number of divisions does not improve the results, and the approximate method does not converge toward the exact solution. It would be a good idea to check the calculations for these cases. It is important, also, to check over the equations on the fourth page for ΔS and ΔD; the equations as they are printed are not correct. Possibly in some of the calculations the incorrect equations were used, so it will be well to look over these calculations.

M. G. Driessen.[9] So far as the writer knows, the author is the first to compute the widely used approximate Donath method for the calculation of these stresses in rotating disks of conical profile. His studies show clearly the magnitude of the error made in applying the sum and difference curves.

The author also introduced a simplification by which the calculation of conical disks can be shortened considerably. He divides the disk in two parts as the radius of gyration, so that the upper part is a cylindrical disk with a width equal to the width at the rim and the lower part also a cylindrical disk with a width equal to that of the hub. He also showed that this latter method is the best approximation for different kinds of conical disks. The author uses the following formula for the radius of gyration X:

$$X = \sqrt{\frac{\frac{b^4}{4} + \frac{a^4}{12} - \frac{ab^2}{3}}{\frac{b^2}{2} + \frac{a^2}{2} - ab}}$$

where b = rim radius

a = hub radius.

This formula is independent of the widths at rim and hub, and the writer would therefore ask the author if the radius of gyration is the same for a large and for a small taper.

Author's Closure

The author wishes to express his gratitude for the constructive criticism given this paper in the discussion.

The general equations to be used in evaluating ΔS and ΔD were not written correctly when the paper was first printed; also, in the numerical example where the equations for ΔS and ΔD were used, the expressions were not written correctly. These changes do not affect any of the results obtained because a careful check of the original calculations has been made and it has been found that the correct forms of the two above-mentioned equations were used at all times.

The dividing point for the "Two-Division Method" was originally called the Radius of Gyration in this paper; it was incorrectly named, however. Since Mr. Driessen has called this glaring fact to the author's attention, stress-distribution curves have been obtained by using the actual radius of gyration of the cross-section as a dividing point in the "Two-Division Method." But the results obtained were not nearly as satisfactory as those obtained by using the dividing point originally introduced in the paper. As the facts stand at the present time, when using the "Two-Division Method," the dividing point originally introduced in the paper gives better results than any other known point; so it would best remain as it is until another can possibly be found when the subject receives further investigation.

Elastic and Inelastic Behavior in Spring Materials[1]

Progress Report No. 7 of the A.S.M.E. Special Research Committee on Mechanical Springs (Technological)

By M. F. SAYRE,[2] SCHENECTADY, N. Y.

AS SUGGESTED at meetings of the committee held a year ago, work during the past year under the auspices of the committee at Union College has been divided between a continuation of the fundamental studies previously started and some items of work of a more immediately practical nature. Progress Report No. 6[3] belongs in the second class. The present report describes the results obtained to date in connection with the more fundamental studies of the elastic behavior of spring materials.

These results may be summarized as follows:

1 A new method of work has been adopted, by which a greatly increased order of accuracy has been obtained in studies of behavior of spring materials in tension. Using a 52-ft. gage length, with dead-weight loading, under carefully controlled temperature conditions, readings of elongation can be taken to one part in fifteen million on the total length of the wire sample, with a probable mean accuracy under favorable conditions of one part in one million.

In most cases the controlling factor in accuracy tends to be the error resulting from the irregular plastic permanent yield, and from the gradual elastic or pseudo-elastic creep and recovery in the wire itself when loading and unloading.

2 Measurements obtained by this method have confirmed in general the tentative conclusions suggested in Progress Report No. 5. In particular it is now possible to give numerical values for the rate of change of Young's modulus of elasticity with stress for several materials. There is reasonably strong evidence that these same equations hold both in tension and in compression, although it has not yet been possible to obtain direct verification in compression.

3 The practical effect of this change of modulus as applied to spring design and manufacture is as follows:

a True stresses in compression are somewhat higher, and in tension somewhat lower, than the values given by the usual formulas. A sufficiently close approximation to numerical results may be obtained by first computing the maximum stress by the usual formula, and determining the per cent difference between the corresponding modulus of elasticity and the modulus as of zero stress. The per cent error in stress will be 70 to 75 per cent as great as the per cent difference in modulus

b The increasing stiffness in compression with increasing stress more or less completely counterbalances the decreasing stiffness in tension, so that apparent stress-deflection curves in bending or torsion will be almost unaffected by the variation in modulus

c In high-strength, highly elastic materials, such as are used in springs, it may be desirable, when selecting values of elastic limit from tensile stress-strain results, to make allowances for the curvature.

4 Tests have confirmed the general principle of a decrease in modulus of elasticity in tension as a result of previous overstrain in tension. This is an important reason for more or less erratic variations in stiffness of springs resulting from overstrain, as in surging. It also appears to be an important reason for a hidden safety factor in design, in that it causes the true stresses in highly overstressed areas to be appreciably smaller than the computed values. The amount of this decrease in modulus with overstressing is evidently different for different materials, and naturally depends upon the previous history of the material. It is therefore difficult to give numerical values, except in general terms.

An article in Japanese published last year by Mr. Tadashi Kawai (*Kinzoku no Kenkyu*, 1930, no. 7, pp. 177–201; abstract in the *Journal of the Institute of Metals*, vol. 43, p. 430) describes an extended study of this effect.

5 Work has been started on studies of the elastic after-effect. This has not yet gone far enough to justify drawing any conclusions.

6 Mechanical hysteresis values for unidirectional stress in tension have been obtained for several additional samples of various materials. Enough data have been obtained to serve as a basis of comparison in further studies of the relative suitability of various materials and of the effect of various types of cold work or heat treatments. A possible correlation between hysteresis values and fatigue strength deserves investigation.

Details of Work

In Progress Report No. 5, the results were given of a series of tests in tension made using an Amsler universal testing machine and a Riehlé-Sayre mirror extensometer. This method gave a relatively high order of precision, but it was evident that still higher accuracy was needed to obtain the best results. It was also evident that, in obtaining this higher accuracy, it was de-

sirable to use a new method sufficiently different in character from the old method to aid in detecting any systematic errors which may have been present. This suggested immediately the use of dead-weight loading rather than a testing machine, and the use of long gage lengths—as long as possible. It also suggested the need for accurate control of temperature.

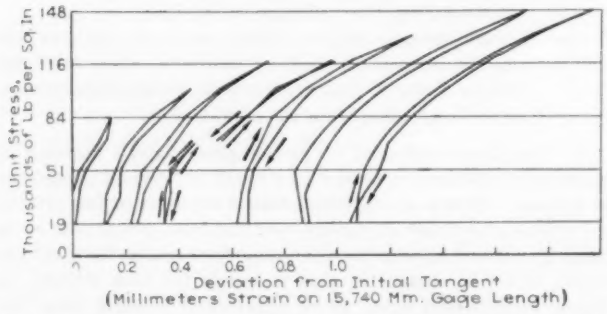

FIG. 2 TYPICAL HYSTERESIS LOOPS—0.67 PER CENT CARBON HEAT-TREATED STEEL WIRE

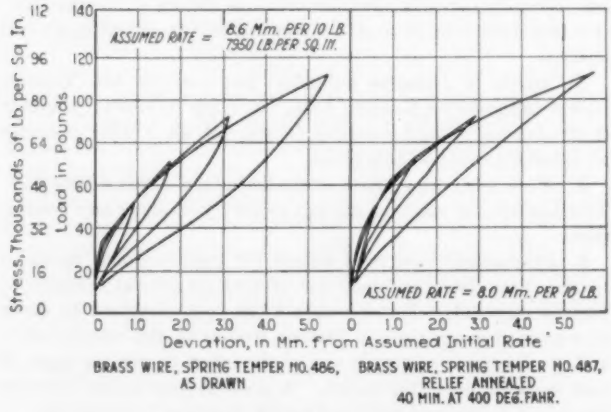

FIG. 3 TYPICAL HYSTERESIS LOOPS

There was available in the college laboratory a standpipe, five feet in diameter by somewhat over fifty feet high, with conical bottom and open top, which was used occasionally for hydraulic experiments. A hole was cut in the conical bottom, 4 in. from the circumference, and a 2-in. vertical steel pipe was placed in the standpipe above this hole, extending to slightly above the top of the tank. In this pipe were suspended two wires of the same material, a test wire and a comparison wire. At the upper end both wires could be sighted by a micrometer-microscope through a hole in the 2-in. pipe, and any vertical movement of either wire could be measured. At the lower end the comparison wire was connected to a lever, to which a small constant load was attached, and the test wire was attached to a basket, which could be loaded with standard weights. Movement of a gage point on the comparison wire, located just below the point where it emerged from the standpipe, was measured by a micrometer-microscope, and movement of the gage point on the test wire was measured by a Gaertner cathetometer, with 100-mm. lead screw. The overall gage length was approximately 15,740 mm., and each scale division on the cathetometer drum 0.005 mm.

The standpipe was filled with water to within a few inches of the top, so holding the temperature of the 2-in. pipe essentially constant during runs. Drafts of air up the pipe were prevented by lightly tucking a little cotton wool around the wires at the lower end of the pipe. The true elongation of the test wire under a given load was taken as equal to the change in the cathetometer reading, less the movement of the test wire at the top as given by the micrometer-microscope, corrected for any change in readings on the comparison wire which simultaneously occurred.

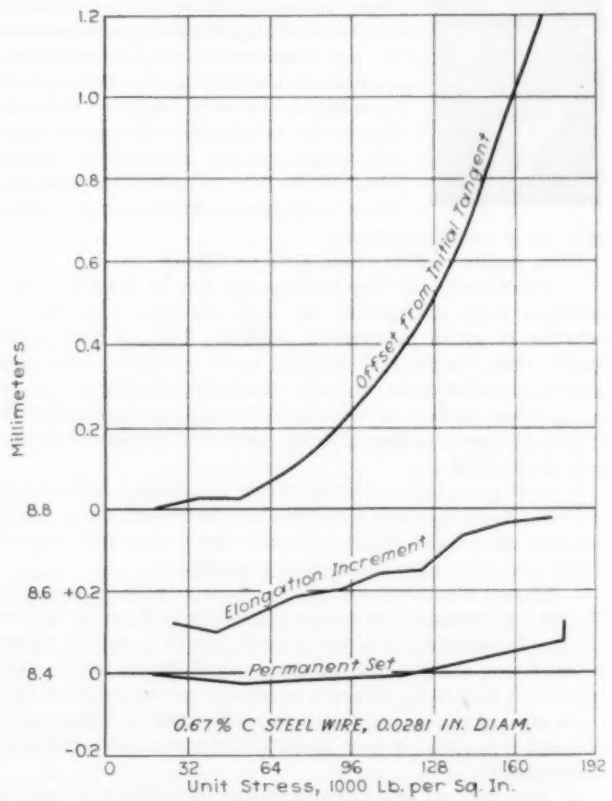

FIG. 4 ELONGATION RESULTING FROM STRESS INCREASE OF 16,000 LB. PER SQ. IN.

After a certain amount of preliminary experience, the following specifications were made up to cover the type of sample desired:

For convenience in loading, the diameter of the wire should be such that its breaking point will run between, say, 150 and 400 lb. Otherwise, the exact diameter does not matter. The method of preparation and heat treatment will, of course, depend upon the particular material, the general principle being to so treat as to develop its best properties for use as a spring.

Of each material there will be needed half a dozen lengths, each 55 ft. long, or, say, 400 ft. length in a single coil, free from sharp kinks or bends, and coiled on a sufficiently large-diameter reel so that it will straighten out under an initial load of 10 to 20 lb. when hung vertically. At first it was thought that the wire would have to receive its last reduction on some form of draw bench, so that it could be pulled out perfectly straight, but recent experience is that much more trouble is caused by small, sharp bends due to careless handling or by attempts to straighten the wire than by gradual curvature due to coiling on a drum. These sharp bends gradually straighten out under loading and ruin the numerical results. However, the larger this drum radius can be made, the better.

Please send with the material information as to the analysis, method of heat treatment, and final steps in the drawing, sufficiently detailed to thoroughly identify the material to others, and to make possible later comparison with other methods of handling.

Samples of 0.67 per cent carbon heat-treated steel, 17 SRT aluminum alloy, phosphor-bronze, and 70-30 brass in a drawn condition and after relief annealing have so far been tested. These samples are later described in detail.

It was of course necessary to overcome various practical difficulties. It was originally planned to use dead-weight loading for the comparison wire and a lever with a three-to-one ratio for the test wire, the lever having curved surfaces against which both the test wire and the load-basket support were carried so that the lever arms did not change as the wire elongated and

No. 2: 7950 lb. per sq. in.
No. 4: 6040 lb. per sq. in.

the lever tilted. Erratic readings were obtained, which were eventually traced to minute frictional resistance in the lever system. To avoid this, the lever was transferred to the comparison wire, and dead-weight loading was used for the test wire. This in turn left the test wire entirely free to swing, so that very careful technique was necessary in applying and removing loads, in order to avoid putting it in vibration. Another source of difficulty was combined backlash and friction in the micrometer used. By adjustments in the micrometer and by following a careful routine in the work, this has been reduced, but it is still a source of trouble.

Certain other difficulties also inhere in the nature of the materials themselves. For the purposes of this work it was desirable to distinguish as far as possible between the elastic elongation, which occurs instantaneously or nearly so; the plastic elongation or "permanent set," which is a function of time, but apparently an irregular function, sometimes stopping then starting again with but little evident cause; and the elastic or pseudo-elastic after-effect, a gradual elongation on loading, followed by as gradual a recovery to original length on unloading.[4]

[4] An investigation of the characteristics of this elastic after-effect has been started and the results will presently be reported.

It is accompanied by mechanical hysteresis or "back error," but the two seem to be more or less independent in character. At the sensitivity present in this work all these factors are large

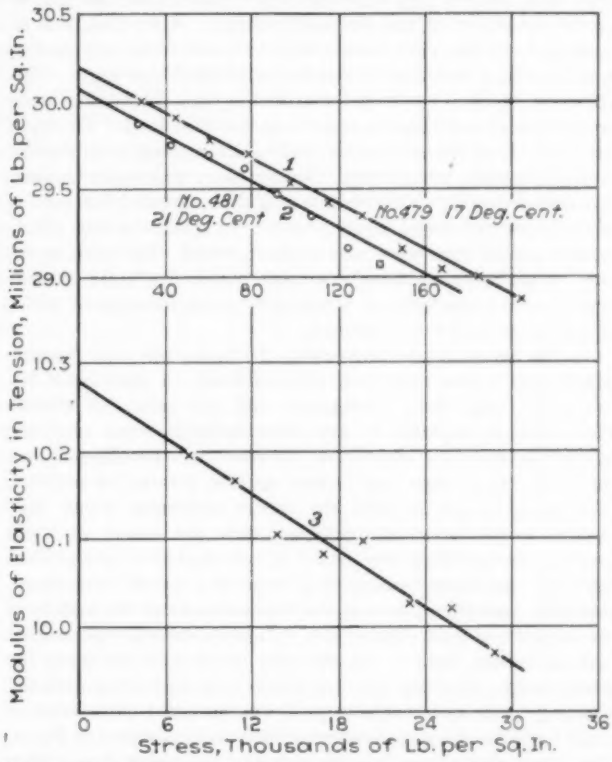

FIG. 6 VARIATION OF MODULUS OF ELASTICITY WITH TENSILE STRESS

(Wire samples 52 ft. gage length.)

enough to be important, and careful planning of work and adherence to a time schedule of observation are needed to avoid widely erratic readings.

In studying hysteresis, the specimen was first loaded to the desired maximum load, and the load left on until plastic yield

had ceased and the length of the specimen had become substantially constant. The specimen was then put through a series of cycles between a nominal initial load and the desired maximum load until it had approached a cyclical state, as judged by the constancy of the zero-load reading. After this, sets of readings were taken for three complete cycles from zero load to maximum load, and back to zero again by small load steps. The difference between readings for ascending and descending loads gave the width of the hysteresis loop for that load. To apply the load, adjust the micrometer, and take a reading, took slightly over one minute per reading. Every effort was made to keep this time constant. This routine was then repeated for successively larger and larger stress ranges. To study the time effect, certain special runs were also made in which after each increment of load a first reading was taken within five to six seconds after the load was applied, followed by other readings at sixty-second intervals for five minutes.

As the stress ranges increased, the hysteresis loop became wider, and it was more and more difficult to distinguish between the true elastic elongation and the collateral effects. This made it desirable to use other methods when studying modulus-of-elasticity variations. In runs made for this purpose, the total stress range was broken up into a series of sections, each short enough so that the elastic hysteresis within that portion would be small. Starting with the lowest of these sections, the specimen was placed in a cyclical or nearly cyclical state by successive loading and unloading within this range. Readings were then taken at the two ends and at the middle of the range for at least three cycles. This routine was repeated for each successive section. In this way, instead of obtaining the stress-strain curve for the specimen with ascending and descending loads as a single loop, it was obtained as a series of small loops touching each other at their tips, as shown in Fig. 1. The slope of a center line through the successive loops, after correcting for plastic yield between the loops, was taken as the true elastic line.

Materials Used

The analyses and physical properties of the wire samples tested, as furnished by the manufacturers, are as follows:

Oil-Tempered Steel Wire

Size	C	Mn	S	P	Si	Tensile strength, lb. per sq. in.	Elongation in 10 in., per cent
0.028 in.	0.67	0.35	0.047	0.054	...	277,000	3.8

Finished with a reduction of 8 B and S Nos. (84.5 per cent reduction of area)

Summary of Results

Typical sets of stress-strain readings for complete closed loops in approximately cyclical condition are given in Tables 6A to 6H.[5] The correaponding stress-strain curves are shown in Figs. 2 and 3. In these figures, stress is used as an ordinate. As an abscissa, is used not the true strain but rather the deviation from an assumed initial rate of strain, the difference between the actual strain and that which would have occurred had the assumed initial rate of strain been uniformly maintained. In this way it has been possible to tremendously exaggerate the variations which it was desired to observe. These curves are plotted point to point from actual observations.

The area of these loops represents the energy lost in internal friction in the corresponding cycle. Converted into terms of inch-pounds of energy per cubic inch of material, these values for the different wires tested are given in Fig. 5. Dividing by the total elastic energy involved per cycle, the per cent loss may also be obtained.

The following general characteristics may be noted:

1 The energy loss increases sharply with stress, at a higher power than the square.

2 It was shown in Report No. 5 that for the heat-treated steel samples there tested, a sharp rise in hysteresis occurred on approaching the yield point of the metal. No such sharp rise has been noticed in the non-ferrous materials. This is a natural result of the nature of the materials, but may be partly connected also to the relative amount of cold drawing following heat treatment in the two cases.

3 The hysteresis loops are unsymmetrical and typically convex upward. In the steel samples, the loops are narrow enough so that they have a definite "string bean" shape, and so that a line midway between the two sides can be taken as approximating the true elastic line. For the phosphor-bronze and the relief-annealed brass wire the ascending line is definitely convex upward, while the descending lines are straight or slightly convex upward.

In successive loops, starting from the same nominal initial load, and rising to successively greater peak loads, the ascending lines essentially coincide, while the descending lines differ for the different loops.

Modulus of Elasticity

Measurements made specifically for the purpose of obtaining modulus of elasticity were, as already described and as indicated in Fig. 1, taken as a series of successive short loops. Measurements were in each case taken only after the specimen had been loaded and unloaded over the load range of that loop a sufficient number of times to place the sample in approximately cyclic condition. Some of the resulting values are given in Tables 3 and 4,[5] first in terms of the actual increments of load, and then in terms of the equivalent moduli of elasticity. These results are shown in graphical form in Figs. 6 and 7. In each case the rate of elastic elongation increases as the stress in tension increases.

Fig. 4 shows these same results for the steel wire in a somewhat different fashion. It also shows the magnitude of the permanent set resulting from the application of various loads to the wire. This did not reach 0.05 mm., or one part in 300,000 until the stress reached 160,000 lb. per sq. in. It will be noticed that both the width of the hysteresis loop (as given in Fig. 2) and the amount of the permanent set are small as compared to the variations in the elongation increments and to the offsets from initial tangent, so that these variations apparently represent the true elastic behavior of the materials rather than deviations from it.

[5] Not published in the present report.

TABLE 1 MODULI OF ELASTICITY OF SPECIMENS TESTED

MEASUREMENTS MADE USING AMSLER MACHINE

Specimen	Material	Temp., deg. fahr.	Modulus
111	0.68% C heat-treated steel wire, 1/8 in. × 1/2 in.	76	29,700,000 — 7.7 × S
112	Do.	76	30,100,000 — 6.8 × S
113	Do.	76	29,500,000 — 8.3 × S
530 } 538 }	3 1/2% nickel steel 1/8 in. diam.	78	29,140,000 — 4.3 × S
476	Do.	73	28,930,000 — 10.9 × S
306	Spring-tempered phosphor-bronze, 1/8 in. × 1/2 in.	72	14,680,000 — 10.8 × S

MEASUREMENTS MADE USING DEAD-WEIGHT LOADING[1]

481	0.67% C heat-treated steel wire, 0.0281 in. diam.	62.6	30,040,000 — 6.6 × S
479	Do., 0.0465 in. diam.	69.8	30,160,000 — 6.5 × S
483	17 SRT aluminum-alloy wire, 0.065 in. diam.	72.5	10,280,000 — 10.9 × S
493	Spring-temper brass wire as drawn, 0.040 in. diam.	72	14,610,000 — 7.1 × S
	Do., after 0.22 per cent permanent set	70	14,300,000 — 4.9 × S
485	Do., relief-annealed, 0.040 in. diam.	69	15,680,000 — 13.8 × S
494	Phosphor-bronze wire, 0.040 in. diam.	70	15,540,000 — 5.0 × S
	Do., after 0.16 per cent permanent set	70	15,380,000 — 4.5 × S

S = unit stress in tension, lb. per sq. in.

[1] The figures obtained using dead-weight loading and long gage length are somewhat more reliable than the other figures.

Due to the amount of elastic creep and recovery present, it is somewhat more difficult to specify true values for modulus of elasticity for the other materials. By varying the technique of operation, varying amounts of this elastic after-effect can be included in the readings, with resulting effect on the apparent modulus of elasticity. After some experimenting, it was found that reasonably consistent results could be obtained by taking the reading in each case at one minute after application of the load increment.

As obtained from the data so far obtained, the values of modulus of elasticity given in Table 1 are tentatively suggested. It should be emphasized that these values represent only the particular materials tested. A large amount of time and attention has been required for each series of tests, and therefore only a limited variety of samples have been tried. The investigation has not yet gone far enough to justify conclusions as to whether the rate of change of modulus of elasticity is a definite characteristic of the material or whether it varies with different types of heat treatment or of mechanical work. Further experiments are in progress for the purpose of covering some of these points.

A detailed study of the original data shows for each material a decrease of modulus of elasticity following overstresses great enough to produce a permanent elongation of the specimen. This is evident even for elongations no greater than one-tenth of 1 per cent, and even for material already severely cold-drawn. The per cent change in modulus is several times as great as the corresponding permanent set, even after all corrections have been made for the change in length and change in area of cross-section. There is a certain amount of evidence suggesting that in some cases with more severe overstressing there may be a reversal, the modulus increasing somewhat. A further knowledge of this factor is needed in order that we may understand the true stress conditions in cold-wound springs or in springs after surging and the investigation is being continued.

Discussion

R. L. TEMPLIN.[6] The author has given some very accurate and very interesting test results obtained from precise measurements of strain using very long gage lengths or specimens. The difficulties encountered in making such tests are quite numerous because factors which can frequently be ignored in the short-time tests may become of considerable significance in tests of the type represented.

It is generally accepted that at stresses near the elastic limit the modulus of elasticity of metals decreases quite rapidly, with the result that many investigators attempt to show that the stress-strain curve is curved from the origin. Dr. R. H. Canfield of the Naval Research Laboratories, Washington, D. C., pointed out before the Third International Congress, held at Stockholm last summer, that there appears to be a threshold stress below which the internal friction or slip was less than any measurable quantity. Interpreted in terms of Figs. 6 and 7 of the paper, this would mean that the curves would tend to become horizontal near the zero stress. Close scrutiny of the data presented by the author would appear to justify this conclusion. Fig. 7 shows data which exhibit this tendency to a marked degree, while there is less of a tendency in that direction shown in the data for Fig. 6.

R. W. CARSON.[7] The author is working on a problem which is interesting many manufacturers of precision apparatus. For rough-and-ready measurements of loads under the elastic limit, Hooke's law is usually satisfactory. However, when an accuracy greater than 1 or 2 per cent is required, these set and creep effects begin to manifest themselves. As the author indicates, the greater the sensitivity, the more involved becomes this elastic after-effect.

Is not the effect of moderate overstrain in cold-drawn phosphor-bronze wire to cause plastic flow in zones having high residual stresses, thus leaving the wire when returned to the unloaded condition with uniformly smaller residual stresses in the direction of the loading? If so, upon again moderately loading the wire in the same direction as that in which the over-stress was applied, the total of all the stresses across the section would then be smaller by an amount equal to the residual stresses relieved. Thus, the difference in elastic limit as noted in Fig. 7 would indicate the intensity of the residual stresses relieved rather than a change in the elastic properties of the material.

The same apparent change in modulus of elasticity might result from a mild heat treatment that would be just sufficient to allow a redistribution of high local stresses which would result in lower average stresses.

If the rate of creep or recovery action decreases with time and increases with stress, at some time very soon after the application or removal of a given load the creep or recovery action might equal the rate of purely elastic strain. Thus, the purely elastic and the creep or recovery action might be continuous and might be one and the same action over the entire time scale from the instant of applying load to the instant of further changing the load.

If such be the case, the width of the hysteresis loops would indicate only a relative amount of creep and recovery dependent on the time at which readings are taken. The recovery action might be of a slightly different order than the creep action, and in that event the reading time after applying load would vary for increasing or decreasing loads. Further, the hysteresis loop would not represent internal friction or work, since with sufficient time all of the work done in creep would be utilized in recovery.

W. G. BROMBACHER.[8] The fundamental nature of the author's work on the elastic behavior of spring materials should be emphasized. While the research does not now appear to have much application in many cases, undoubtedly, as with most fundamental research work, the results will be found to be use-

ful. There is a tendency at the present time in metallurgical literature to avoid giving exact data on the moduli of elasticity. It is the practice to give either approximations or the two limiting values of the moduli. This is a clear recognition of the lack of precise knowledge as to the moduli of a given material under various conditions. The author's experiments are bringing light on this matter. His results show clearly that "elastic after-working" and "elastic hysteresis" must be considered in obtaining accurate and complete experimental data. These elastic effects have long been known and recognized by workers, especially those in the field of precision instruments. The first clear analysis of these phenomena was presented by Boltzmann, and it may be added that but very little improvement has been made up to the present in his theoretical presentation.

Special attention should be called to the author's method of experimentation since it is peculiarly well adapted for obtaining satisfactory data. It has two distinct advantages over most methods which should be clearly recognized. First, the specimen is uniformly stressed during the experiments. Second, the large length of the specimen, about 50 feet, permits results to be obtained to the essential high order of sensitivity with a minimum of expense and complication. The first advantage, of course, pertains only to the data obtained when the specimen is stressed in tension. The method will also enable data to be obtained for the torsional stresses, in which case the stressing will be non-uniform.

The lack of a satisfactory and universally accepted nomenclature should be stressed. Thus the author uses the term "elastic after-effect," which is referred to in the literature on the subject by such terms as "after-working," "drift" or "creep," and "recovery." These terms usually refer to the effect which is dependent on the time of application of the load as well as on the fiber stress and the material. The term "mechanical hysteresis" used in the report has been designated by other workers as "statical hysteresis," "elastic hysteresis," and "elastic lag due to elastic hysteresis." These terms usually refer to the effect which is independent of the time of the application of the load, but of course may depend on the fiber stress and the material. It should not be assumed that the preceding list of terms is complete, since many other expressions have been coined. It would appear desirable that workers in this field give consideration to obtaining the universal acceptance of a consistent nomenclature.

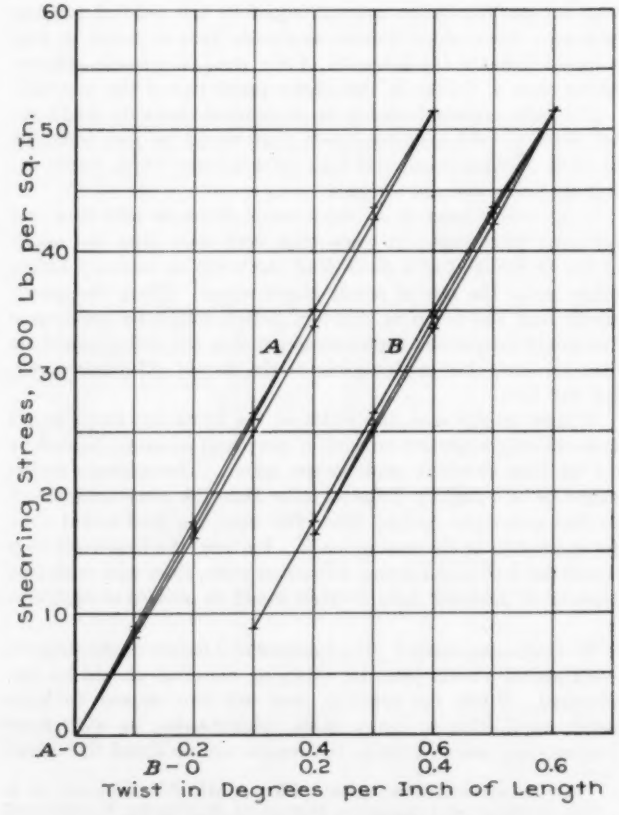

FIG. 8 HYSTERESIS CURVES—MILD STEEL

W. J. SWEETSER.[9] The author mentions the noticeable vibration set up in the test specimen when a truck passed at some distance from the building in which the work was being done. It seems probable that some of the apparently erratic behavior of the test specimen under constant load may be due to vibrations which are not detectable by ordinary means. The set-up of the test with suspended load is ideal for producing impact by vibration, and even unobserved vibrations of the foundation under the tank might give observable changes in elongation, especially when the order of magnitude of the measurements is so small.

Fig. 1 shows the curves for hysteresis and modulus-of-elasticity measurements, but in work which we have been doing at the University of Maine on steel in torsion, we have been unable to get such a series of readings as indicated at (*b*). Fig. 8 shows the hysteresis curve of an overstressed piece of mild steel in torsion. Three months before these curves were made the steel had been stressed to over 60,000 lb. per sq. in. in torsion and had been allowed to rest in the meantime. In curve *A*, the stress was increased gradually up to the maximum shown and then reduced to 0, giving a complete hysteresis loop. It was then restressed up to 35,000 lb. per sq. in. and returned to 0, giving the narrow hysteresis loop. The up curves in the two cases coincide. Curve *B*, shown at the right, shows a second hysteresis loop made by reducing the load from the maximum down to a stress of about 16,400 lb. per sq. in. and then returning to the maximum stress. In this case the curve coming down coincides with the original down side of the loop.

It is quite evident that the down side of the small loop in *A* is steeper than the down side of the larger loop, and similarly the up side of the small loop in *B* is steeper than the up side of the large loop, which would indicate that if a series of these small loops were put together as shown in (*b*), Fig. 1, the general slope of the series of small loops would not be the same as the mean slope of the curves shown at (*a*).

Taking the up curve of one of the small loops in (*b*), if it were continued it would tend to cross over and to the right of the coming down side of the loop above, and the writer is unable to see how this condition is possible.

D. E. ACKERMAN.[10] In his presentation of the paper the author mentioned that the curvature of the wire due to coiling on a drum was an important source of experimental error, and stated that several lots of wire had to be discarded because they had been coiled on too small a radius. It would be of interest to know the order of magnitude of the error, introduced in this way, as a function of the wire diameter and radius of curvature.

In Figs. 6 and 7 the author has indicated that the modulus-of-elasticity–tensile-stress relationship is linear. The writer would ask him whether the scattered data of curves 1 and 3,

[9] Professor of Mechanical Engineering, University of Maine, Orono, Me. Mem. A.S.M.E.

[10] Research Laboratory, International Nickel Co., Inc., Bayonne, N. J.

Fig. 7, are indicative of a high experimental error in these two cases, or whether the relationship for the corresponding materials simply follows a law of higher order; smooth curves can be drawn through the points plotted for the two curves in question. This point is of practical interest, for if the true relationship is of a higher order the plotted data suggest that at high tensile stresses the more severely cold-worked material may have the higher modulus of elasticity.

Author's Closure

One of our greatest difficulties in securing satisfactory results in these long-wire tests has been that of obtaining wire which was sufficiently straight for the purpose. The effect of local kinks or of curves in wire is, of course, greatest under light loads, the wire straightening out under heavier loads. As a result, there has been frequently found a spurious low modulus of elasticity under light loads. This has been very marked, indeed, in several cases, and unmistakable in its origin. It has therefore been necessary to discard altogether the results obtained from certain samples of wire and to use a grain of salt in interpreting other results where the author did not feel justified in discarding them entirely. Of the wires listed in Figs. 6 and 7, the steel ones were almost perfectly straight as received. The sample of aluminum wire which we were able to use was sufficiently straight so that it gave us very little trouble. The phosphor-bronze and brass wires were coiled on smaller-sized spools and so had a more pronounced curvature. This leads the author to regard with some suspicion the readings for these wires taken under light load.

On all the bona-fide straight samples which we have tested so far, our stress-strain line has been curved from the beginning. The one point of doubt remaining in the author's mind is as to the effect of elastic creep or elastic after-working upon the results. When a metal is loaded, most of the elongation occurs practically instantaneously, but it continues to elongate at a rapidly decreasing rate for five minutes or longer. This is true even at very low stresses. On removing the load an identical phenomenon occurs, but in the reverse direction. It is just possible that if our readings could be made coincidentally with the application of the load, and this after-effect entirely removed, our stress-strain line would be perfectly straight.

There are, however, very strong theoretical reasons for believing that this would not be so. For example, it has been definitely known for some time that the modulus of elasticity of a material under hydrostatic compression increases with increasing loads. The modulus in hydrostatic tension will obey the same equation as for hydrostatic compression, but with reversed sign, decreasing with increasing loads. Unidirectional tension is essentially a combination of hydrostatic tension and shear, and a direct relation should exist between the variation with stress of the moduli for hydrostatic tension and for direct tension. This is simply one of a series of theoretical reasons which make the author feel that it is highly unlikely that a stress-strain line for such relatively homogeneous materials as those which are here under investigation will be anything else but curved. Inhomogeneous materials such as wood, concrete, and cast iron also show a curved stress-strain line, but this curvature occurs for different reasons and is of an entirely different character, the modulus decreasing with increasing stress both in tension and in compression.

Reference may well be made to various comments on the erratic behavior shown by the plotted points in Fig. 7 for the 70–30 brass relief-annealed wire. A second wire of the same material, tested since December, has given the same curved line arrangement of points, so that it is apparently characteristic of the material. In certain of the other materials the decrease in modulus of elasticity at high stresses can be attributed to the permanent lowering of modulus which is likely to follow overstressing, but this does not appear to be the case in the wire just mentioned. No other material so far tested has duplicated this phenomenon, and the author does not as yet know how to explain it. It might, however, be well to notice that at low stresses the curved line which best represents the readings for wire No. 3 becomes asymptotic to the inclined line for specimen No. 1 rather than to a horizontal line.

The suggestion made by Mr. Carson that the creep or recovery action might be essentially continuous with the purely elastic action, is identical with the theories advanced by von Bennewitz in a paper in the *Physikalische Zeitschrift* for 1924. Von Bennewitz gave mathematical equations based on experiment to justify his theory, but these equations involved so much extrapolation beyond the limits of his experimental work that they have not been regarded with favor.

Figure 1(*b*) is misleading in that it shows the series of small loops as directly in line at their tips. Experimentally, when passing from cyclic condition for one load range to cyclic condition for a slightly higher load range, there is inevitably a certain amount of permanent, or semi-permanent, deformation so that two loops do not exactly match at their tips. This deformation will, the author believes, account for the discrepancies mentioned by Professor Sweetser as compared to his curves *A* and *B* in Fig. 8. When computing the modulus of elasticity, correction was made for this deformation so that figures were based on the effective slope of the individual small loops only.

APM-53-9

Forced Vibrations With Combined Coulomb and Viscous Friction

By J. P. DEN HARTOG,[1] EAST PITTSBURGH, PA.

Steady-state vibrations of mechanical systems damped by a combination of dry and viscous friction occur quite frequently, but until very recently no method for their calculation existed. A very satisfactory approximation was presented by L. S. Jacobsen before the A.S.M.E. in June, 1930. In the present paper the author gives the exact solution of the problem, together with a number of test results.

THE damping forces occurring in practical engineering vibration problems are of a great variety. The four types met most frequently are:

1 "Viscous" damping, where the force is proportional to the velocity, which fairly accurately describes the condition in viscous fluids

2 "Coulomb" damping, or dry friction, where the force is independent of the velocity, and depends only on the normal pressure

3 "Air resistance," which is assumed to be proportional to the square or some higher power of the velocity, and

4 "Internal hysteresis," where the force is independent of the velocity and depends only on the amplitude of motion.

The calculation of the steady-state vibrations of a damped system is possible with comparatively simple means only in the case of pure viscous damping, while for the other types of damping no solutions are known.

Whenever such problems were attacked in the past, the actual damping was usually replaced by some equivalent "viscous" damping, the amount of which was either assumed or calculated from an experiment.[2]

Recently a more rational method has been proposed for finding this "equivalent" viscous damping constant, consisting of calculating the amount of energy dissipated during a cycle of the vibration and adjusting the viscous damping constant to such a value that this dissipation in the calculated viscous case agrees with the actual case. This method was used by Southwell and Carter[3] for the case of Coulomb or dry friction at resonance; by Lewis[4] and Kimball[5] on internal hysteresis in metals, while Jacobsen[6] generalized the method for any damping proportional to the nth power of the velocity.

The accuracy of this general procedure, in the author's opinion, cannot be estimated unless its results are compared with those of an exact solution, which for most of the cases enumerated above has not been found as yet. Eckolt[7] has published a solution for a special case (motion with one stop) of pure Coulomb damping. His results are erroneous in several places. The author[8] has given a solution for another special case (non-stop motion) for combined Coulomb and viscous damping. The present paper, however, contains a complete solution of the problem.

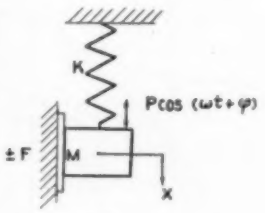

FIG. 1

FORCED VIBRATIONS WITH DRY FRICTION ONLY

Consider the simple system shown in Fig. 1, where a mass m is suspended from a spring with a stiffness of k lb. per inch and is acted upon by a periodic disturbing force $P \cos(\omega t + \varphi)$. In moving, the mass rubs against a solid wall which exerts a frictional force F on it opposing its motion but is otherwise constant and entirely independent of the velocity. After the system has been in motion for some time a "steady state" will have been reached which must satisfy the following conditions: (1) The frequency of the motion must be the same as that of the disturbing force; and (2) the downward half-cycle of the motion must follow the same law as the upward half-cycle. Figs. 2 and 3 show two possible types of such a motion.

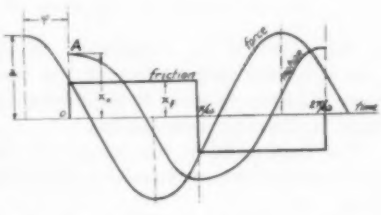

FIG. 2 DIAGRAM OF MOTION WITHOUT STOPS

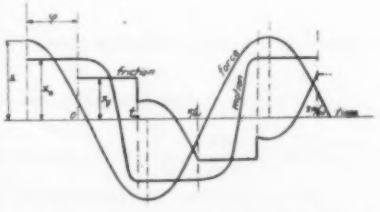

FIG. 3 DIAGRAM OF MOTION WITH ONE STOP

In Fig. 2 it is assumed that the mass never comes to a dead stop. Since the frictional force is always opposed to the motion it must be represented by the rectangular top curve shown in

the figure. The spring force acting on the mass is k times the deflection or motion, so that the motion curve can be regarded as representing the spring force. It will be noticed that at the upper and lower peaks the motion curve suddenly changes its curvature. The explanation of this is that the curvature is proportional to the second derivative. The second derivative

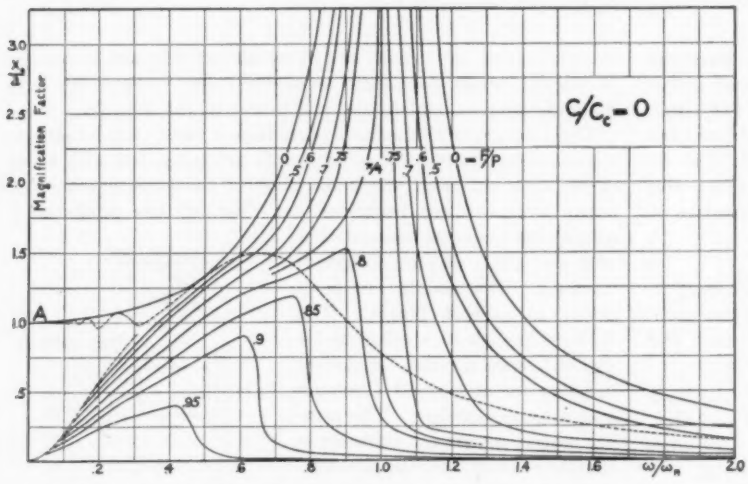

FIG. 4 AMPLITUDE DIAGRAM WITH COULOMB DAMPING ONLY

of the motion is the acceleration, which is proportional to the sum of all the forces acting on the mass. Since the frictional force suddenly reverses at the peaks, the curvature there must show a discontinuous change.

The amplitudes of the motion of the type shown in Fig. 1 have been solved analytically in Appendix No. 1, with the result that

$$\frac{x_0}{a} = \sqrt{V^2 - \left(\frac{F}{P}\right)^2 U^2} \quad \ldots\ldots\ldots\ldots [1]$$

where $\frac{x_0}{a}$ is the "magnification factor,"

$V = \frac{\beta^2}{\beta^2 - 1}$ the "response function,"

$U = \frac{\beta \sin \beta\pi}{1 + \cos \beta\pi}$ the "Coulomb damping function," and

$\beta = \omega_n/\omega$ the "frequency ratio."

These expressions will become clear from an inspection of Fig. 4, where the numerical results of [1] are plotted in a family of curves. Only the part of the diagram above the broken line corresponds to Formula [1] and Fig. 2.

The "frequency ratio" is the ratio between the natural frequency of the undamped system and the frequency of the disturbing force.

The "magnification factor" is the ratio between the actual amplitude of the motion and the amplitude which would occur without friction and with an infinitely slow motion.[9] It can be easily seen from Fig. 1 that this latter "statical" amplitude must be equal to P/k. In Fig. 4 it is represented by the point A.

The "response function" is the magnification factor as a function of the frequency when there is no friction. In Fig. 4 it is the upper curve of the diagram. It is a well-known and fundamental curve in all vibration investigations.[10]

In Formula [1] there are two terms under the radical sign. Both are squares and therefore necessarily positive. It is seen from the formula that without damping ($F/P = 0$) the magnification factor is given by the response function V, and that for any value of the friction, F/P the magnification factor is smaller than without damping, as it should be. A remarkable property of the solution [1] is that for any friction ratio F/P smaller than $\pi/4$ or 0.785 the amplitude becomes infinitely large. In other words, even with a considerable amount of dry friction, the amplitudes at resonance still extend to infinity. This apparently paradoxical fact can be understood by considering the energy involved as follows:

Referring to Fig. 1, before the system, excited at resonance ($\omega = \omega_n$), reaches the "steady state," the energy per cycle put into the system by the force $P \cos(\omega t + \varphi)$ will be proportional to the product of the force and the amplitude,[11] and since the force does not depend on the amplitude, the energy input per cycle will be proportional to the first power of the amplitude. The work absorbed by the constant damping force F will be also proportional to the amplitude for the same reason. Both will be represented by straight lines in Fig. 5(a). The slope of the input curve depends on P and the slope of the dissipation curve on F. As long as F is small enough to make the slope of the dissipation curve smaller than that of the input curve (which happens for $F/P < \pi/4$) there will be always positive work input into the system, which will make the amplitude larger and larger.

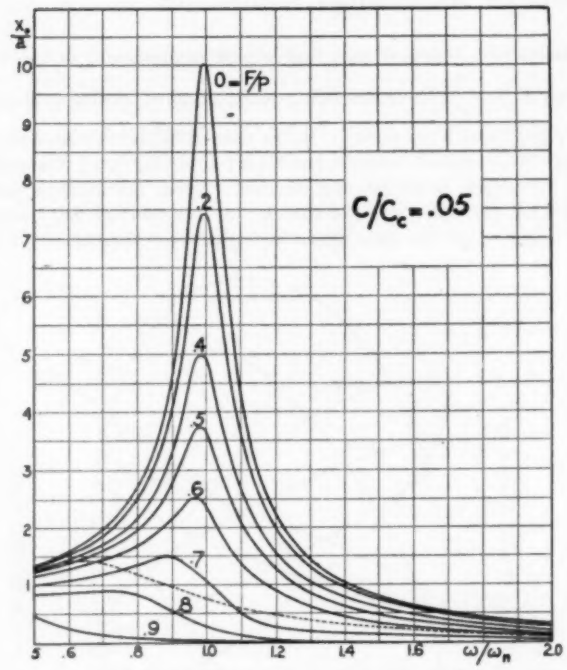

FIG. 7 AMPLITUDE DIAGRAM WITH MIXED DAMPING

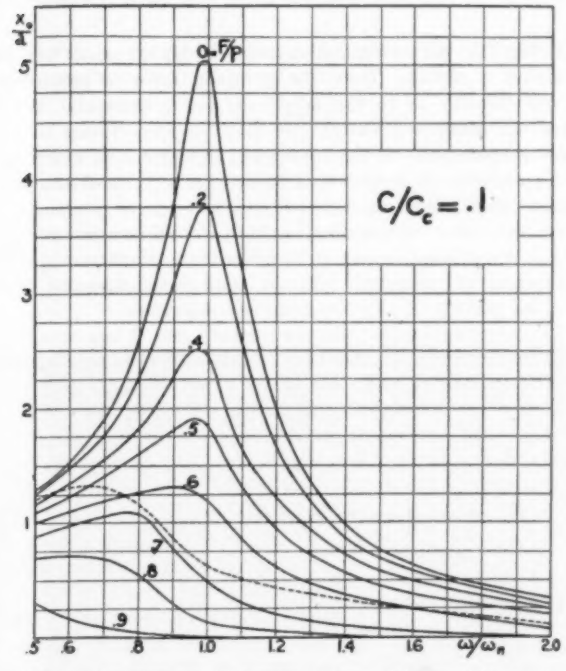

FIG. 8 AMPLITUDE DIAGRAM WITH MIXED DAMPING

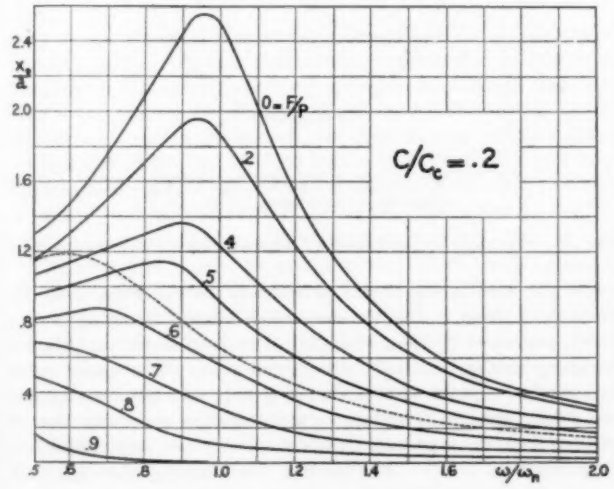

FIG. 9 AMPLITUDE DIAGRAM WITH MIXED DAMPING

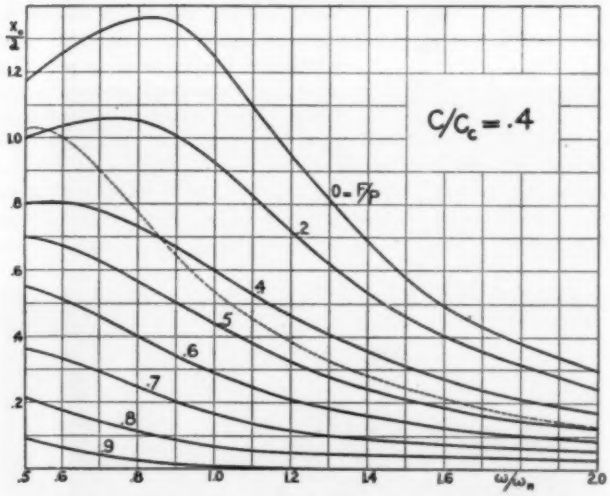

FIG. 11 AMPLITUDE DIAGRAM WITH MIXED DAMPING

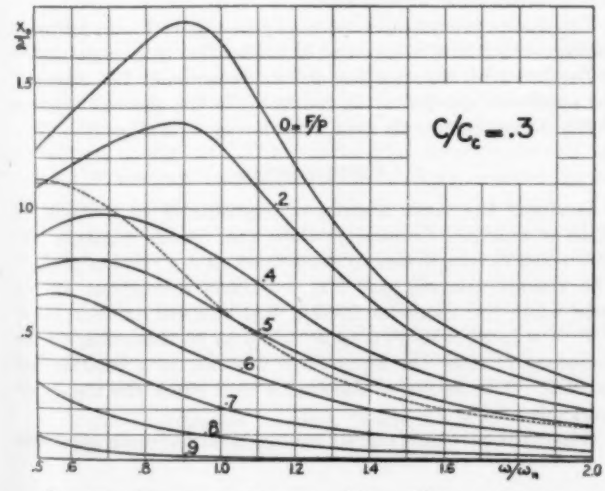

FIG. 10 AMPLITUDE DIAGRAM WITH MIXED DAMPING

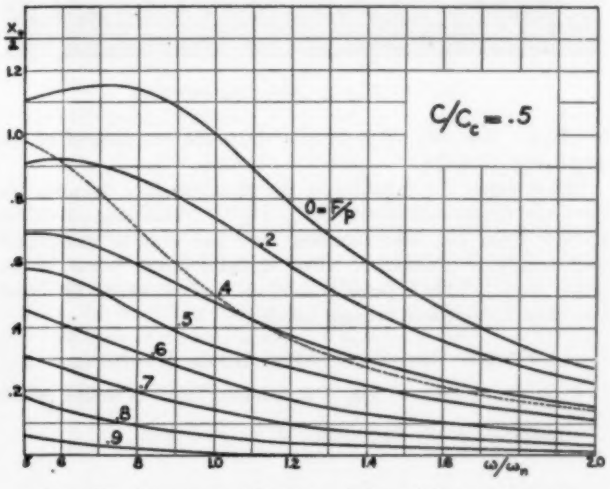

FIG. 12 AMPLITUDE DIAGRAM WITH MIXED DAMPING

In Fig. 5(*b*) the corresponding condition for the usual "viscous" damping is shown. Here the damping force is proportional to the velocity or to the amplitude for a sinusoidal motion. Thus the dissipated energy per cycle is proportional to force times amplitude or to the square of the amplitude, which plots as a parabola. It is seen that even for a very small amount of viscous friction the input and dissipation curves intersect. At the amplitude corresponding to this point of intersection there will be energy equilibrium, so that this is the amplitude at which the system will ultimately vibrate. For viscous damping, therefore, no infinite amplitudes occur at resonance.

At other frequencies than the resonant one, it has been found that an increase in the damping force F will decrease the amplitude of motion (Fig. 2) and will also reduce the curvature at A in Fig. 2. When F reaches a certain value, this curvature becomes zero, and for larger values of F than this, the motion of Fig. 2 cannot exist and will be replaced by that of Fig. 3. During each half-cycle the mass m will stop moving for a while, and while stopping the value of the friction force may be anything between $+F$ and $-F$. Since the mass m during this interval has no acceleration, the sum of the disturbing force $P\cos(\omega t + \varphi)$, the spring force $-kx$, and the friction force must be zero. This determines the friction force as shown in Fig. 3. Motions of this type are also solved analytically in Appendix No. 1, though the result cannot be put in an explicit form like [1]. The calculation has to be done point by point, with the result shown in the curves below the broken line of Fig. 4.

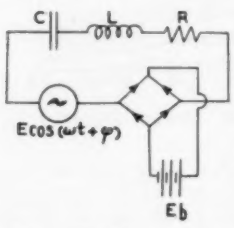

Fig. 13 Equivalent Electrical System

It will be noticed that there is a somewhat triangular area at the left of Fig. 4 which is not filled in. In this area no motions of the two types discussed are possible, but motions with more than one stop per half-cycle must occur. This could not be demonstrated analytically because of the great complications involved. However, experiments show the correctness of the conclusion (Fig. 18).

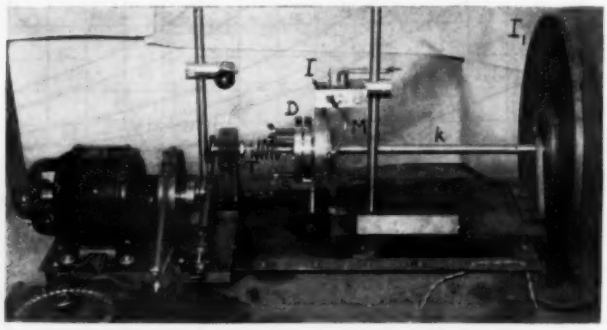

Fig. 14 Model for Experiments

Fig. 6 shows the behavior of the phase angle φ between the force and the motion as defined by Fig. 2. This diagram differs greatly from the corresponding one for viscous damping,[12] and mainly at resonance, where definite jumps occur in the phase angle. This is possible only on account of the fact that the amplitudes there become infinite.

Forced Vibrations With Mixed Damping

If on the system of Fig. 1 a damping force is acting which consists of a constant part and a part proportional to the velocity $F + c\frac{dx}{dt}$, the same two general types of motion as shown in Figs. 2 and 3 can occur. In the case of motion without stops (Fig. 2) an explicit solution has been found (Eq. [31], Appendix No. 2) which is rather complicated. Again for motions with one stop per half-cycle the calculation can be done only point by point. All the derivations are given in Appendix No. 2,

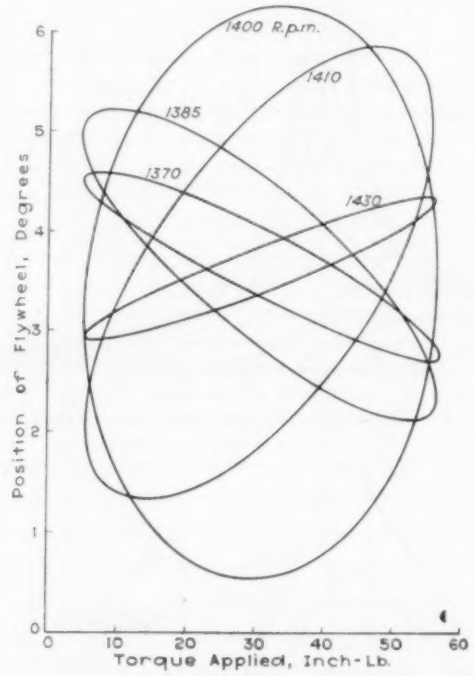

Fig. 15 Records With Viscous Damping Only Near Resonance

while the results are shown graphically in the Figs. 7 to 12. In each of these figures the amount of viscous damping is constant, expressed by c/c_c, which is the ratio of the actual viscous damping to the "critical" viscous damping. The upper curve in each figure is for viscous damping only and has been known for a long time.[10] The lower curves are for a combination of viscous friction (expressed by c/c_c) and dry or Coulomb friction (expressed by F/P). The broken line running through each figure denotes the boundary between non-stop and one-stop motion; the type of motion of Fig. 2 occurring above and that of Fig. 3 below the broken line.

The results given in the various figures apply to any physical problem which can be regarded as a vibration of a single degree of freedom with the damping under discussion.[8] For instance, the maximum charge on the condenser in the electrical system of Fig. 13 can be directly read from the curves of Figs. 6 to 12.

Experimental

Jacobsen[8] has made a series of experiments on a vibrating table at Stanford University where the viscous damping was very small in comparison to the amount of dry friction present. The viscous damping was $c/c_c = 0.0058$ throughout all the tests while the Coulomb friction was changed in four steps. $F/P = 0.21\ \beta^2$, $0.30\ \beta^2$, $0.48\ \beta^2$, and $0.65\ \beta^2$, depending on the frequency β, since the input force was due to a rotating unbalance. The results of Jacobsen's tests check the theory remarkably well.

Some tests have been carried out by the author on an apparatus

[12] Timoshenko, loc. cit., p. 30.

which was primarily designed for the investigation of torsional-vibration dampers.[13] Fig. 14 is a photograph of the apparatus, and it is seen that the system, instead of being a linear one as in Fig. 1, is a torsional one. The flywheel I takes the place of the mass m; the shaft k represents the spring and the flywheel I_1, in this case clamped to the frame, represents the solid wall at the top of Fig. 1. The two disks D are pressed against a third one between them, which is rigidly attached to I and lined

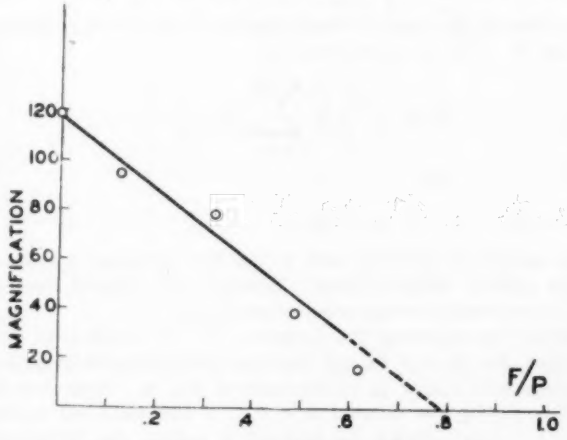

FIG. 16 RESULTS OF TESTS AT RESONANCE

with brake lining. The pressure is adjustable by means of the springs S. For this experiment, the moment of inertia of the disks D is made practically infinite by attaching to them two very long arms with weights at the ends, not shown in the photograph. This transforms the disks D into a solid rubbing wall as shown in Fig. 1. The harmonic force P in Fig. 1 here is a harmonic torque supplied by the spring T, one end of which is moved back and forth through an angle of about 30 deg. by means of an eccentric on the motor shaft.

The recording is done by means of a small mirror M mounted on universal pivots. This mirror is oscillated about a vertical axis by a wire driven by the moving end of the spring T. When the machine is running and there is no vibration in I, a ray of light reflected from the mirror describes a horizontal path on a screen or photographic plate. The vibration is transmitted by another wire to the mirror in such a way that when I is oscillating and the motor is standing still, a vertical path is described on the screen by the light ray. In any actual case the combination will be a Lissajous figure.

Fig. 15 shows several of such figures taken at various speeds near resonance with a small amount of viscous damping, and no Coulomb damping, giving pure ellipses. The shift in the phase angle is roughly indicated by the inclination of the ellipse. Records like this have been taken for several values of F/P, namely, for $c/c_c = 0.0042$ and $F/P = 0$, 0.12, 0.31, 0.48, and 0.62. The theoretical curve and the five experimental points are shown in Fig. 16. The experimental determination of the friction F was not very accurate, which may account for the discrepancy between theory and test shown in the figure. Fig. 17 is a record taken at a much larger magnification in the vertical direction than in Fig. 15, at approximately half critical speed $\omega/\omega_n = 0.5$. It illustrates a motion with one stop per half-cycle of the type shown in Fig. 3. Fig. 18 shows a motion having two stops per half-cycle with rather small friction and very slow speed. This figure would be represented by a point in the triangular area at the left of Fig. 4, and it is an experimental verification of the conclusion that in this area only motions with more than one stop are possible.

[13] "Torsional-Vibration Dampers," Trans. A.S.M.E., 1930, APM-52-13, closure to the discussion.

CONCLUSIONS

1 A solution has been found for the problem of the steady-state vibration of a system with a single degree of freedom, damped by a combination of viscous and Coulomb friction.

2 The theoretical results are presented in the diagrams of the Figs. 4 and 6 to 12, inclusive.

3 The results of tests on a model illustrated by Figs. 14 to 18 are in fair agreement with the theory.

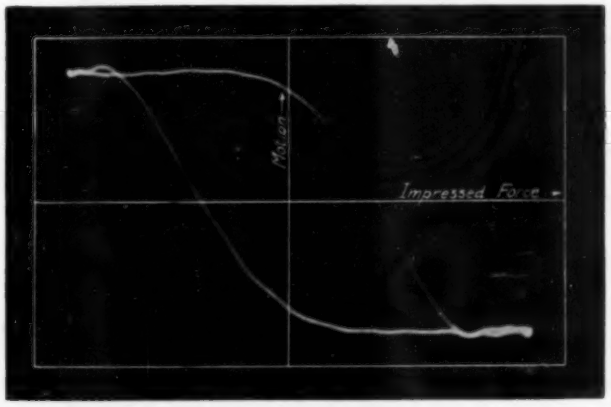

FIG. 17 RECORD OF MOTION WITH ONE STOP PER HALF-CYCLE

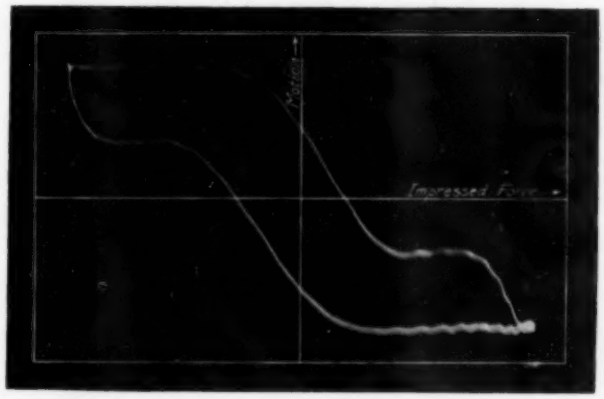

FIG. 18 RECORD OF MOTION WITH TWO STOPS PER HALF-CYCLE

Appendix No. 1

FORCED AMPLITUDES WITH COULOMB DAMPING ONLY

The differential equation of motion of the mass of Fig. 1 are:

$$m\ddot{x} + kx \pm F = P \cos(\omega t + \varphi) \quad \ldots\ldots\ldots\ldots [2]$$

where the + sign before the damping force F holds when the mass moves in the + x-direction, and vice versa. The "phase angle" φ in the disturbing force has no meaning in a differential equation and is only included for the purpose of subsequently writing the boundary conditions [4] in a simple form. During the half-cycle of the motion $0 < t < \pi/\omega$ of Fig. 2 the velocity is always negative so that [2] holds with the — sign before F. Using the abbreviations:

$$P/k = a, \quad F/k = x_f, \quad k/m = \omega_n^2$$

the differential equation for that interval of time can be written as:

$$\ddot{x} + \omega_n^2 (x - x_f) = a\omega_n^2 \cos(\omega t + \varphi) \quad [3]$$

A "steady-state solution" as pictured in Fig. 2 has to fulfil the following boundary conditions:

$$\left.\begin{array}{llll} t = 0 & x = x_0 & \dot{x} = 0 \\ t = \pi/\omega & x = -x_0 & \dot{x} = 0 \end{array}\right\} \quad [4]$$

These are four conditions, and the general solution of [3] contains only two integration constants. The two superfluous equations will be used for determining the unknown quantities x_0 and φ, that is, the amplitude and the phase angle.

The general solution of [3] is:

$$x = C_1 \sin \omega_n t + C_2 \cos \omega_n t + aV \cos(\omega t + \varphi) + x_f \quad [5]$$

where V, the "response function," is defined for [1]. By means of the two conditions at $t = 0$ in [4] the constants C_1 and C_2 can be solved, giving the result

$$x = x_0 \cos \omega_n t + x_f(1 - \cos \omega_n t) + aV\left[\cos\varphi(\cos\omega t - \cos\omega_n t) + \sin\varphi\left(\frac{1}{\beta}\sin\omega_n t - \sin\omega t\right)\right] \quad [6]$$

where $\beta = \omega_n/\omega$ is the frequency ratio. Now the two conditions [4] at $t = \pi/\omega$ can be substituted in [6], giving two equations which can be written in the form:

$$\left.\begin{array}{l} A\cos\varphi + B\sin\varphi + C = 0 \\ P\cos\varphi + Q\sin\varphi + R = 0 \end{array}\right\} \quad [7]$$

where

$$\begin{aligned} A &= -aV(1 + \cos\beta\pi) \\ B &= +aV\frac{\sin\beta\pi}{\beta} \\ C &= x_0(1 + \cos\beta\pi) + x_f(1 - \cos\beta\pi) \\ P &= aV\omega_n \sin\beta\pi \\ Q &= aV\omega\,(1 + \cos\beta\pi) \\ R &= (x_f - x_0)\omega_n \sin\beta\pi \end{aligned}$$

From [7] we deduce that

$$\cos\varphi = \frac{BR - CQ}{AQ - PB} \quad \text{and} \quad \sin\varphi = -\frac{CP - AR}{AQ - PB}$$

Substituting the values A, B, etc., in these formulas and reducing they can be written:

$$\cos\varphi = \frac{x_0}{a}\frac{1}{V} \quad \text{and} \quad \sin\varphi = -\frac{x_f}{a}\frac{U}{V} \quad [8]$$

where the "damping function" U has been defined for [1]. Elimination of φ from the two Equations [8] gives

$$\frac{x_0}{a} = \sqrt{V^2 - \left(\frac{x_f}{a}\right)^2 U^2} \quad [9]$$

which is the amplitude equation (same as [1]) for non-stop motions of the type of Fig. 2.

Substantially the same result can be obtained in another way. It is possible to write the differential equation [2] without the $\pm$ ambiguity by expressing the square-top damping curve of Fig. 2 analytically as a Fourier series:[14]

$$m\ddot{x} + kx - \frac{4F}{\pi}\sum_{n=1,3,5\ldots}\frac{1}{n}\sin n\omega t = P\cos(\omega t + \varphi) \quad [10]$$

The steady-state solution of this equation is:

$$\frac{x}{a} = V\cos(\omega t + \varphi) + \frac{4}{\pi}\frac{F}{P}\beta^2\sum_{1,3,5\ldots}\frac{\sin n\omega t}{n(\beta^2 - n^2)} \quad [11]$$

The phase angle φ must be such that at $t = 0$, $\dot{x} = 0$, as shown in Fig. 2. This condition leads to

$$\left.\begin{array}{l} \sin\varphi = \dfrac{4}{\pi}\dfrac{F}{P}\dfrac{\beta^2}{V}\displaystyle\sum_{1,3,5\ldots}\frac{1}{\beta^2 - n^2} \\ \text{and} \\ x_0 = aV\cos\varphi \end{array}\right\} \quad [12]$$

This solution is identical with [1] (or [9]), although it appears in an entirely different form. However, the original formula [1] is preferable for numerical computations.

Before investigating the boundary of the validity of this solution, let us pass on and find the steady-state solution for motions with one stop, of the type of Fig. 3. Here there is motion during the interval $0 < t < t_0$ and standstill during $t_0 < t < \pi/\omega$; during the interval of motion the differential equation [3] is valid, while the boundary conditions are:

$$\left.\begin{array}{llll} t = 0 & x = x_0 & \dot{x} = 0 \\ t = t_0 & x = -x_0 & \dot{x} = 0 \end{array}\right\} \quad [13]$$

The problem is the same as before, with the exception that there is a fifth unknown quantity, t_0. The additional relation necessary for its determination can be found from a consideration of what happens just before $t = 0$ in Fig. 3. The mass is in rest and consequently has no inertia force. The sum of the disturbing force, spring force, and damping force, therefore, has to be zero. At the instant $t = 0$ this still must be true, and moreover the amount of damping force is then known to be F. This gives the desired relation: $-kx + F + P\cos(\omega t + \varphi)$ must vanish at $t = 0$, or

$$-kx_0 + F + P\cos\varphi = 0 \quad [14]$$

The conditions [13] and [14] are sufficient to determine the five quantities C_1, C_2, x_0, φ, and t_0. First C_1 and C_2 are found from the first two conditions [13], giving the result [6]. With these the last two conditions [13] can be written as:

$$0 = x_0(1 + \cos\omega_n t_0) + x_f(1 - \cos\omega_n t_0) + aV\left[\cos\varphi(\cos\omega t_0 - \cos\omega_n t_0) + \sin\varphi\left(\frac{1}{\beta}\sin\omega_n t_0 - \sin\omega t_0\right)\right]$$

and

$$0 = (x_f - x_0)\beta\sin\omega_n t_0 + aV[\cos\varphi\{\beta\sin\omega_n t_0 - \sin\omega t_0\} + \sin\varphi\{\cos\omega_n t_0 - \cos\omega t_0\}]$$

Now [14] is used to eliminate x_0 from the last two equations by direct substitution, giving:

$$0 = 2\frac{x_f}{a} + \cos\varphi\left[1 + \cos\omega_n t_0 + V(\cos\omega t_0 - \cos\omega_n t_0)\right] + \sin\varphi V\left[\frac{1}{\beta}\sin\omega_n t_0 - \sin\omega t_0\right] \quad [15]$$

[14] This was done independently by Prof. E. O. Waters and the author; see discussion to Jacobsen's paper, loc. cit.

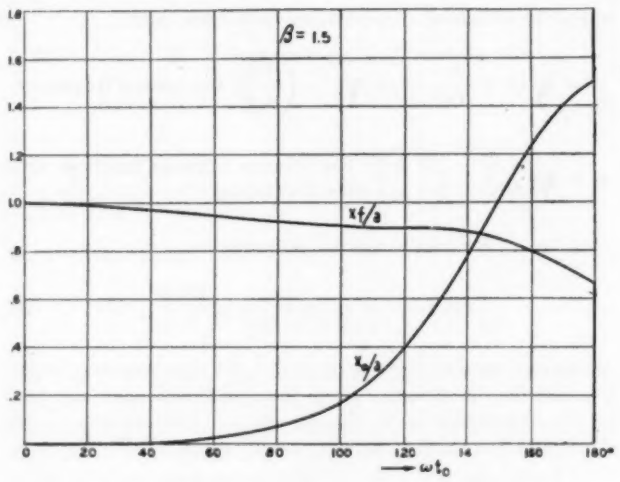

FIG. 19 DIAGRAM FOR STOP MOTION ($\beta = 1.5$)

and

$$0 = \cos\varphi\left[\frac{1}{\beta}\sin\omega_n t_0 - \sin\omega t_0\right] + \sin\varphi\left[\cos\omega_n t_0 - \cos\omega t_0\right] \quad \ldots\ldots [16]$$

From [16]

$$\cos\varphi = \frac{\cos\omega_n t_0 - \cos\omega t_0}{\sqrt{\left(\cos\omega_n t_0 - \cos\omega t_0\right)^2 + \left(\frac{1}{\beta}\sin\omega_n t_0 - \sin\omega t_0\right)^2}} \quad [17]$$

and substituting this in [15] we obtain an equation in which t_0 is the only unknown:

$$\frac{2}{V}\frac{x_f}{a} = \frac{\left(\cos\omega t_0 - \cos\omega_n t_0\right)\left(\frac{1}{V} + \cos\omega t_0 - \frac{1}{\beta^2}\cos\omega_n t_0\right) + \left(\sin\omega t_0 - \frac{1}{\beta}\sin\omega_n t_0\right)^2}{\sqrt{\left(\cos\omega t_0 - \cos\omega_n t_0\right)^2 + \left(\sin\omega t_0 - \frac{1}{\beta}\sin\omega_n t_0\right)^2}} \quad \ldots\ldots [18]$$

It would be logical next to solve t_0 from [18] and substitute it in [17] and then in [14] to find the expression for x_0. However, [18] is transcendental and an explicit solution is not possible. Instead [18] is used for a numerical calculation of x_f/a for a number of values of t_0 between 0 and π. By means of [17] and [14] the corresponding values of x_0/a are calculated. Fig. 19, for example, shows the result of such calculations for $\beta = 1.5$. From this diagram and from similar ones for other β-values the diagram of Fig. 4 has been plotted.

There is one slight complication in this process. It is seen that [18] takes the form 0/0 for $\beta = 1$ or $\omega = \omega_n$. In this case it is necessary to substitute in [18] $\beta = 1 + \delta$, where δ is a small quantity, and evaluate the limit when δ approaches zero. This gives

$$4\frac{x_f}{a} = \frac{(\omega t_0 + \sin\omega t_0)^2}{\sqrt{(\omega t_0\sin\omega t_0)^2 + (\sin\omega t_0 - \omega t_0\cos\omega t_0)^2}} \quad \ldots\ldots [19]$$

from which the diagram for $\beta = 1$ has been constructed.

Now, since the amplitude formulas for the two types of motion have been determined, it becomes necessary to discuss their validity. First let us return to the non-stop formulas [1], [6], and [8]. These have been derived under the assumption that $x < 0$ for $0 < t < \pi/\omega$; consequently they are valid only under this condition. By differentiation of [6] this condition becomes:

$$\frac{x_0}{x_f} \geqslant \beta^2\left[\frac{\beta\sin\omega_n t + U(\cos\omega t - \cos\omega_n t)}{\beta^2\sin\omega t}\right] \quad \ldots\ldots [20]$$

for $0 < t < \pi/\omega$

It can be verified that the bracketed portion of this expression becomes unity for $t = 0$. It has been found by numerical calculation that for all values of $\beta < 2$ this is also the absolute maximum of the bracketed quantity. For $\beta > 2$, the absolute maximum during $0 < t < \pi/\omega$ is sometimes unity, and sometimes greater. It has been found convenient to denote this value by S, so that [20] can be written:

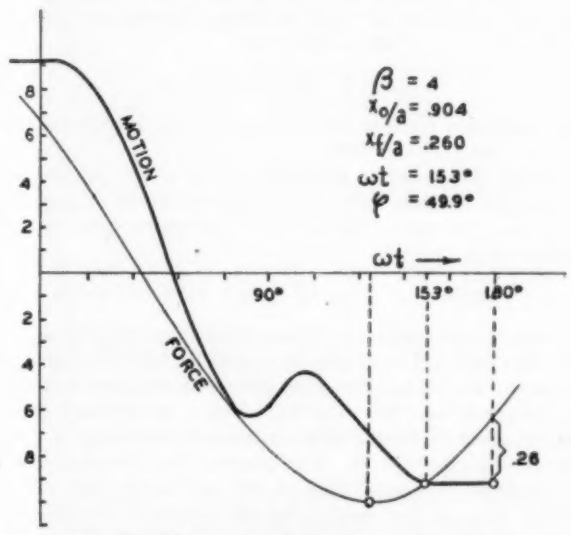

FIG. 20 MOTION VIOLATING CONDITION [19]

$$\frac{x_0}{x_f} \geqslant \beta^2 S \quad \ldots\ldots [20a]$$

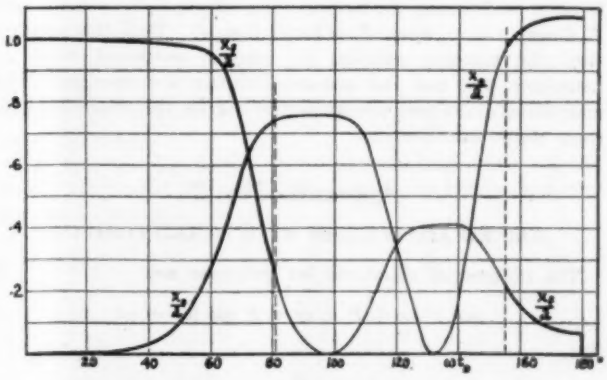

FIG. 21 DIAGRAM FOR STOP-MOTION ($\beta = 4$)

The combination of Equation [20a] with Equation [1] leads moreover to the following expressions for the condition of validity of [1]:

$$\frac{x_0}{a} \geqslant \sqrt{\frac{V^2}{1 + (U/S\beta^2)^2}} \quad \ldots\ldots [21]$$

$$\frac{x_f}{a} \leqslant \sqrt{\frac{V^2}{(S\beta^2)^2 + U^2}} \quad \ldots\ldots\ldots\ldots [21a]$$

With the aid of these formulas, the boundary of the region of validity of the non-stop motion has been plotted in Fig. 4.

With $S = 1$ the formulas [20a], [21], and [21a] also give the limit of the motion of Fig. 3. If in [17] and [18] we substitute $\omega t_0 = \pi$, the stop shrinks to zero and by means of [14] the results [20], [21], and [21a] are obtained. This completely determines the lower boundary of the non-stop motion in Fig. 4.

Let us next consider the validity of the solution [17], [18]. Since each half-cycle is made up of two distinct parts, a condition will be found for each of them. During the period of motion $0 < t < t_0$ the condition is:

$$x < 0 \quad \text{for} \quad 0 < t < t_0 \ldots\ldots\ldots\ldots [22]$$

The expression for $\dot{x}$ is found from [6] after substitution of φ and x_0 from [17] and [18].

During the period of standstill $t_0 < t < \pi/\omega$ the condition is that the absolute value of all external forces acting on the mass—i.e., the disturbing force and the spring force—shall be smaller than F:

$$|\cos(\omega t + \varphi) + x_f/a| \leqslant x_f/a \text{ for } t_0 < t < \pi/\omega \ldots [23]$$

In order for the solution to have a physical meaning, it is necessary that both [22] and [23] be satisfied. Fig. 20 gives an example of a motion satisfying the differential equation but violating the condition [20]. Fig. 21, which is of the same type as Fig. 19, gives the results of the numerical calculation of [16] to [18] for the case $\beta = 4$. The solution thus obtained is valid for values of ωt_0 smaller than 81 deg. and larger than 155 deg. For values of ωt_0 just over 81 deg. the condition [23] during the stop is violated, while for angles just below 153 deg. the condition [22] during the motion period is violated as Fig. 20 illustrates. It is seen that for $\beta = \omega_n/\omega = 4$ no solution can be found for $x_f/a = F/P$ between 0.22 and 0.26. In this case, no motion of either the types of Fig. 2 or 3 is possible, and it seems that the only possibility is a motion with more than one stop per half-cycle. This has been verified by experiment as shown in Fig. 18.

In the previous analysis the friction has been assumed to be entirely independent of the velocity. Sometimes the physical conditions can be better described by assuming the friction force to be F during the motion independent of the velocity and F_s during a stop, where F_s is larger than F. With this assumption, the non-stop solution [1] remains unaltered, while its boundary [21] and the one-stop solution are changed. The analysis as given here can be carried out for this case also, with some slight modifications.

Appendix No. 2

FORCED AMPLITUDES WITH MIXED DAMPING

The differential equations for this case are:

$$m\ddot{x} + kx \pm F + c\dot{x} = P\cos(\omega t + \varphi)$$

or

$$\ddot{x} + \omega_n^2 (x - x_f) + \frac{c}{m}\dot{x} = a\omega^2 \cos(\omega t + \varphi) \ldots\ldots [24]$$

when only motions with $x < 0$ are considered. The analysis of this equation runs parallel to that of the one in Appendix No. 1. The general solution of [24] is known to be:

$$x = e^{-\frac{c}{c_c}\omega_n t}\left[C_1 \cos pt + C_2 \sin pt\right] + \frac{a}{q}\sin(\omega t + \epsilon) + x_f \ldots [25]$$

where the following abbreviations have been used:

$p = \sqrt{\omega_n^2 - \frac{c^2}{4m^2}} = \omega_n \sqrt{1 - \left(\frac{c}{c_c}\right)^2}$, the natural frequency

$q = \sqrt{\left(\frac{1}{V}\right)^2 + \left(\frac{2}{\beta}\frac{c}{c_c}\right)^2}$, the inverse response function with viscous damping

$c_c = 2m\omega_n$, the critical viscous damping.

$$\tan(\varphi - \epsilon) = \frac{c\omega}{k - m\omega^2} = \frac{2V}{\beta}\frac{c}{c_c} \ldots\ldots [26]$$

Assuming a motion like that in Fig. 2, the four boundary conditions [4] hold as before. These four conditions again are used for the calculation of C_1, C_2, x_0, and φ. First C_1 and C_2 are eliminated by means of the two conditions at $t = 0$:

$$x = e^{-\frac{c}{c_c}\omega_n t}\left[(x_0 - x_f)\cos pt - \frac{a}{q}\cos\epsilon\cos pt + \frac{c}{2pm}(x_0 - x_f)\right.$$
$$\left.\sin pt - \frac{ac}{2pqm}\cos\epsilon\sin pt + \frac{a\omega}{pq}\sin\epsilon\sin pt\right]$$
$$+ \frac{a}{q}\cos(\omega t + \epsilon) + x_f \ldots [27]$$

Then the two conditions at $t = \pi/\omega$ can be written in the form

$$\left.\begin{aligned} A\cos\epsilon + B\sin\epsilon + C &= 0 \\ P\cos\epsilon + Q\sin\epsilon + R &= 0 \end{aligned}\right\} \ldots\ldots [28]$$

where

$$A = -\frac{a}{q}e^{-\frac{\pi c}{2m\omega}}\cos\frac{p\pi}{\omega} - \frac{ac}{2pmq}e^{-\frac{\pi c}{2m\omega}}\sin\frac{p\pi}{\omega} - \frac{a}{q}$$

$$B = \frac{a\omega}{pq}e^{-\frac{\pi c}{2m\omega}}\sin\frac{p\pi}{\omega}$$

$$C = (x_0 - x_f)e^{-\frac{\pi c}{2m\omega}}\cos\frac{p\pi}{\omega} + \frac{c}{2pm}(x_f - x_0)e^{-\frac{\pi c}{2m\omega}}\sin\frac{p\pi}{\omega} + x_f + x_0$$

$$P = \frac{a}{q}e^{-\frac{\pi c}{2m\omega}}\sin\frac{p\pi}{\omega}\left[\frac{c^2}{4m^2p} + p\right]$$

$$Q = \frac{a\omega}{q}\left[1 + e^{-\frac{\pi c}{2m\omega}}\cos\frac{p\pi}{\omega} - \frac{c}{2mp}e^{-\frac{\pi c}{2m\omega}}\sin\frac{p\pi}{\omega}\right]$$

$$R = -(x_0 - x_f)e^{-\frac{\pi c}{2m\omega}}\sin\frac{p\pi}{\omega}\left[\frac{c^2}{4m^2p} + p\right]$$

From [28] we deduce:

$$\sin\epsilon = \frac{CP - AR}{AQ - BP} \quad \text{and} \quad \cos\epsilon = \frac{BR - CQ}{AQ - BP}$$

Substituting the values just given in these equations,

$$\sin\epsilon = -qH\frac{x_f}{a}\cos\epsilon = q\left[\frac{x_0}{a} + G\frac{x_f}{a}\right] \ldots\ldots [29]$$

where G and H are functions independent of the Coulomb damping:

$$G = \frac{\sinh(\beta\pi c/c_c) - \sqrt{\frac{c/c_c}{1-(c/c_c)^2}} \cdot \sin\beta\pi \sqrt{1-(c/c_c)^2}}{\cosh(\beta\pi c/c_c) + \cos\beta\pi \sqrt{1-(c/c_c)^2}}$$

$$H = \frac{\beta}{\sqrt{1-(c/c_c)^2}} \cdot \frac{\sin\beta\pi \sqrt{1-(c/c_c)^2}}{\cosh(\beta\pi c/c_c) + \cos\beta\pi \sqrt{1-(c/c_c)^2}} \quad [30]$$

Eliminating ϵ from the equations of [29]:

$$\frac{x_0}{a} = -G\left(\frac{x_f}{a}\right) + \sqrt{\frac{1}{q^2} - H^2\left(\frac{x_f}{a}\right)^2} \quad [31]$$

which is an expression for the amplitude and will reduce to the response function for viscous damping $1/q$ when $x_f/a = F/P = 0$. The phase angle φ can be found in each case from [29] and [26]. This gives a complete solution for the non-stop motion, the results of which are plotted above the broken lines in Figs. 7 to 12.

Assuming a motion with one stop per half-cycle [Fig. 3] the solution [25] holds for the interval of motion $0 < t < t_0$. For the determination of C_1, C_2, x_0, φ, and t_0, the five conditions of [13] and [14] are available. Elimination of C_1 and C_2 gives the result [27].

By means of [14] and the last two conditions of [13] we solve x_0, φ, and t_0 from [27] exactly as was done in Appendix No. 1. The rather complicated result can be written as:

$$\begin{aligned} 2\frac{x_f}{a} = {} & e^{-\frac{c}{c_c}\beta\omega t_0} \cos pt_0 \left[-\cos\varphi + \frac{\cos\varphi}{Vq^2} + \frac{2}{\beta}\frac{c}{c_c}\cdot\frac{1}{q^2}\sin\varphi \right] \\ & + e^{-\frac{c}{c_c}\beta\omega t_0} \sin pt_0 \left[-\frac{c}{c_c}\frac{\omega_n}{p}\cos\varphi + \frac{c}{c_c}\frac{\omega_n}{p}\cdot\frac{1}{Vq^2}\cos\varphi \right. \\ & + \frac{2}{\beta}\left(\frac{c}{c_c}\right)^2 \frac{\omega_n}{p}\cdot\frac{1}{q^2}\cdot\sin\varphi - \frac{\omega_n}{p}\cdot\frac{1}{\beta}\frac{1}{q^2V}\cdot\sin\varphi \\ & \left. + \frac{\omega_n}{p}\frac{2}{\beta^2}\cdot\frac{c}{c_c}\cdot\frac{1}{q^2}\cos\varphi \right] + \left[-\cos\varphi - \left(\frac{\cos\varphi}{Vq^2} \right.\right. \\ & \left.\left. + \frac{2}{\beta}\frac{c}{c_c}\frac{1}{q^2}\sin\varphi \right) \cos\omega t_0 + \left(\frac{\sin\varphi}{q^2V} - \frac{2}{\beta}\frac{c}{c_c}\cdot\frac{\cos\varphi}{q^2} \right) \sin\omega t_0 \right] \end{aligned} \quad [32]$$

in which the angle φ is determined by:

$$\sin\varphi = \frac{A}{\sqrt{A^2+B^2}}; \quad \cos\varphi = \frac{B}{\sqrt{A^2+B^2}} \quad [33]$$

where

$$\begin{aligned} A = {} & \frac{1}{Vq^2} e^{\frac{c}{c_c}\beta\omega t_0} \sin\omega t_0 - \frac{1}{q_2}\cdot\frac{2}{\beta}\cdot\frac{c}{c_c} e^{\frac{c}{c_c}\beta\omega t_0} \cos\omega t_0 + \beta\frac{\omega_n}{p}\sin pt_0 \\ & - \beta\frac{\omega_n}{p}\frac{1}{Vq^2}\sin pt_0 - \frac{2}{\beta}\left(\frac{c}{c_c}\right)^2\frac{\omega_n}{p}\cdot\frac{1}{q^2}\sin pt_0 + \frac{2}{\beta}\frac{c}{c_c}\cdot\frac{1}{q^2}\cos pt_0 \end{aligned}$$

$$\begin{aligned} B = {} & -\frac{2}{\beta}\frac{c}{c_c}\frac{1}{q^2} e^{\frac{c}{c_c}\beta\omega t_0} \sin\omega t_0 - \frac{1}{q^2V} e^{\frac{c}{c_c}\beta\omega t_0} \cos\omega t_0 \\ & + \frac{\omega_n}{p}\frac{2}{q^2}\frac{c}{c_c}\sin pt_0 - \frac{c}{c_c}\frac{\omega_n}{p}\frac{1}{q^2V}\sin pt_0 + \frac{1}{q^2V}\cos pt_0 \end{aligned}$$

For any chosen value of ωt_0 the corresponding values of x_f/a and x_0/a are calculated from [32] and [14], and diagrams like those of the Figs. 19 and 21 are drawn. From these the curves in Figs. 7 to 12 below the broken line are constructed.

The broken lines in these several diagrams indicate the boundary between the motions without stop and with one stop per half-cycle. They can be calculated either as the lower limit of the non-stop motion or as the upper limit of the one-stop motion.

For the non-stop motion, the condition of validity is again: $\dot{x} < 0$ for $0 < t < \pi/\omega$, which can be written as:

$$\frac{x_0}{x_f} \geqslant \frac{e^{-\frac{ct}{2m}}}{\sin\omega t} \cdot \left\{ \left(\frac{p}{\omega} + \frac{c^2}{4m^2p\omega} \right)(1+G)\sin pt + H\left(\frac{c}{2pm}\sin pt - \cos pt \right) \right\} + H\cos\omega t - G \quad \text{for} \quad 0 \leqslant t \leqslant \pi/\omega. \quad [34]$$

It is found that for $\beta < 2$ the maximum value of this expression occurs at $t = 0$, so that it simplifies to:

$$\frac{x_0}{x_f} \geqslant -G + 2H\beta c/c_c + \beta^2(1+G) \quad [35]$$

For values of $\beta > 2$ the maximum of [34] may occur at a different time than $t = 0$. In that case let S_1 be the ratio of this maximum to the value of [34] at $t = 0$. In most cases, including all those of the Figs. 7 to 12, $S_1 = 1$. Then the condition [34] in combination with [29] can be written as:

$$\frac{x_0}{a} \geqslant \frac{S_1(I-G)}{q\sqrt{H^2 + \{S_1I + (1-S_1)G\}^2}} \quad [36]$$

$$\frac{x_f}{a} \geqslant \frac{1}{q\sqrt{H^2 + \{S_1I - (1-S_1)G\}^2}} \quad [37]$$

where

$$I = 2H\beta c/c_c + \beta^2(1+G)$$

With [36], in which $S_1 = 1$, the broken lines in Figs. 7 to 12 were calculated.

For the one-stop motion, the two conditions [22] and [23] hold. The results [35], [36], and [37] can also be obtained from [32] by substitution of $\omega t_0 = \pi$.

APM-53-10

Strength of Materials Subjected to Shear at High Temperatures[1]

By FRANKLIN L. EVERETT,[2] ANN ARBOR, MICH.

This paper treats of an experimental program which is basically fundamental in the study of creep. Uniformly pure shear is produced in a thin tubular specimen submitted to twist, whereas the usual method employs a solid bar in tension. This torsion form of test permits of greater accuracy in the measurement of creep and provides the simplest stress condition, besides offering other decided advantages.

Since this work in twist represents virtually a pioneer attack, it has been necessary to develop practically from the beginning each phase of the investigation. The type of specimen, apparatus for the creep tests, including the measuring instruments, and experimental technique are described.

The experiments have been of three kinds: (1) Room-temperature tests were first made to determine the usual physical properties in torsion and in tension; (2) at various temperatures short-duration tests were made to learn the effect of different rates of loading, the modulus of elasticity in shear, and the ultimate strength in shear; (3) at 400 deg. cent. and 500 deg. cent. several creep tests in shear of relatively long duration were conducted. An accelerated method of making creep tests has been devised. In addition several special problems were investigated such as a study of the increase of the yield point by creep and the restoration of the original yield point by annealing, the effect of vibrations which included a continuous record of creep, and the effect of temperature fluctuations.

INTRODUCTION

1 Statement of the Problem

THE outward manifestations of creep are now generally recognized. In cases of commercial importance, metal which is subjected to the simultaneous action of stress and high temperature undergoes gradual distortion. A large number of investigators of creep and others interested in the problem, particularly in the United States and Europe, have contributed considerable information on the practical significance of creep and data applicable for purposes of design of equipment which operates under conditions where creep obtains. So satisfactorily has this part of the subject of creep been covered that it appears neither necessary nor possible to devote more than an occasional sentence to a review.

It is felt that the broad subject of creep deserves more fundamental study. The manner in which creep occurs is too interesting a question to remain unexplained. Very low rates of creep are required to furnish a more complete picture of the problem. The immediate investigation is believed to approach more closely than is possible by tension methods a situation which permits this fundamental research.

A large amount of work has been done to determine creep characteristics of metals in tension. In the present study the attack is different—creep in uniformly pure shear is produced by using a tubular specimen in twist.

In this study there have been developed the machines, type of specimen, and the measuring instruments which give more refined readings than are known to have been obtained in any other laboratory. The experimental technique has also been developed.

Some results have been obtained for giving the characteristics of medium-carbon steel at three temperatures, namely, 400, 450, and 500 deg. cent., and in addition some work has been accomplished at ordinary temperatures. Only one material has been used in the tests, since it was desired to prepare as complete information for comparative purposes as was possible.

The experimental work has been of three kinds: (1) A number of tests have been performed at room temperature to learn the usual physical properties of the material; (2) a series of short-duration tests at high temperature were made in order to establish the more important physical properties under such conditions and to provide some preliminary tests which might be useful in predicting the behavior of the material in creep; and (3) a few long-duration creep tests were run to study the material when it was exposed to service conditions of high temperature and stress over some time.

Also several special problems have received attention which deal with practical considerations relating to the matter of creep.

2 Torsion Vs. Tension

Torsion methods of studying the problem of creep present certain advantages over those in tension. It is due to these and the basic value of creep results in general that the present project has been undertaken and developed.

As a result of temperature fluctuations of the specimen during a test, the effect upon strain measurements is much more serious in the case of tension than in torsion. Due to a thermal change of 1 deg. cent. on the length alone, the effect upon strain readings in tension tests is 1.2×10^{-5} inches per inch of length, whereas

Dr. Everett was graduated in mechanical engineering from the University in 1925, with the degree of B.S.E. in M.E. During the following three and one-half years he was connected with the Standard Oil Co. (New Jersey), first as a member of the student-engineering course and later as an inspector of refinery high-pressure equipment in the general engineering department. He returned in February, 1929, to the University of Michigan to continue graduate work, and received the degree of M.S.E. in M.E. in June of the same year. Since that time he has been connected with the department of engineering research at the University. He obtained the degree of Ph.D. in June, 1931.

in torsion the geometric changes due to temperature are of only very slight consequence. Consideration of all effects upon measurements in torsion is given in a discussion in Section V, Article 3. This situation immediately presents a distinct advantage of torsion methods over tension.

Means of obtaining very fine measurements of strain in torsion are simpler than in tension. It is possible to combine mechanical and optical levers favorably so as to detect very refined values of strains due to torsion.

In torsion a moment of constant magnitude is easily designed to act automatically on the specimen throughout the experiment. The usual tension creep apparatus requires that the load beam be readjusted to maintain a uniform force on the specimen during elongation.

The maximum-shear theory is usually selected as the basis of design of machine parts, so that information concerning the shearing stress of ductile material such as steel is of practical importance. It is generally accepted that deformation of ductile material, such as steel, takes place due to gliding resulting from shearing stresses, the maximum gliding occurring on the plane of maximum shear.

Experiments in uniformly pure shear provide the simplest stress condition and therefore allow the most favorable situation for making a study of such a problem as is offered by creep. Tension methods produce a more complicated stress condition on the plane of maximum shear, since normal tensile forces are also present.

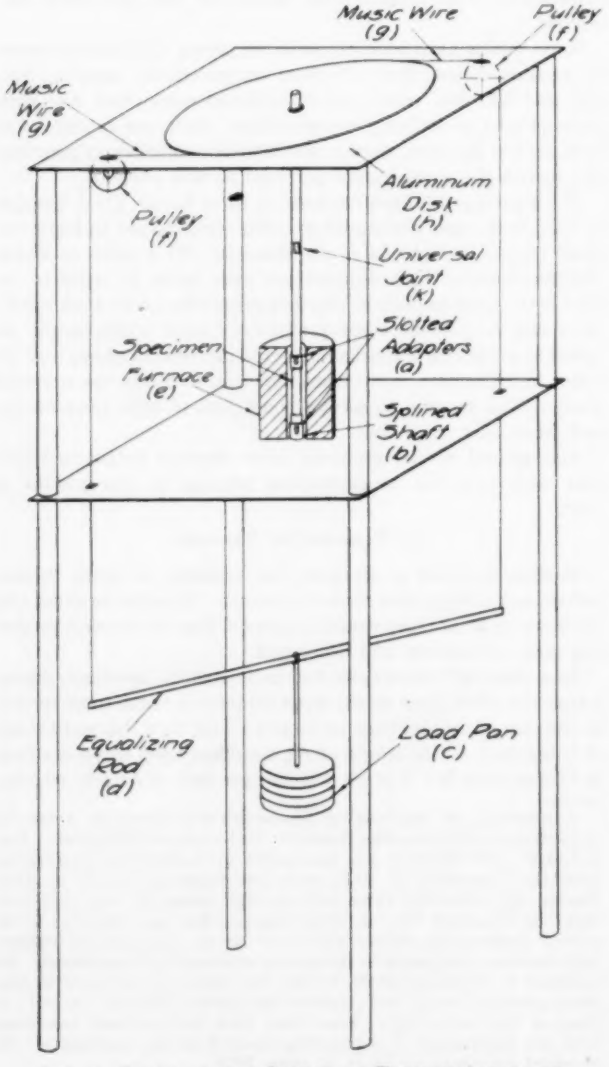

FIG. 1 DIAGRAMMATIC SKETCH OF TORSION APPARATUS

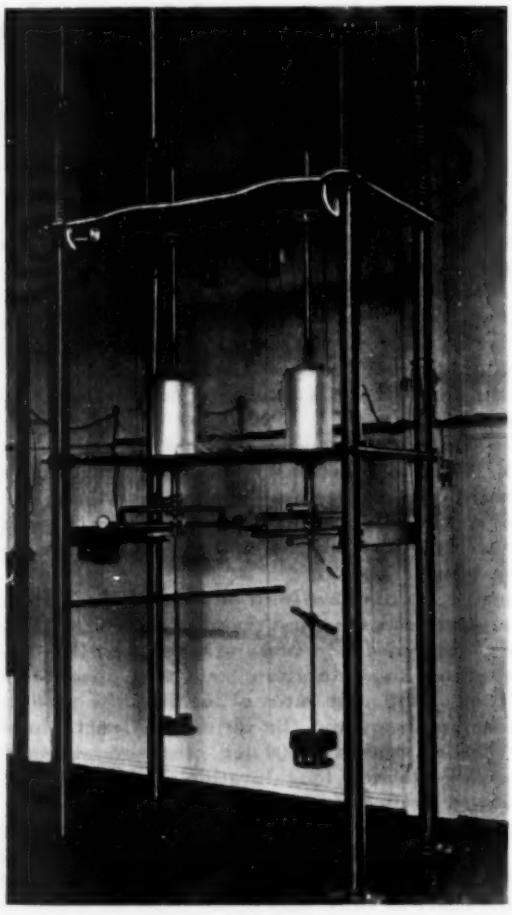

FIG. 2 NOS. 2 AND 3 TORSION MACHINES

I—APPARATUS AND SPECIMENS

1 TORSION MACHINES

In the design of the apparatus for the torsion investigation, a number of requirements were imposed. The specimen was to be tubular, held rigidly at one end, and twisted free from bending or longitudinal pressure at the other end with a known moment which remained constant during angular deformation of the specimen. Friction was to be held to a minimum. The specimen was to be contained in a furnace and maintained at constant temperature. Some provision had to be made for accurately measuring shear strain.

A diagrammatic sketch of the essential features of the torsion machine is given in Fig. 1. Two of the new machines built integral in the same frame are shown in Fig. 2. Discussion will be directed toward the design of the improved apparatus of the last two units. The fact that the torsion specimen was tubular established the form of the slotted adapters (*a*), Fig. 1. The end which resisted rotation was made a splined shaft (*b*) to allow for axial adjustment in inserting and removing the specimen. The other end was connected to a large, lightweight aluminum disk (*h*) on the circumference of which two fine music wires (*g*) produced a couple. These wires passed over pulleys (*f*) of relatively large diameters and were fastened

to both ends of an equalizing rod (*d*), to the center of which a platform (*c*) was attached for applying loads. The large disk and pulleys were mounted on ball bearings to reduce the friction. Between the rigid end and the aluminum disk which furnished the moment, a universal joint (*k*) was supplied in the shaft to eliminate the possibility of bending action upon the specimen.

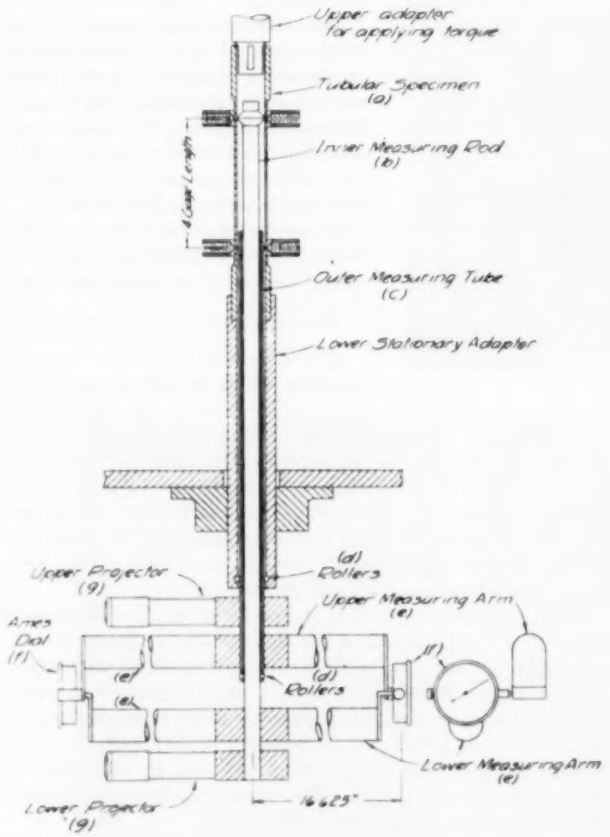

FIG. 3 SHEAR-STRAIN MEASURING DEVICES

Some play between the specimen and the adapters allowed axial thermal expansion without causing longitudinal pressures.

Since the furnace (*e*) surrounded the specimen, part of the shear-strain-measuring apparatus had necessarily to be within the heated zone. It was decided that it was best to select a vertical design of machine in order to permit these measuring devices to hang downward and thereby avoid bending and general distortion due to the heat. Detailed descriptions of the instruments and furnaces are given in the following articles.

A salt or lead bath to protect the specimen from excessive oxidation could be used very easily with this apparatus. The design of the machine is favorable to this arrangement.

2 STRAIN-MEASURING INSTRUMENTS

Exceeding simplicity and accuracy have been embodied in the principle and design of the devices for measuring angular deformations of the specimen. It was necessary to devise means of measuring the relative angular motion of two cross-sections of the specimen. Several methods have been developed, and during various stages of the same test, each, depending upon the rate of movement and the degree of sensitivity demanded, may be employed. The systems are mechanical, optical, or combinations of the two. The different methods that have been developed number four and will be discussed in the order of the accuracy which they are capable of obtaining.

The gage length which has been arbitrarily selected as 4 in. is constant in all experiments where strain is measured. A concentric rod and tube, accordingly, are clamped by suitable means inside the specimen. A sectional drawing which illustrates the method of securing the rod and tube at the gage points and the attachment of the strain-measuring instruments is given in Fig. 3. The relative angular movement between this rod and tube describes the shear strain of the 4-in. portion of the specimen (*a*) which is under investigation. To the rod (*b*) and tube (*c*) one or more of the devices (*f*, *g*) for measuring the strain are attached. Rollers (*d*) are provided to steady the rod and tube at the lower ends.

The simplest method of measuring shear strain which is employed throughout the entire test consists of a pair of projectors (*g*), one each attached to the rod and tube, equipped to cast a sharp vertical shadow on a curved graduated scale. The projectors may be readily seen in Figs. 4 and 5. This optical lever is used in connection with either of two scales of 96-in. and 174-in. radius, respectively. The smallest reading that can be observed on the scales is 0.01 in., which corresponds to angles of 1.04×10^{-4} and 5.75×10^{-5} radians, respectively. The shear strain which can be measured is then 1.29×10^{-5} and 7.09×10^{-6} in order. Although this method constitutes the least refined means of measuring the strain, the minimum rate of creep, for example, over a 12-hour period, may be read to 1.07×10^{-6} for the 96-in. and 5.91×10^{-7} for the 174-in.-radius scale, strain

per hour. When rates are so low that more refined devices must be resorted to, this projector method furnishes a check and the amount of the total deflection.

The other three more delicate methods of measuring the strain take advantage of a mechanical-lever mechanism in addition to the sensitivity provided by the various strain instruments themselves. Arms (*e*) in Fig. 3 are fastened rigidly to the rod and to the tube. Various types of instruments (*f*) are mounted which measure the relative linear displacement of the outer ends. It is assumed, at the comparatively large radius at which the instruments are located, that for small angular movements the arc and chord are equal. Linear-strain-measuring devices serve to indicate these movements.

In the first of these cases Ames dials (*f*), which will permit of a minimum reading of $^1/_{10,000}$ of an inch, are employed. Rates of creep with readings at 12-hour intervals are accurately read to some 6.19×10^{-8} strain per hour. This method gives very satisfactory results for rates of creep within this range. Fig. 4 is a photograph which shows the Ames dials being employed for measuring the shear strain.

The Huggenberger tensometers, which are more widely used in European laboratories than in this country, permit the measurement of linear displacements of the order of $^1/_{100,000}$ of an inch. These instruments consist essentially of a compound set of mechanical levers. The Huggenberger instruments are attached to the end of the arms (*e*, Fig. 3) in the same manner as the Ames dials. It is seen that the accuracy obtained is about ten times as great as with the Ames dials. The minimum rate of creep is of the order of 5.15×10^{-9} strain per hour when the readings are made at 12-hour intervals.

The Martens-type mirror instruments, seen in Fig. 5, provide a method of obtaining a slightly greater sensitivity than is furnished by the Huggenberger tensometers. The rate of creep which can be detected is about 5×10^{-9} shear strain per hour, based on the same interval previously used. This method furnishes the most sensitive means which has been developed at the laboratory for measuring creep.

3 DEVELOPMENT OF SPECIMEN DESIGN

It was desired to find a shape of specimen which would approach a condition of uniformly pure shear. Obviously a solid shaft in twist presents an unfavorable situation. The phenomenon is complicated due to the fact that the stresses are not uniform. A thin tubular section was therefore selected, for which the assumption can be made that stresses are evenly distributed over the cross-section, and their magnitude is based on the mean radius.

Numerous tests were made in torsion of such tubes at room temperature. The length of the thin section for determinations of angular deformation necessarily had to be of appreciable amount. Experience showed that it was not possible to obtain the ultimate shearing strength, since sudden buckling occurred and failure took place due to tension. Photographs of an unstressed tube, one following a creep test and one after buckling failure, are given in Fig. 6. This design was certainly adapted only to a stress somewhat below ultimate.

Since buckling was not observable in the least until the final

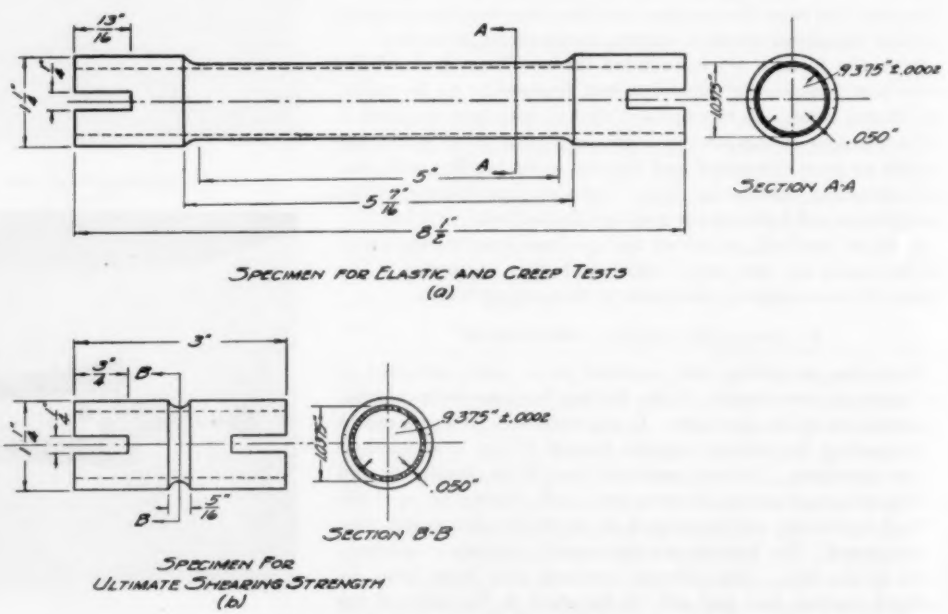

FIG. 8 TUBULAR SPECIMENS

stage of the test, observations of strain during the first part of the test, which was the important part for creep measurements, were not affected.

In order to get data for ultimate strength, the final design adopted was merely a rounded groove with a long radius at the bottom, a photograph of which is shown in Fig. 7 both before and after failure.

The two standard type specimens, then, which were employed throughout the torsion tests reported here, were of the design described in the above-mentioned development. The specimen which was used for the investigation of all elastic and creep-test determinations is shown in Fig. 8(*a*), while the design adopted for the few tests where ultimate strength was required is given in Fig. 8(*b*).

Later tests have indicated conclusively that no measurable buckling took place when the specimen chosen for creep tests was subjected in the usual experiments to shear stress over long periods of time.

II—MATERIAL

1 Rough Stock

As much care as possible was exercised in the selection of material for the program of experiments. It was desired to have a steel which exhibited usual physical properties and which at the same time was homogeneous. Since the finished specimens were to assume the form of a thin hollow cylinder, tubular stock was preferred. A medium-carbon seamless steel mechanical tubing was chosen.

This steel has properties which are well known at ordinary temperatures. The material was obtained in one lot sufficient for the entire investigation. The manufacturer's chemical analysis furnished the following:

	Per cent
Carbon	0.34
Manganese	0.80
Phosphorus	0.02
Sulphur	0.03
Silicon	0.10

An analysis in the University laboratory showed the carbon content of the tubes to be 0.347 per cent, with a maximum variation of 0.001 between samples.

Upon receipt in the laboratory the tubes were cut to the length desired for the specimens and annealed in an electric furnace in an atmosphere of air. The annealing temperature in all cases was 900 deg. cent., which was maintained for a period of from fifteen to thirty minutes. The tubes were permitted to cool slowly in the furnace.

2 Preliminary Tests at Room Temperature

It was desired to investigate the physical properties of the material in tension and in torsion at ordinary temperatures by the usual short-time methods. For the tension tests two types of specimens were used. Small rectangular strips were cut from the walls of both unannealed and annealed tubular stock and subjected to tension. From these tests it was decided that only annealed material would be used in subsequent experiments, since uniformity in results and a sharp yield point could be obtained only when the material was in the annealed condition. Tubular specimens, as the second type, were tested in tension also. The tube stock was turned down into the same essential form which was adopted for the torsion experiments, as seen in Fig. 8(*a*).

(*a*) (*b*) (*c*)

Fig. 9 Photomicrographs of Material

[(*a*) Highly decarburized inner surface. (*b*) Homogeneous interior structure. (*c*) Slightly decarburized outer surface.]

TABLE 1 TENSION TESTS AT ROOM TEMPERATURE

Type of specimen	Condition	Mark No.	Prop. limit, lb. per sq. in.	Yield point, lb. per sq. in.	Tensile strength, lb. per sq. in.	Elongation, per cent	Red. of area, per cent	Modulus $E \times 10^6$, lb. per sq. in.
Strip	Unannealed	1	60,000	...	91,200	13	45	30.5
Strip	Annealed	3	40,700	40,700	72,300	36	48	28.9
Tube	Annealed	4	34,350	34,350	67,600	35.5	..	29.3

The magnitudes of proportional limit, yield point, ultimate tensile strength, elongation, reduction of area, and modulus were obtained for each specimen. In the case of the tubular form, all of these values were consistently lower than for the strip type. This was later attributed to the fact that there was a thin layer of decarburized material at the inner surface of the original tube stock which formed a larger proportion of the cross-section in the thin tubular specimen than in the thicker strip. Representative tension tests are reported in Table 1.

It was further decided to subject the material to metallographic examination. Sections at right angles to the axis of both

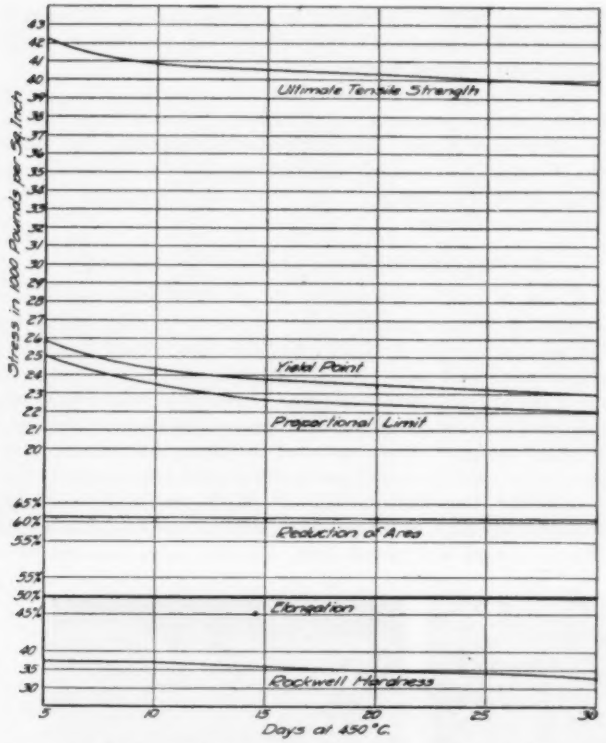

FIG. 10 MECHANICAL TESTS OF THIN STRIPS AT ROOM TEMPERATURE AFTER VARIOUS LENGTHS OF HEATING AT 450 DEG. CENT.

the strips and tubes were polished and photomicrographs prepared. As can be seen by referring to Fig. 9, the material throughout the cross-section is not homogeneous. Fig. 9(*a*) shows the structure of more than half of the thickness of the tube specimen. A large proportion is decarburized and consequently weaker than the interior material. A photomicrograph of a section of the strip showing the center is given in Fig. 9(*b*). This is the normal structure. Another sample was taken from the thick end at the grip of a tubular specimen. The outer surface, as may be seen in Fig. 9(*c*), is slightly decarburized.

From this study it was perceived that the tubular specimens must be redesigned so as to include only homogeneous material which was not decarburized. This was accomplished by merely increasing the internal diameter as well as the external diameter in order to maintain the same wall thickness of 0.050 in. The material of the final form of specimen, then, consisted wholly of the homogeneous structure shown in Fig. 9(*b*).

For the torsion tests at room temperature, annealed tubular specimens of two forms were used. To determine the elastic properties the original design described above was employed. In order to obtain the value of ultimate shearing strength a special type was devised of considerably shorter length and of reduced section. Details of this form of specimen and its development have been discussed in Section I, and reference in that connection may be made to Figs. 7 and 8(*b*).

Table 2 gives the characteristic data derived from the torsion tests at room temperature.

The yield point in torsion for this annealed material was well defined. In the case of the specimen with only $^1/_{32}$ in. length of reduced section it is probable that the dimensions of the wall were not accurately known. The value of ultimate shearing strength obtained from No. 71 specimen is considered reliable.

Bearing in mind that the reduced section of the tubes with the exception of No. 71 consisted to an appreciable extent of weaker decarburized material, we can relate the information of the tension and torsion tests. Comparing the values of yield point, the ratio obtained in uniformly pure shear to that in tension at ordinary temperatures assumes the value of approximately 0.6, which is in good agreement with the maximum-energy theory.

3 EFFECT OF LONG-TIME HEATING ON PHYSICAL PROPERTIES AT ROOM TEMPERATURE

It has been conjectured that steel subjected to the continued effect of high temperatures may undergo some structural change. This alone may produce differences in the physical properties, so that in creep tests it may be possible that the specimen becomes continually weaker—or perhaps stronger—under the single action of prolonged heating. Furthermore there is a possibility that long-time exposure to some temperatures at which creep tests are conducted results in decarbonization of the surfaces of the metal

These questions were approached by investigating strips of steel $^1/_{16}$ in. thick and 1 in. in width, of 0.068 ± 0.004C content. The strips were given an initial anneal at 900 deg. cent. and allowed to cool in the furnace. They were then heated for various lengths of time at 450 deg. cent. This temperature was arbitrarily selected. Two strips were heated for 5 days, two for 10 days, and so on through 30 days, so that twelve specimens were prepared. At the conclusion of the heating periods the strips were again allowed to cool slowly in the furnace.

After the heating, mechanical tests were made on the strips at room temperature to determine their hardness and tensile properties.

Although it is appreciated that the hardness of strips as thin as $^1/_{16}$ in. undoubtedly cannot be accurately determined by means of the method of the Rockwell machine,[3] the $^1/_{16}$-in.-diameter ball and 100-kg. weight were used to study the relative hardness of the strips. It was felt, however, that the consistency of the observed values for a given specimen and the reasonable qualitative agreement with the subsequent tension tests presented interesting information. It was found that prolonged heating resulted in a continual softening of the material. The curve for hardness is given in Fig. 10.

Each strip was tested in tension at ordinary temperatures. The general physical properties—proportional limit, yield point, ultimate tensile strength, breaking strength, reduction of area, and elongation—were determined. Again it is observed by further reference to Fig. 10 that the effect of heating was to weaken the steel, and that there is a material falling off in the magnitude of tensile strength, yield point, and proportional limit. The reduction of area and elongation appear to remain unchanged.

The results of this particular set of tests are offered as a qualitative indication only of what may obtain in situations where metal is subjected for long periods to high temperatures. More experimental evidence is needed to establish convincing arguments concerning the problem.

III—SHORT-DURATION TESTS AT HIGH TEMPERATURES

1 Problems Investigated

All of the experiments at high temperature in twist where the tubular specimen was subjected for the major part of the test to a varying load and uniform temperature are for convenience discussed here under "Short-Duration Tests." Some of these single tests required as much time as two or three weeks, while others took only a few minutes.

Three types of problems were investigated: (1) the effect of various rates of loading; (2) the determination of modulus of elasticity in shear; and (3) the value of ultimate strength in shear. These tests were made at temperatures ranging up to 500 deg. cent.

2 Effect of Various Rates of Loading

Prior to making the regular creep tests, a series of experiments at each of several selected temperatures was run to study the effect of the rate of application of the load and the behavior of the creep during the intervals between loading. The form of specimen is shown in Fig. 8(*a*). These tests were directly used to predict roughly what creep rates could be expected subsequently in the long-duration creep tests. It was felt that later a more accurate method of prediction could be discovered, based on these short-time tests.

The same general procedure of applying the load was followed in each of these experiments. A specimen was loaded with equal increments (always 10-lb. weights, which corresponded to about 1600 lb. per sq. in. shear stress, depending upon the exact measurements of the particular specimen) at definite intervals of time. These loading periods in each series were 1 minute, 1 hour, and 24 hours, and the tests repeated for 400, 450, and 500 deg. cent.

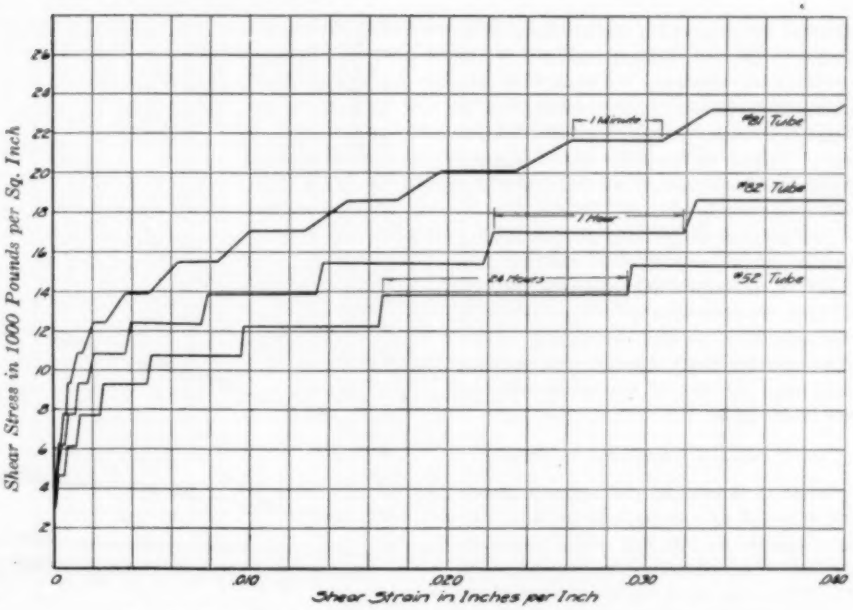

Fig. 12 Effect of Various Rates of Loading at 450 Deg. Cent.

The results are given in the curves of Figs. 11, 12, and 13.

During the interval between the addition of the loads in the case of the one-day period, several observations of strain were made, as frequently as each two to four hours in the early stages after each loading, and the rates of creep determined. Fig. 14 shows representative curves obtained in this manner at 500 deg. cent. It was an interesting discovery to find that the logarithm of the rate over the last 12 hours of each 24-hour period plotted against the corresponding stress which was acting, resulted substantially in a straight line. It was further significant in the case of the tests at 400 deg. cent. that this line paralleled the one which represented the minimum rate obtained in long-time creep tests. Such a comparison may be made by reference to the broken-line curves of Fig. 18 for 400 deg. cent. and Fig. 19 for 500 deg. cent. It is believed that some relationship may exist between the two curves so that predictions of minimum rate can be made on the basis of knowledge gained from such short-time tests and only a few regular creep tests.

The method of measuring angular deformations in all of these short-time tests was by the projectors and 96-in.-radius scale. The various devices for strain-measurement determinations have been described in Section I.

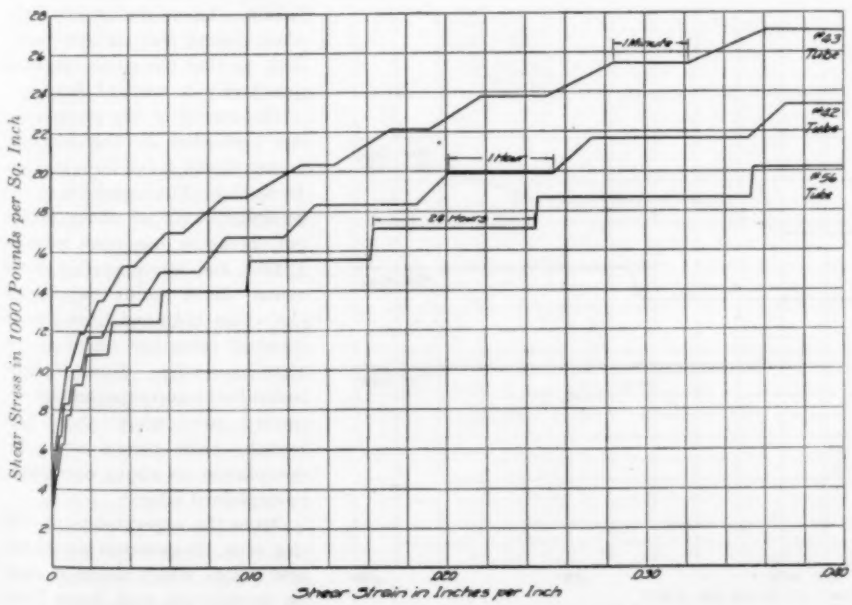

Fig. 11 Effect of Various Rates of Loading at 400 Deg. Cent.

3 Modulus of Elasticity in Shear

Modulus of elasticity in shear of the material at various temperatures from normal to 500 deg. cent. was determined, employing the specimen in Fig. 8(*a*). A curve is plotted from the resulting data in Fig. 15. This is in close agreement with studies in tension by McVetty and Mochel[4] on similar

[4] P. A. McVetty and N. L. Mochel, "The Tensile Properties of Stainless Iron and Other Alloys at Elevated Temperatures," *Trans. A.S.S.T.*, vol. II (1927), pp. 82, 100.

material by employing the relation: $G = E/2(1 + \mu)$. In this expression G is the modulus of elasticity in shear; E the modulus of elasticity in tension, and μ Poisson's ratio, which is about 0.3 for steel. It can be assumed that Poisson's ratio remains constant at this value for any temperature.

The manner of arriving at satisfactory values of the modulus of elasticity in shear at elevated temperatures was by making observations of shear strain of the specimen during unloading rather than upon loading. Angular deformations were read by use of the projectors and the 96-in. scale.

4 Ultimate Strength in Shear

Tests to determine the ultimate shearing strength at various temperatures from atmospheric to 500 deg. cent. were conducted. Short-length specimens shown in Fig. 8(*b*) were used, which precluded the possibility of buckling. The results are given in Fig. 16 in the form of a curve.

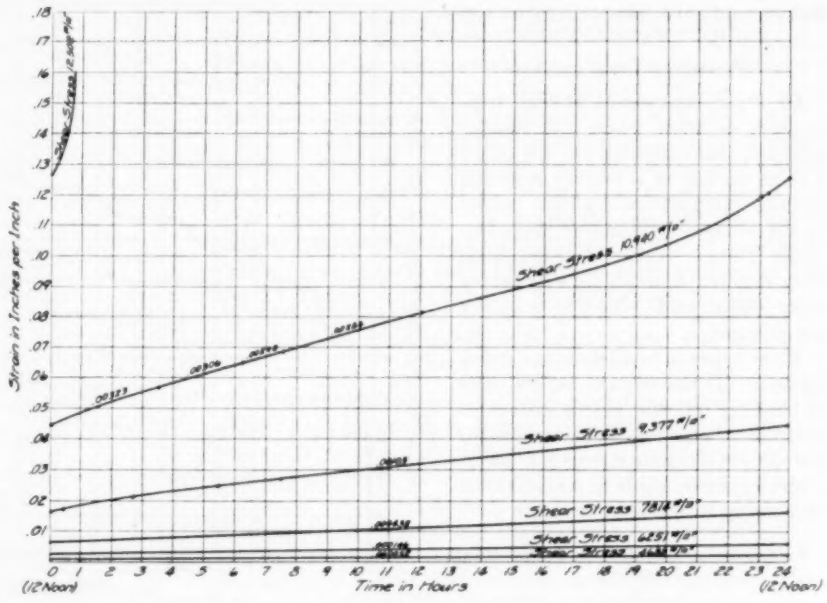

Fig. 14 Creep Rate Between 24-Hour Loadings at 500 Deg. Cent.

In loading the specimens to determine ultimate shearing strength, increments of 10 lb., and in the latter part of the test, 5 lb., were used. The rate of application of the loads was particularly important in these experiments, and a rate of 10 lb. (1600 lb. per sq. in.) per 30 sec. was carefully observed.

This curve does not look like those usually obtained for ultimate strength in tension at different temperatures. One of the reasons for the appearance of the curves in tension may be the complicated condition caused by necking. This situation is not present in experiments in uniformly pure shear produced by torsion. More experiments are required.

IV—LONG-DURATION TESTS AT HIGH TEMPERATURE

1 Results of Long-Duration Tests

Long-duration creep tests of tubular specimens of medium-carbon steel subjected to uniformly pure shear were made at temperatures of 400 and 500 deg. cent.

A number of the creep tests in shear were conducted in the usual manner, that is, the specimen was brought to the required temperature and the stress increased to a predetermined value, after which strain measurements were observed at certain time intervals. It was noted that the minimum rate of creep in each instance occurred at approximately the same total shear strain, and that buckling of the tube took place soon afterward. Strain, then, appeared in these cases to be the criterion of minimum rate of creep and also of buckling failure. Fig. 17 gives a family of time-deflection creep curves of the usual type of test made at 400 deg. cent. It is clearly seen from the first four curves that the minimum rate of creep occurs in each case at about 0.10 shear strain. The sharp upward turn in the curves denotes the initial stage of buckling failure. Large deflections take place during this sudden buckling, so that the curve becomes practically a vertical line.

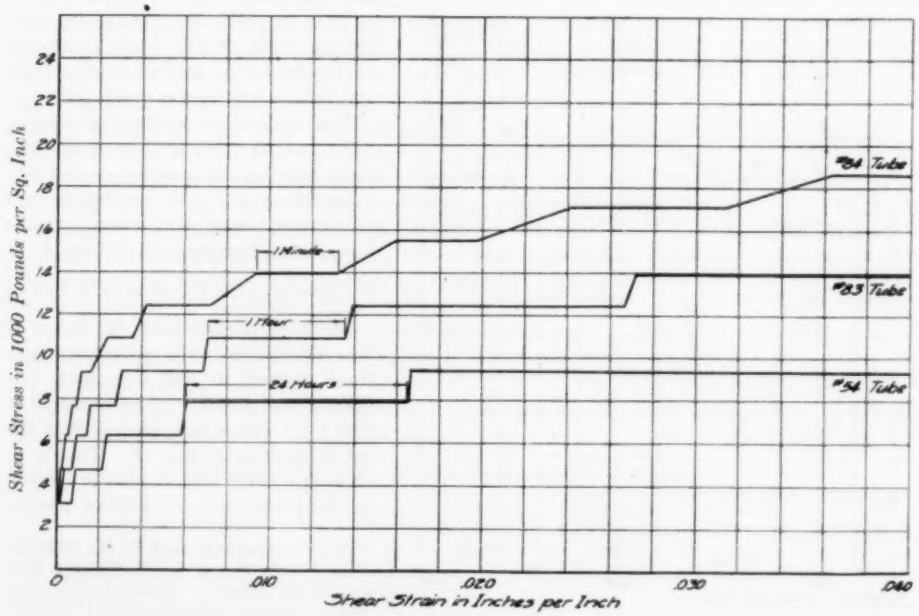

Fig. 13 Effect of Various Rates of Loading at 500 Deg. Cent.

The results of the creep tests are presented in the form of curves shown in full lines in Figs. 18 and 19. The logarithm of the minimum rate of shear strain per 24 hours has been plotted against the corresponding shear stress. Each point represents the value obtained from an individual creep test noted at the right-hand edge. Some of these individual creep experiments extended over more than one month, while others were accomplished in about one week, as explained later.

From the experiments at 400 deg. cent. the generous number of test points which describe such an unmistaken path leave little doubt as to the character of

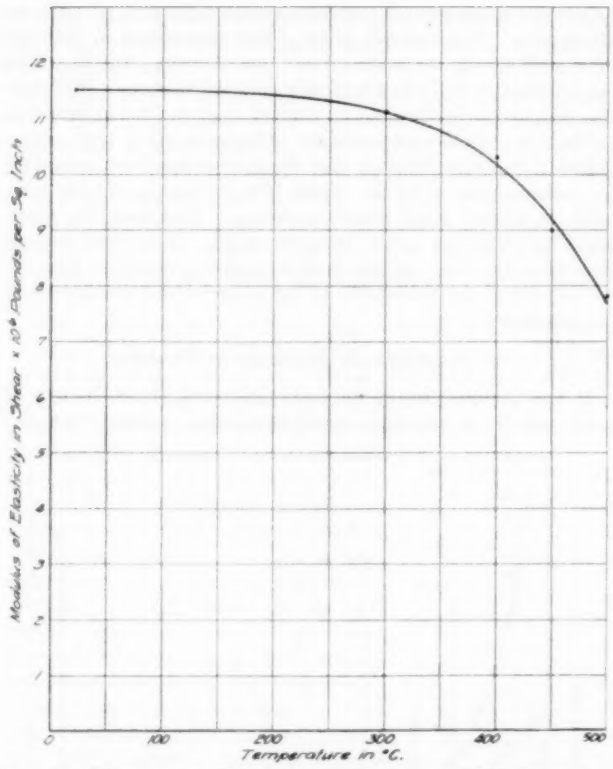

FIG. 15 MODULUS OF ELASTICITY IN SHEAR OF 0.34C STEEL AT VARIOUS TEMPERATURES

creep in shear of this material. The similar trend of the curve at 500 deg. cent. is established with reasonable assurance. Over a large portion of the curve for higher rates of creep the points fall in a straight line, but at lower rates there is a marked decrease in the creep rate for decreasing shear stress. In no creep tests has creep ceased. It is hazardous to predict beyond experimental evidence, but it appears that although there is a decided drop in the creep rate at the smaller stresses, delicate instruments which are furnished by this present method and further investigation of the problem may reveal the existence of creep very much beyond the range that has hitherto been supposed. The curve may even be asymptotic to the axis of the abscissa. Further experiments are in progress at present to establish more data for these low rates.

It may be reasoned that at the upper end of the curve very high rates of creep may be produced by large shear stresses. A physical maximum shear stress may well exist which causes instantaneous failure or, better, an infinite rate of creep. This stress is probably in the neighborhood of ultimate shearing strength, and so it seems the upper part of the curve becomes asymptotic to this practical limiting shear stress.

It was stated above that the values of the points which designated the shape of the curves of Figs. 18 and 19 represented the minimum rates of creep. From all of the tests made, a constant rate of creep has not been observed over any appreciable period of time, but rather a decreasing, or, in the case of approaching buckling failure, an increasing rate of creep. Fig. 20 is a typical curve which illustrates this point. These curves are obtained from any creep test by merely dividing the amount of shear strain which has taken place during an interval between readings by the length of the interval in hours, usually about twelve. There are three quite distinct parts of such a curve. The first portion, denoted by (*a*), is characterized by a rapidly falling rate. In some tests this occurs comparatively quickly. This part is followed by a region (*b*) of very much more uniform

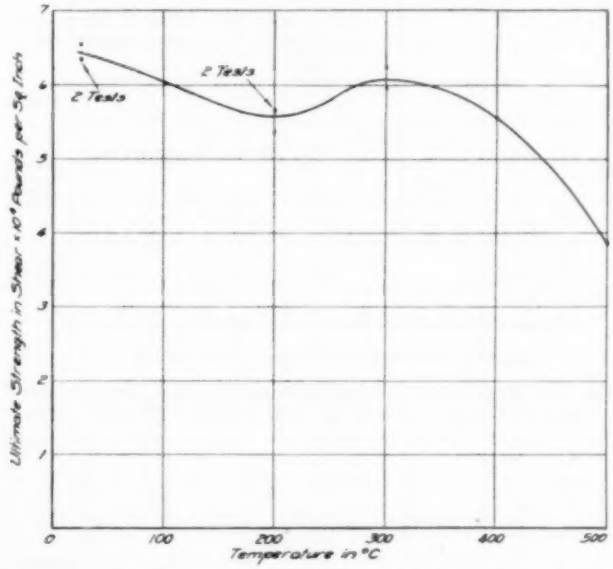

FIG. 16 ULTIMATE STRENGTH IN SHEAR OF 0.34C STEEL AT VARIOUS TEMPERATURES

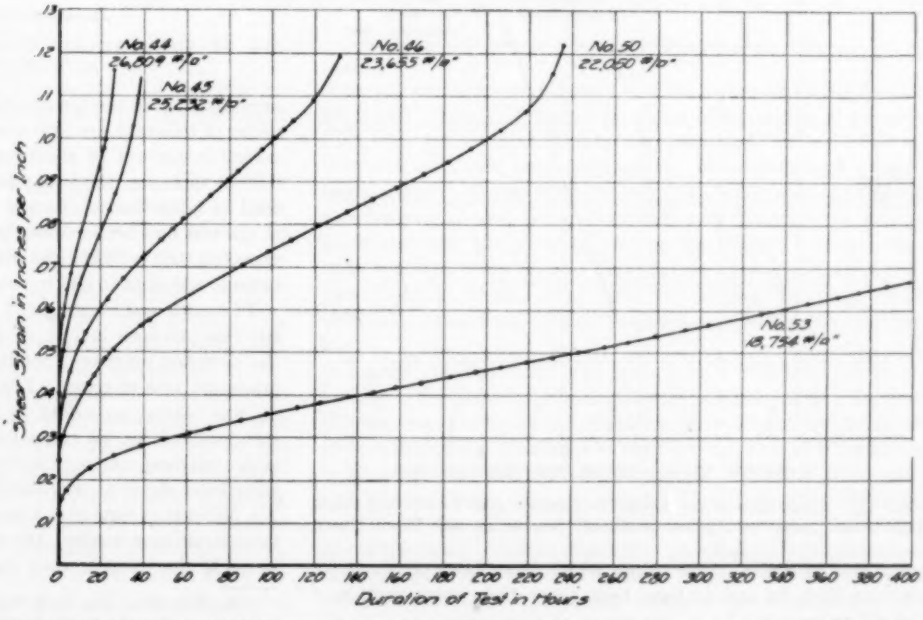

FIG. 17 SHEAR STRAIN VS. DURATION OF CREEP TEST FOR VARIOUS AMOUNTS OF SHEAR STRESS AT 400 DEG. CENT.

rate of creep, but all observations indicate it is not constant. The last stage (*c*) precedes buckling of the tube and shows a very sudden increase in rate. It can be conceived for practical purposes that the middle zone may be considered to be one of con-

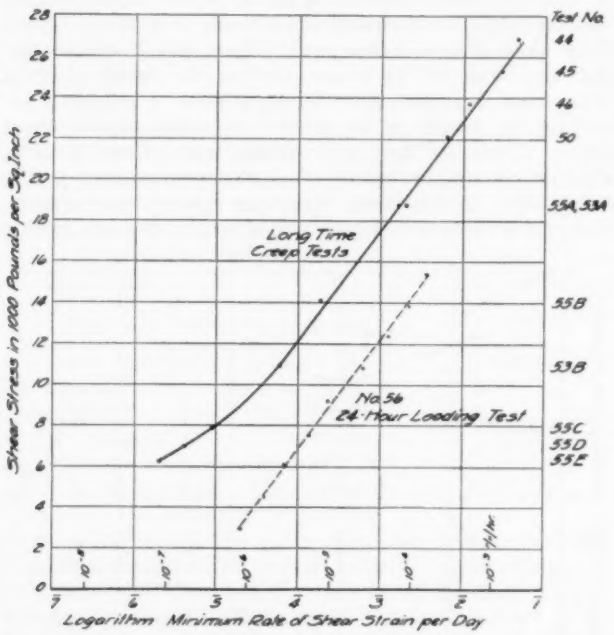

FIG. 18 COMPARISON OF SHORT-DURATION AND LONG-DURATION TESTS OF CREEP IN SHEAR OF 0.34C STEEL AT 400 DEG. CENT.

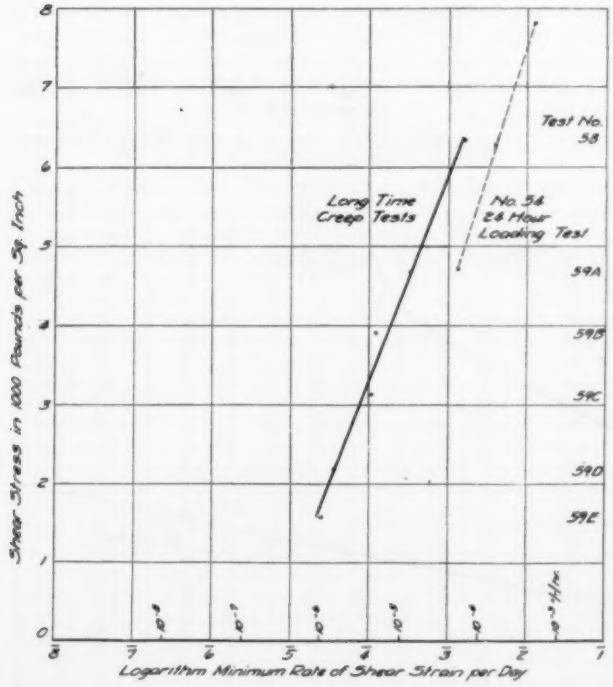

FIG. 19 COMPARISON OF SHORT-DURATION AND LONG-DURATION TESTS OF CREEP IN SHEAR OF 0.34C STEEL AT 500 DEG. CENT.

stant rate of creep. The values which have been obtained for plotting Figs. 18 and 19 have been taken from some portion of this (*b*) stage.

Mention was made earlier of the care which had been exercised to procure specimens of homogeneous material and of uniform dimensions. This was felt to be of first importance in entering upon such a program as the present one of creep. Fig. 21 shows the loading curves for five randomly chosen specimens. Although the manner of loading, as to rate of applying loads, was felt to be of no significance upon the subsequent creep test, nevertheless it was customary to load the tubular specimen according to a selected rate of 10 lb. (about 1600 lb. per sq. in.) per min. until the desired shear stress was acting. As is seen, the specimens for which the curves are given in Fig. 21 received various final loads, but the coincidence of the curves presents an interesting picture of the uniformity of the material and dimensions of the specimens.

2 ACCELERATED METHODS OF TESTING

It was postulated that the favorable point where the rate of strain was at a minimum could be reached quicker than was

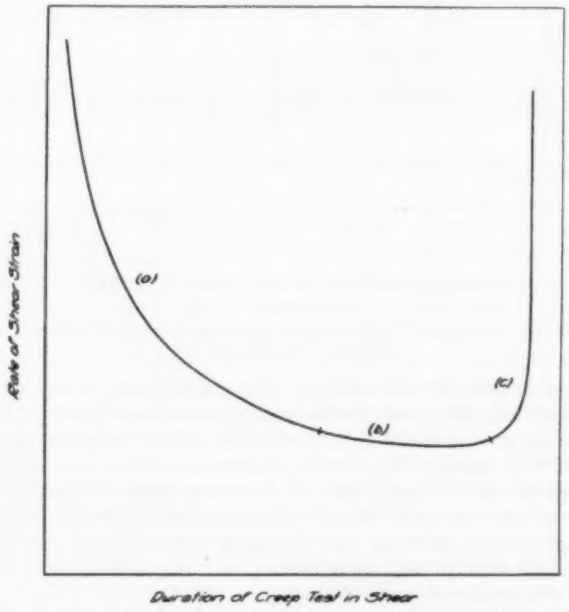

FIG. 20 CHARACTERISTIC CURVE OF RATE OF SHEAR STRAIN VS. DURATION OF CREEP TEST IN SHEAR

accomplished in the tests shown in Fig. 17, without affecting the value of this rate, by first overstressing the specimen. When a desirable amount of shearing strain had been obtained, about 0.08 in this case, the load would be reduced and creep would be read as a function of the new stress as though the entire history of the test had been according to common practice. It would be expected that a short time would be required for the specimen to become adjusted to the reduced stress.

This plan was investigated by selecting first a test (Tube No. 53, Test A[5]) seen in Fig. 18 that had been previously begun in the accepted manner of loading and which was approaching the minimum rate of creep. The new specimen (Tube No. 55, Test A) was loaded according to the same method which had been standardized for all creep tests, but the amount of the initial stress imposed was such as to produce in a few hours nearly the same total strain as was obtained with the other specimen (Tube No. 53) at that time over a period of about two weeks. When this total strain was reached, the excess load was removed so that the stress in the tubes in each experiment was the same. The rate

[5] Each tubular specimen was numbered, and when more than one test was made which employed the same specimen the experiments were designated by Test A, Test B, and so on.

of creep soon dropped in the accelerated test to values which approximated within experimental limits the rate of creep shown by the usual test.

So close was the agreement in the two tests that the points when plotted according to the logarithm of the minimum rate against shear stress nearly coincided. Fig. 18 may be referred to for comparison of the results seen as two adjacent test points. The procedure developed for this test was considered worth adopting for further tests. Two weeks only were saved in this case, but for lower values of stress, and consequently of strain, it is seen that a far greater saving of time is capable of being effected.

Furthermore, should we be willing to accept the premise that no appreciable effect upon the minimum rate of creep is caused by this accelerated method of loading, it is reasonable to expect that all of the creep data necessary to plot the curve of the logarithm of the minimum rate of creep against the corresponding stress can be obtained from a test of one specimen. The specimen would then be loaded and quickly strained to a point slightly below that for the minimum rate of creep. The load would be reduced then sufficiently to produce a rate of creep within the desired range. After the creep rate had been found for this stress, the load would be decreased and the new creep rate at this stress obtained, and so on. In this manner it seems likely that enough information could be secured within a period of several weeks or months to afford a reliable indication of the properties of the material.

Several tests of this kind have been made with apparent success, but further study is required to substantiate the degree of accuracy of this form of test procedure. The points for rates of creep of 10^{-4} shearing strain per hour, and less, in the experiments at 400 deg. cent. and all the tests at 500 deg. cent. were obtained in this manner. These data are represented by the curves plotted as stress against the corresponding logarithm of the minimum rate of creep for the particular temperature in Figs. 18 and 19.

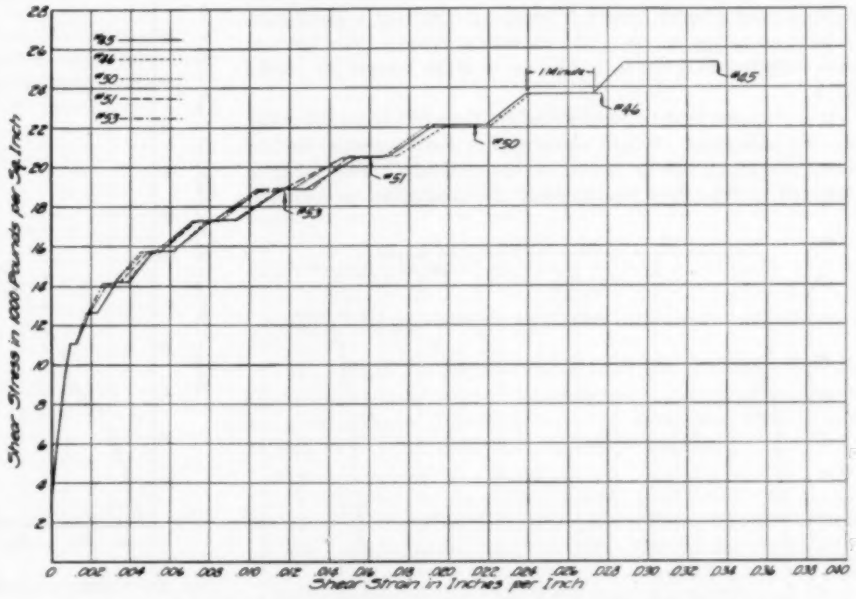

FIG. 21 LOADING CURVES FOR TUBULAR SPECIMENS AT 400 DEG. CENT.

V—SPECIAL PROBLEMS

1 INCREASE OF YIELD POINT BY CREEP AND RESTORATION OF ORIGINAL YIELD POINT BY ANNEALING

In order to investigate the effect of creep upon the physical properties in subsequent room-temperature tests, a tube (No. 56) which had already undergone considerable creep was studied. Following the test at 400 deg. cent., which was reported in Fig. 11, the specimen was unstressed and permitted to cool slowly in the furnace. At room temperature the tube was loaded in torsion until the yield point was reached at about 29,450 lb. per sq. in., and then unloaded. Then by annealing the tube at 900 deg. cent. in the usual manner, all effect of any previous cold working was removed. The tube was again tested at ordinary temperature in twist and the yield point observed to be about 24,950 lb. per sq. in. The respective curves are given in Fig. 22. From these experiments it is seen that the creep test at 400 deg. cent. caused an increase in the yield point of about 20 per cent, based on the usual tests at room temperature.

This phenomenon differs from what we know of room-temperature tests where yield point is increased only by large loading. This increase of yield point was produced by comparatively small loads. It is also significant that Hooke's law is maintained practically up to the value of the new yield point. Usually in cold working, the increased yield point is attended by a marked rounding off of the curve preceding the yield point.

From other tests on unused specimens in torsion at room temperatures, curves like the one shown in Fig. 22(*b*) have been obtained. The material, then, which was subjected to creep and later annealed, resembles the original condition of the steel.

2 NATURAL JARS AND VIBRATIONS

It was felt for some time that vibrations, and particularly jars produced in the building, caused dynamic in addition to the static loads applied to the specimen under torsion. Although all observations of suddenly high creep rates did not follow known jars, these higher values were observed when jars were known to have occurred. During the assembly of heavy apparatus in a nearby room very erratic rates of creep were observed.

In normal times, rates were usually alternately high and low in reference to a smooth curve. In analyzing this condition it was discovered that the reading taken in the morning was the lower one and the evening reading the higher. Observations were recorded twice daily. This appeared consistent, since more jars, however small, were produced during the day, which resulted in the greater rate of creep observed at the evening reading.

A more detailed study was made over a four-hour period one evening when jars and vibrations were at a minimum. Readings of creep were recorded at five-minute intervals on two specimens (Nos. 53 and 55). Reference to the curves of Fig. 23 is suggested.

No creep was observed for the first hour and a half in the specimen whose average rate was about 3×10^{-4} shearing strain per hour until the observer unintentionally caused a sudden jar across the room. This jar resulted in an apparently instantaneous large creep, after which no further change was observed in the remaining two and a half hours. Rates of the order of 4×10^{-7} strain were observed without difficulty, and form the least count for plotting the curve.

The second specimen, whose average rate of creep was slightly greater, about 8×10^{-6} shearing strain per hour, showed alternate stages of creep and of no creep. When the small jar reported above was produced, these observations also showed that a considerable movement had taken place.

It is interesting to note that there is quite an obvious average rate of creep noticeable in the case of the upper curve of Fig. 23. Just before the sudden creep, the specimen is apparently strained less than the average amount, which prepares it particularly well for the occurrence which follows. The jar, then, not only brings the strain up to the "average rate line," but causes excess straining which results in a slowing up in the rate. The period which follows appears to indicate that the material tends to maintain an average rate of creep.

From these experiments it would be concluded that creep is a discontinuous process. Whereas creep is generally read as being continuous, it is probably in reality stepwise in nature.

A special apparatus has been constructed which is designed to make a photographic record of creep by directing a small spot of light on to the mirror of the measuring device. The beam is then reflected back on to a film on a drum turned by clockwork.

It is proposed later to make a study of the effect of intentionally applied pulsations. A light motor with a small eccentric load to cause vibrations will be placed on the load pan. This study is designed to reproduce qualitatively the conditions encountered

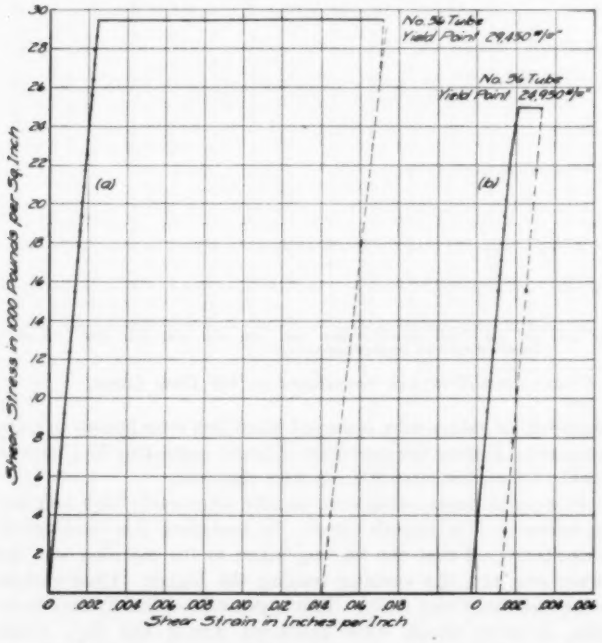

FIG. 22 TORSION TESTS AT 26 DEG. CENT.: (*a*) AFTER CREEP TEST; (*b*) AFTER SUBSEQUENT ANNEALING

in power plants where pulsations are frequently imposed in addition to static stress and high temperature.

From the study of jars which has been made, it was decided to mount the torsion-test equipment on springs. Springs were chosen in such a way as to make the frequency of the system a very low one so that outside jars and vibrations would not produce disturbances upon the torsion apparatus. The machines were therefore suspended from above, as seen by reference to Fig. 2. This eliminated the trouble caused by jars and vibrations. The temperature fluctuation effect is discussed in the following article.

3 TEMPERATURE FLUCTUATIONS

We must anticipate variations in temperature throughout any experiment of the order of one degree centigrade above and below the desired amount. In tension tests we know that these fluctuations materially affect the sensitivity of the readings of creep. They are far less serious in the case of torsion, but it is worth while to study the magnitude of their effect. An increase in temperature results in an increase in both the polar moment of inertia and the length of the specimen, and a decrease in the modulus of elasticity in shear. The resistance of the specimen to shear, then, tends to increase with a larger polar moment of

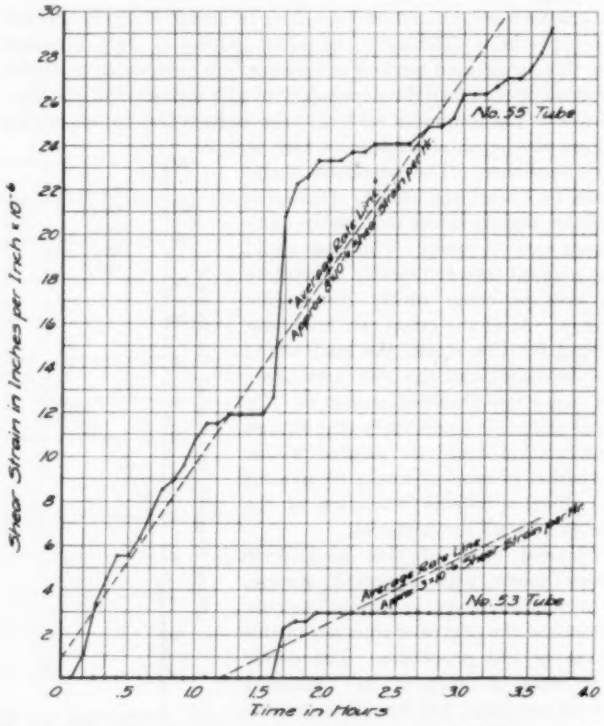

FIG. 23 CONTINUOUS RECORD OF CREEP FOR LOW RATES AT 400 DEG. CENT.

inertia, but shows a decrease with greater length and smaller modulus. The temperature effect upon modulus of elasticity in shear is very great compared with that upon the polar moment of inertia and the length. The ratio, in order, is about 150:5:1.25.

In the extreme case when the applied torque moment is large, the effect due to a two-degree-centigrade temperature fluctuation will be read as a shear strain of approximately 1×10^{-6}. With intervals of twelve hours between creep readings the effect of temperature fluctuations upon creep measurements amounts to rates of less than 1×10^{-7} shear strain per hour. The following calculations for an extreme particular case will help to make this evident.

Let:

θ = angle of twist in radians

t = 400 deg. cent., say, the desired temperature of specimen

M_t = 1×10^3 in-lb. = maximum torque moment

L = 4 in. = gage length at temperature t

G = 1×10^7 lb. per sq. in. = modulus of elasticity in shear at temperature t

I_p = 4×10^{-3} = polar moment of inertia of tubular cross-section at temperature t

c = 0.4375 in. = mean radius of tube at temperature t

$\Delta\theta$ = difference in angle of twist in radians due to temperature change

α = 1.25×10^{-6} in. per in. = change per inch of L due to 1 deg. cent. temperature fluctuation at temperature t (coefficient of expansion)

β = 150×10^{-6} lb. per sq. in. = change per unit of G due to deg. cent. temperature fluctuation at temperature t (determined experimentally; this is discussed in Section III and an experimental curve is given in Fig. 15)

γ = $4 \times 1.25 \times 10^{-6}$ in.^{4} = change per unit of I_p due to 1 deg. cent. temperature fluctuation at temperature t

δ_s = shear strain in tubular specimen.

Then, due to a fluctuation of $\pm$ 1 deg. cent. from temperature t,

$$\theta_{t \pm 1^\circ C.} = \frac{M_t L(1 \pm \alpha)}{G(1 \pm \beta) I_p (1 \pm \gamma)}$$

Therefore the difference in the angle of twist expressed in radians due to a 2-deg. cent. temperature change is, since α, β, and γ are small quantities,

$$\Delta\theta = \frac{2M_t L}{GI_p}(\alpha - \beta - \gamma)$$

and by substitution of the values for the symbols:

$$\Delta\theta = \frac{2 \cdot 1 \cdot 10^3 \cdot 4}{1 \cdot 10^7 \cdot 4 \cdot 10^{-2}} (1.25 \cdot 10^{-6} - [-150 \cdot 10^{-6}] - 5 \cdot 10^{-6})$$

so

$$\Delta\theta = 3 \times 10^{-6} \text{ radians}$$

Since

$$\delta_s = \frac{c \cdot \Delta\theta}{L}$$

Then, due to an angular deformation $\Delta\theta$ caused by a 2-deg. cent. temperature change, the resulting shear strain becomes

$$\delta_s = \frac{0.4375 \cdot 3 \cdot 10^{-6}}{4}$$

or

$$\delta_s = 3 \times 10^{-6} \text{ in. per in. strain}$$

When readings are made at 12-hour intervals, the effect of temperature fluctuations which will result in fluctuations in creep rate will be

$$\delta_s/\text{hr.} = \frac{3 \cdot 10^{-6}}{12}$$

or

$$\delta_s/\text{hr.} = 2.5 \times 10^{-7} \text{ strain per hour}$$

The figures in the results of these calculations have in several cases been rounded off to the nearest whole number. This latter value, then, represents the minimum reliable value which may be observed when temperature fluctuations of the specimen are in the order of $\pm$ 1 deg. cent. and all other conditions noted above regarding torque moment and dimensions are imposed. This temperature fluctuation registers its effect in changing the modulus of elasticity in shear, the polar moment of inertia, and the length.

It will be appreciated that as the torque is decreased, as is the case when small rates of creep are required, the magnitude of the effect due to temperature fluctuations is decreased in direct proportion. Rates of 1×10^{-6} strain per hour under such circumstances can readily be determined without difficulty when readings are made as frequently as 12 hours.

ACKNOWLEDGMENTS

Prof. S. Timoshenko conceived the importance and possibilities of investigating creep phenomena by uniformly pure shear, presented the problem to the author, and directed the entire program. To him credit is due for the vision and practical success of the project up to the present time. The author wishes to record his deep appreciation to Professor Timoshenko, moreover, for his personal interest and limitless encouragement.

To Prof. A. E. White and the Department of Engineering Research, of which he is director, the author wishes to indicate his appreciation for sympathetic interest in the problem, which included the assistance in the matter of personal expenses. The author also acknowledges with gratitude the generous support of the Department of Engineering Mechanics under the supervision of Prof. E. L. Eriksen, especially for the funds for the construction of the special equipment used in conducting the investigation.

Discussion

T. McLean Jasper.[6] This paper indicates considerable ingenuity in testing. There are, however, two very important assumptions which are made, which are very difficult to substantiate. They are that a thin tube in torsion will allow one to reach the yield point of the metal without buckling at a much lower stress, and that one can discover the ultimate strength in torsion of even a brittle material when using a thin tube and the mathematics quoted.

The problem is analogous to that of the slender column in which the apparent yield point of the same steel is reached at various apparent stresses, depending upon the slenderness ratio of the column used. The ultimate strength, in this case, is very much obscured.

It is believed that the method of testing adopted by the author should be very good in determining the shearing modulus of steel at high temperatures, provided that the whole of the gage length of the specimen is known to be at a definite temperature and that the straight portion of the stress-strain diagram is used.

The best method to determine this modulus that has been devised, it is believed, was adopted by Sutherland, in which he used the torsion pendulum for his work. This was reported in *The Philosophical Magazine* about 1891. The work by Sutherland has been summarized for steel and other metals in the magazine of 1923, pp. 617–618.

The writer is somewhat nonplused by the nonchalant assumption that the maximum-shear theory of failure has been proved.

The most exhaustive set of tests on which this is generally based was performed by Guest, who made a very detailed tabulation of his results in *The Philosophical Magazine*. The writer would call attention to the fact that Guest made as many as 20 tests on some of his thin tubes. He tested them in a simple torsion, and in torsion combined with other forms of stress. After a test in simple torsion on a tube, he made as many as 15 tests in some cases, and in others 18, in which he exceeded the straight-line stress-strain relation by other combinations of stress. When he finally tested by simple torsion, he was able to repeat the results originally obtained. Any one familiar with exceeding the elastic limit or yield point of steel knows that the new values obtained on the same specimen will not check with the original ones. The writer is not criticizing the test values obtained by Guest, because they were made in a

[6] A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

most painstaking manner and by a man most trusted as an investigator. What he is suggesting, however, is that Guest never exceeded the elastic properties of the steel in his test tubes, but that they buckled considerably below the elastic limit of the steel because of the slenderness of these tubes. The writer has proved that slender torsion tubes will buckle in this manner by actual tests, and has obtained results in torsion of thin tubes similar to the Euler curve for columns by varying the ratio of thinness.

J. J. KANTER.[7] Incidental to his studies on creep under shear stresses, the author has considered possibilities of structural change in steel due to the effects of high temperature alone. He offers some data which indicate that in less than 30 days of continual heating at 450 deg. cent. (842 deg. fahr.) appreciable loss of tensile strength, yield point, proportional limit, and Rockwell hardness is sustained by low-carbon strip steel, normalized. It might well be inferred on the strength of these data that in a year of heating, for instance, much greater difference than measured in 30 days would be found. The author suggests that more experimental evidence on this point is to be desired.

It has been shown by several investigators that carbon steel tested in creep-elevated temperature is not seriously changed in its mechanical properties. Tensile tests have been made upon specimens subjected to as much as a year of creep testing. Tests such as these seem to show only a slight annealing at temperatures in the range of 900 and 1000 deg. fahr. (483 and 538 deg. cent.). Creep testing in the range of 750 deg. fahr. (400 deg. cent.) tends to produce a slight increase of tensile strength and yield point, presumably due to strain hardening. Carbon steel does not seem to deteriorate in any alarming degree as a result of exposure to creep conditions.

The conditions for structural change which the author considers in the present discussion, however, do not involve stress—only temperature and time. Some tests of this type involving

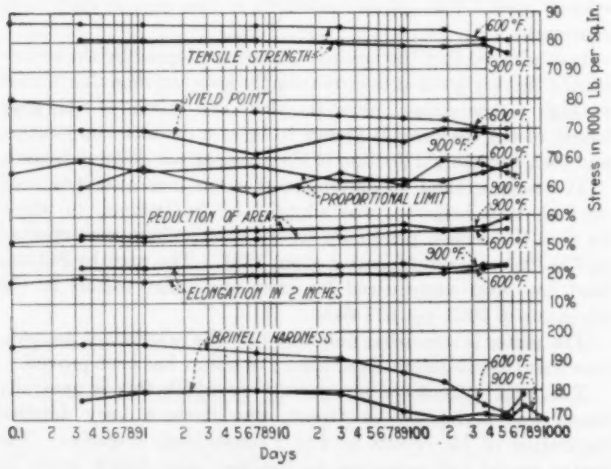

FIG. 24 MECHANICAL TESTS ON 0.45 PER CENT CARBON-STEEL ROD AT ROOM TEMPERATURE

(After various lengths of heating at 600 and 900 deg. fahr., 315 and 483 deg. cent. Analysis: C, 0.45; Si, 0.08; Mn, 0.54; S, 0.04; P, 0.012. Heat treatment: Normalized at 1650 deg. fahr., 900 deg. cent.; quenched from 1500 deg. fahr., 815 deg. cent.: drawn 2 hours at 1500 deg. fahr., 678 deg. cent.)

up to three years' exposure will probably be of interest at this time. Figs. 24 and 25 represent the mechanical test results of two carbon-steel materials given long-exposure tests at 600 and 900 deg. fahr. (315 and 483 deg. cent.). The results represent part of a comprehensive survey of various steels and alloys, under long-time heating conditions, started in 1923. The

[7] Metallurgical Department, Crane Company, Chicago, Ill.

soaking temperatures are maintained constant and uniform in two cast-iron blocks each containing a number of drilled holes to admit test specimens suitable for machining to standard 0.505-in. tensile bars. These blocks are insulated with magnesia and kept heated to temperature by means of thermostatically controlled gas burners. The variations in temperature amount to about ±25 deg. fahr. (±15 deg. cent.) of those stated. The heating blocks were kept continually at temperature, specimens being withdrawn at desired intervals.

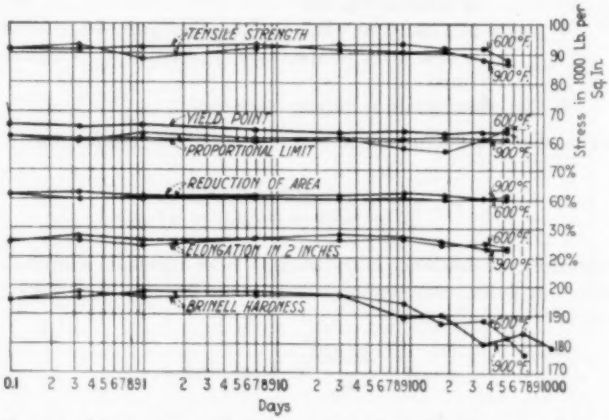

FIG. 25 MECHANICAL TESTS ON COLD-ROLLED BESSEMER-STEEL ROD AT ROOM TEMPERATURE

(After various lengths of heating at 600 and 900 deg. fahr., 315 and 483 deg. cent. Analysis: C, 0.09; Si, 0.03; Mn, 0.72; S, 0.105; P, 0.089.)

The effects of long exposure at 600 and 900 deg. fahr. (315 and 483 deg. cent.) of 1 in. diameter 0.45 per cent carbon-steel rod are shown in Fig. 24. These specimens were uniformly heat treated to 195 Brinell hardness, in the following manner:

Normalize at.....	1650 deg. fahr. (900 deg. cent.)
Quench from.....	1500 deg. fahr. (815 deg. cent.)
Drawn 2 hr. at.....	1250 deg. fahr. (678 deg. cent.)

Very little change in tensile strength was found for heating periods up to 18 months at either 600 or 900 deg. fahr. (315 or 483 deg. cent.). At 900 deg. fahr. (483 deg. cent.) after 6 months of exposure a slight loss is apparent. Changes in yield point and proportional limit, elongation, and reduction of area are similarly of small magnitude up to 18 months of heating. The changes in Brinell hardness are recorded up to 24 months at 600 deg. fahr. (315 deg. cent.) and 40 months at 900 deg. fahr. (483 deg. cent.). Neither of these temperatures produced a definite hardness change until after 30 days of heating had been exceeded. A greater percentage of loss in hardness than in tensile strength apparently is sustained in the long-time heating.

Long-time heating tests upon 1-in.-diameter cold-rolled bessemer steel rod are shown in Fig. 25.

Unlike the heat-treated 0.45 per cent carbon steel, there are marked differences in the changes in mechanical properties brought about in raising the temperature from 600 deg. fahr. (315 deg. cent.) to 900 deg. fahr. (483 deg. cent.). Gradual loss in tensile strength, yield point, and Brinell hardness, with corresponding gradual rise in elongation and reduction of area, are shown at 600 deg. fahr. (315 deg. cent.). At 900 deg. fahr. (483 deg. cent.), however, but 8 hours of heating was required to bring about the approximate total change in properties which accumulated in a year at 600 deg. fahr. (315 deg. cent.). Given time enough, therefore, 600 deg. fahr. (315 deg. cent.) is a high enough temperature to effectively relieve the hardening and internal straining due to cold work. At 900 deg. fahr. (483 deg. cent.), where the same relief is accomplished in a few hours,

further heating up to 3 years produces no drastic additional changes.

The changes which do take place at 900 deg. fahr. (483 deg. cent.) from 8 hours on are quite similar to those shown in Fig. 24 for 0.45 per cent carbon drawn steel.

These tests, together with those of the author, seem to indicate that the principal possible source of instability of mechanical properties in low- and medium-carbon steels, not hardened, is due to internal strain. The rate at which such strain is relieved apparently is a function of temperature and time, not dependent upon any critical or recrystallization temperature; 600 deg. fahr. (315 deg. cent.) is seemingly as effective over a long-time period as 450 deg. cent. (842 deg. fahr.), which is ordinarily considered to be the lowest temperature for recrystallization. The $^1/_{16}$-in.-thick strip steel used in the author's tests, although annealed at 900 deg. cent. (1652 deg. fahr.) before the exposures, may have retained some of the effects of the drastic cold working which thin strip steel is usually subjected to. The losses found by the author in the period between 5 and 30 days of heating at 450 deg. cent. (842 deg. fahr.) are of much greater magnitude than those found for similar intervals in the tests upon the two rod steels at 900 deg. fahr. (483 deg. cent.). It is quite probable that the changes take place more rapidly in $^1/_{16}$-in.-thick strip sections than in 1-in.-diameter rods.

On the strength of what evidence is at hand, there need be little anxiety over the deterioration or troublesome structural changes as a result of heating in ordinary structural carbon-steel products. It is of course known that certain heat-treated alloy stee's are affected structurally and chemically in the course of heating, but so far as low- and medium-carbon steels are concerned it is found that heating, under ordinary conditions, affects principally the state of strain hardening, whether stress is being applied or not.

GEORGE C. PRIESTER.[8] The author should be commended on the painstaking and ingenious method devised for the determination of his data. The phenomenon of creep in metals subjected to stress is of prime importance in several phases of engineering design. While most investigators have confined their analyses of this phenomenon to specimens subjected to tensile stress, this is the first paper that has come to the writer's attention which deals with creep when the specimen has been subjected to a shearing stress. The fact that the shearing deformation of a specimen subjected to torque can be measured with a much higher degree of accuracy and with simpler instruments has long been recognized by many investigators in the properties of the strength of materials, but as yet very little use has been made of this fact It remained for the author of this paper to demonstrate this, and it is the hope of the writer of this discussion that more use will be made of it.

Some six years ago in the materials-testing laboratory of the University of Minnesota, an instrument employing the use of the Ames dial was devised for measuring shearing deformation in specimens subjected to torque. The basic principle of this instrument is the same as that used by the author. The results obtained were gratifying and even beyond the expectation of the writer as to the accuracy with which these deformations could be read. This instrument is still in use.

In referring to the author's paper, in Section III-4, where he states that "This curve does not ook like those usually obtained for ultimate strength in tension at different temperatures," it is not quite clear to the writer just what significance this may have, when one compares the different manner in which an ordinary tension test is carried out with the one used by the author. In the ordinary tension test the specimen is stressed by producing a deformation in it. The author stressed his specimen by loading the specimen by direct torque, and naturally if any phenomenon of necking did take place, it would be practically impossible to measure stress and strain simultaneously in the range in which necking takes place by the method he used. Also the specimens the author used would preclude any phenomenon of necking.

In the second paragraph of Section IV, the author states that "It was noted that the minimum rate of creep in each instance occurred at approximately the same total shear strain." He also states that this occurs at a shear strain of about 0.10 in. per in., and then later on in his paper used this as a basis for "Accelerated Methods of Testing." It seems to the writer that the author would have encountered less difficulty and obtained a more reliable basis for the accelerated tests had he used the minimum rate of change of creep instead of the minimum rate. From Fig. 17 of the author's paper it will be noted that there is a minimum rate of change in all the curves at about 0.08 in. per in. shear strain. Also this minimum rate of change of creep is not affected by any buckling phenomenon and occurs at a point which could be determined with more accuracy than the one suggested by the author. By selecting the points of inflection in a set of curves there is also a greater possibility that the phenomenon will lend itself to a more rational mathematical treatment should one desire to investigate the problem from this standpoint.

On the whole the author is to be congratulated on the thorough manner in which he undertook and carried out his tests on this new phase of creep. The writer sincerely hopes that he may be able to continue productive work along this line.

A. E. WHITE.[9] This is a material contribution to the data which is accumulating on this subject. So far as the writer is aware, this is the first time that an outstanding attempt has been made to measure shear at elevated temperatures. The torsion machine which was developed for the measurement of shear represents a distinct contribution. One of the advantages which it possesses is the fact that shear creep measurements, at least in accordance with the method described in this paper, are not materially affected by the coefficient of expansion, which value always has to be considered when creep values of a high degree of accuracy are made in tension.

P. G. MCVETTY.[10] The paper is a valuable contribution to our knowledge of creep of metals at elevated temperatures. While it has not yet been proved that creep results from shear within the individual crystals rather than from some form of viscous flow of the intercrystalline material, a study of shear phenomena appears to be a step in the right direction.

Some mention should probably be made of the pioneer work of R. W. Bailey in this field, reported at the World Power Conference in Tokyo in 1929. He also used a tubular specimen and a similar method of applying a torque moment, and in addition, studied the effects of a superimposed axial stress. His conclusion that creep also occurs on planes other than those of maximum shear appears to be worthy of further consideration. This indicates that creep is even more complex than was supposed, and the necessity for further fundamental research is evident.

There are several questions which may be asked relative to the methods used in measuring and controlling temperatures. The effects of temperature fluctuations are undoubtedly less serious

[8] Professor of Materials of Engineering, University of Minnesota, Minneapolis, Minn.

[9] Professor of Metallurgical Engineering and Director of the Department of Engineering Research, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[10] Mechanical Engineer, Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

in a torsion test than in the usual tension creep test. However, it is assumed that the temperature is uniform over the gage length, and it would be interesting to know the extent of temperature variation within the length of the test specimen. If, for example, the specimen is 10 deg. hotter at the center than at the ends of the gage length, the angle of twist will not increase uniformly from one end to the other, and a considerable error may be introduced.

From a study of the apparatus used it is probable that considerable heat is conducted away from the specimen through the upper and lower grips and the strain-measuring device. This results in temperature gradients within the furnace, and it would be desirable to have more information about the location of the thermocouple used for temperature measurement and control.

The writer has also found a difference between readings taken in the morning and in the evening. This difficulty was experienced in some early tests before instruments were used to furnish a continuous record of furnace temperatures. This was finally traced to faulty temperature control during the night, resulting in a lack of temperature equilibrium in the apparatus at the time of the morning reading. The trouble has been completely eliminated by improvements in temperature control.

There is now much evidence to indicate that creep is a discontinuous process. The sudden slips observed by the author are probably stopped by strain hardening, after which a considerable time at the test temperature may be necessary to produce softening and further slip. In the April, 1931, issue of MECHANICAL ENGINEERING, Dr. Jeffries mentioned some interesting observations of this phenomenon as affected by grain size and method of loading. The author's proposed tests with pulsating loads should throw light on the important question as to whether the results of static creep tests are applicable to service conditions.

The apparatus developed by the author is admirably adapted to the study of very low creep rates, and the results of his further tests at low stresses will be awaited with much interest.

A. NÁDAI.[11] Experiments on the phenomenon of creep are today very important. In the industrial laboratories much work has been done during past years to determine the behavior of metals under stress at elevated temperatures. In most of these tests cylindrical specimens have been subjected to tensile loads and the extension of the specimens observed while the load was kept constant over a long period of time. The observation of a small longitudinal extension of a comparatively short gage length in a tensile test is difficult. Mr. P. G. McVetty has called attention to sources of error due to such arrangements. Small changes of the temperature of the bar may have a great effect on the observed elongation due to the inequality of the temperature between the test piece and the comparison strips of the extensometers; the thermal expansion of the latter introduces errors in the readings of the extensometer which may become serious. It is therefore a step toward the improvement of creep-testing methods used in industry to test materials, according to the suggestions of Professor Timoshenko, in torsion instead of in tension. Shear deformations are not affected by volume changes due to thermal expansion. The shear-testing apparatus designed by Dr. Everett might prove useful as it eliminates certain difficulties encountered in the usual methods in long-time testing.

On the other hand, certain new difficulties seem to be introduced by the use of thin-walled tubes subjected to torsion on account of the instability of the equilibrium of such tubes. The compressive stresses acting at 45 deg. to the axis of the tube might produce buckling. Thin-walled tubes at higher temperatures than those applied by Dr. Everett would probably buckle because of the known lowering of the critical buckling forces as soon as plastic buckling occurs, as compared with the critical values of the forces of purely elastic deformations.

The work of experimenters who have investigated the plastic range of the deformations at normal and at elevated temperatures under various stress conditions, is closely related to the problem of creep investigated in the paper. Mention should have perhaps been made of some of the elaborate tests which have been carried out under combined stress and in which the rules of plastic flow at normal temperatures have been carefully studied. Among these tests are, especially, those made in England (several years ago), more recent tests made in Germany (W. Lode[12]) and in Switzerland (Rôs and Eichinger[13]) which might also be of interest in connection with the subject of the present paper, as some of the results of these tests might have their useful applications also to the phenomenon of creep. Torsion tests with metals at elevated temperatures have been made previous to those reported here by R. W. Bailey[14] in England.

Referring now to some of the experimental results, mention should be made that the logarithmic rule as expressed by Fig. 18 was discussed by P. Ludwik as far back as 1908.[15] Presumably Ludwik was the first to propose the formula that the stress under which a metal yields slowly is proportional to the logarithm of the ratio of the velocities of deformation with which the bar is extending. This was found for metals having a low melting point and under room temperature, that is, perhaps under conditions which in some way may correspond to creep tests of steel at elevated temperatures. A logarithmic equation has been suggested independently by Cassebaum,[16] expressing the ordinates in the ordinary tensile stress-strain diagram of steel taken for the same amount of deformation, but at various speeds of extension, referred to each other. From his torsion tests, R. W. Bailey finally arrived at a similar conclusion. This last investigator distinguishes also as Dr. Everett does between three phases of the creep test under constant load, and he finds from his torsion test that if he plots the logarithms of the rate of creep for what he calls the second stage of creep (this corresponds to Dr. Everett's "minimum creep rate") as the abscissas and the stresses as ordinates, he obtains a straight line.

In Section II, in the last paragraph, the author quotes the ratio 0.6 as the value of the yield point in uniform shear to that in tension at normal temperatures,[17] finding that this is in good agreement with the maximum-energy theory. If the full amount of the maximum-strain energy, including that of the volume dilatation, was meant here, this statement needs to be corrected as it can readily be seen that the maximum-energy theory cannot be, in general, a correct criterion of the conditions of yielding.

Although it would seem at first glance as if on account of similar

[17] The figure 0.6 mentioned may also depend on the ratio of the wall thickness of the tubes tested to their outer diameter, if computed according to the "Code for Design of Transmission Shafting," Eng. & Ind. Standards, B17c-1927.

results obtained by independent investigators, consideration should be given to apply these results at once in practical work, the writer thinks that as far as creep at elevated temperatures is concerned, this at the present time might be still premature. The observations mentioned above with regard to rules combining stress and velocity of deformation refer to various modes of yielding, namely, plastic yielding of steel at room temperature (Cassebaum) and also to creep (Ludwik, Bailey, Everett). This seems at first astonishing, as it is assumed that the mechanism of plastic flow at normal temperatures in polycrystalline materials such as steel may differ from that of such materials at elevated temperatures where the thermal agitation of the atoms has more and more influence. Observations by Mr. McVetty at the Research Laboratories seem to indicate more and more definitely that certain very slow processes taking place in a metal exposed to elevated temperatures, may, over a period of months and perhaps years, depending on the conditions, still influence the creep characteristics of a metal subjected to a long-duration test. Much experimental work will still have to be done in investigating these and similar factors until it is possible to establish quantitative rules for the slow deformations of the metallic alloys at elevated temperatures.

Although many points may need further approval in this difficult field of investigation of creep all new contributions should be much appreciated, especially the valuable work presented by Dr. Everett, in which he has attempted to attack various points from new sides. It is hoped that by repeating such efforts it may be possible in the succeeding years to arrive at a more satisfactory understanding of the slow movements and deformations of metals at higher temperatures.

Author's Closure

Mr. Jasper suggests that buckling of a thin tube in torsion may occur at stresses below the yield point of the material. The ratio of the thickness of the tubes used in the investigation discussed in the paper to the diameter was about 1 to 20, and the matter of buckling of tubes with such proportions at stresses below the yield point is absolutely impossible. In discussing the information given in Table 2 and later in connection with Fig. 22, the author explained the results of representative experiments indicating that the stability of the thin tubes was maintained at least beyond the yield point. The problem of buckling was encountered in stresses well in excess of the yield point, as has been covered in Section II-3.

The second point raised by Mr. Jasper considers the ultimate strength in torsion. Since stress concentration, although of great importance in brittle materials, does not enter into the problem of ultimate strength of a ductile material, a tubular specimen with a reduced section so short that buckling is impossible was investigated. The cross-section of this short tubular specimen was identical with that of the long specimen, but the possibility of buckling was entirely eliminated by the shortness of the small section as can be seen in Fig. 8.

The modulus of elasticity in shear at various temperatures was determined from the straight-line portion of the curve of shearing stress and shearing strain upon unloading the specimen. The effect of creep during unloading was found to be practically negligible, and a relatively long straight-line portion was obtained from which the modulus in shear was calculated with considerable accuracy. Care was exercised in providing uniform temperature conditions over the gage length of the tubular specimen. As can be seen by reference to the curve of Fig. 15, a variation of even ± 5 deg. cent., which is an extreme range, would not appreciably affect the character of the curve.

In practice many designers adopt for ductile materials the maximum-shear theory—mentioned in the Introduction of the paper—as being in most general agreement with analysis and experiment. In some cases other theories appear to fit the conditions more closely. Some of the results of the preliminary experiments made by the author coincide with the maximum-energy theory, as reported in Section II-2.

Mr. Jasper mentions the work of Guest in a complimentary manner. Guest himself favored the maximum-shear theory as a basis for determining working stresses.

In Mr. Kanter's tests, the specimens were machined subsequently to the heating period, whereas the thin specimens studied for the effect of long-time heating and reported in the paper were tested "as heated." In the latter the additional possibilities of weakening by decarburization and oxidation of the surfaces formed the reason for selecting very thin strips having a large ratio of surface area to cross-sectional area, which paralleled the condition encountered with thin tubes used in the creep tests. Mr. Kanter's tests compare as to the possibility that further releases of internal strains are not completely removed in the preliminary annealing and the growth of grains, with consequent weakening effect.

Mr. Kanter's generalization that higher temperatures have the same effect upon the physical properties as do lower temperatures operating over a longer times seems justifiable. It is known that internal strains which will become released after several months at ordinary room temperatures will be released to the same extent by placing the specimen in boiling water (100 deg. cent.).

Regarding some of the questions propounded by Professor Priester, in determining the ultimate strength of carbon steels, at least, in tension at various temperatures, it is usual to find a maximum value in the vicinity of 200 to 300 deg. cent. A gradual improvement in tensile strength frequently precedes the maximum point. Since the results obtained for the ultimate strength in shear appeared to disregard both of these characteristics, it is of interest to make this observation. We can usually look to what takes place in shear for an interpretation of tension conditions, but in ultimate strength, necking in tension tests, in addition, perhaps, to other factors, appears to contribute a further complication.

Professor Priester suggests that greater accuracy is obtainable in locating the point of minimum rate of creep by considering the minimum rate of change of creep. Curves similar to that shown in Fig. 20 and mentioned in Section IV-1 were made as the tests reported in Fig. 17 and others progressed. From such curves the minimum rate of change (zero rate) was readily observed.

Professor White has emphasized an important point in mentioning the higher accuracy obtainable by torsion methods compared with those in tension as affected by temperature variations of the test specimen.

Mr. McVetty points out, and properly so, that the investigation of creep in tubes by R. W. Bailey deserves mention. The author has studied his work with considerable interest, but it appeared only in the early part of 1930 and the investigation discussed in this present paper had progressed considerably by that time. The complete bibliography in connection with the present investigation includes the contributions of Mr. Bailey.

It appears important, as Mr. McVetty mentions, that a knowledge of the temperature at all points of the specimen be possessed. In some preliminary experiments early in the investigation as much difference as 10 deg. cent. was observed over the gage length of 4 in., representing the very worst condition that has been found. This information on temperature was the result of placing three thermocouples on the specimen, at the gage points and the mid-point, and reading on one potentiometer. The error caused by a temperature differential along the length of the tube specimen only affects strain readings as a result of a different value of the modulus of elasticity in shear, Fig. 15, as the temperature deviates from the correct amount, unless, of course, there is a

fluctuating temperature, in which case the discussion under Section V-3 applies. The error due to a constant temperature condition, admitting a small temperature differential along the gage length, is then seen to be really inconsequential. It means that the creep test is being conducted within a small temperature range, and that the creep readings are not caused to vary as a direct result of this.

There is actually a generous transfer of heat by conduction outward through the grips which hold the specimen. Both the check of the temperature at three points along the specimen as described above and the relatively long furnace, which has a ratio of about three to one compared with the specimen, assure reasonable temperature conditions. During every experiment a thermocouple attached to the mid-point of the specimen is connected to an indicating potentiometer which describes the temperature of the test. The thermocouple which leads to the automatic temperature control is fastened to the mid-point of the alundum tube of the furnace. Each furnace is equipped with its individual control instrument.

Observations from the indicating potentiometer have shown no appreciable difference in the temperature during the evening or the day. The fluctuating results of shear strain reported in Section V-2 caused by jars to the apparatus disappeared upon mounting the machines on springs.

Dr. Nádai mentions that volume changes due to thermal changes do not affect shear deformations. The author attempted to show in Section V-3 that changes in gage length and polar moment of inertia, and also modulus of elasticity in shear, combined to produce some possible error appearing in shear-strain measurements. Their combined effort is, fortunately, slight.

The question of buckling was given much careful study both preparatory to and during the long-time creep tests. In Section I-3 some remarks are made to the effect that buckling of the tube walls, if present, was not measurable on specimens after creep tests by means of a micrometer. It appears from the author's experiments that buckling takes place only after relatively large angular distortions, and that the amount of distortion during which creep data are obtained is in all cases considerably below any evident buckling condition. It is to be expected that higher temperatures will cause a lowering in the critical amount of buckling forces, but the shear stresses are also materially decreased in such creep experiments.

Referring to the value of 0.6 for the ratio of the yield point in pure shear to that in tension as found from certain room-temperature experiments mentioned in the paper, it can be said that this value, in a general way, is approximately correct, considering total strain energy and also only that part due to distortion, lying somewhere betweeh the two ratios.

Some reluctance appears to be expressed by Dr. Nádai in the matter of accepting creep data for design purposes. For industrial needs, however, information regarding creep phenomena is required and the available data, although insufficient, must be used. Such men as Baumann, Tapsell, and Hatfield believe that there are sufficient data available from which to draw some practical conclusions.

The author wishes to thank those who have contributed to the the discussion of this paper.

Recent Advances in Photoelasticity

And an Investigation of the Stress Distribution in Square Blocks Subjected to Diagonal Compression

By MAX M. FROCHT,[1] ANN ARBOR, MICH.

After discussing the principle of optical equivalence of stressed isotropic bodies, the author deals respectively with current methods to determine (P — Q); the fringe method; annealing of bakelite; fringe photographs of various models; membrane method to determine (P + Q); the photoelastic investigation of stress distribution in square plates subjected to diagonal compression; isoclinics; trajectories; (P — Q) from fringe method; P and Q by graphical integration. He then summarizes the approximate theoretical analysis by the strain-energy method, gives comparative curves, discusses results, describes new equipment, and in conclusion, derives fundamental equations for the evaluation of P and Q by graphical integration.

THE growth of high-speed and large-size machinery, as well as the personal influence of a few outstanding men, is beginning to convince industrial executives of the need and value of mechanics as an engineering tool. With the general recognition of mechanics must go a special recognition of photoelasticity. Only the simplest problems in stress distribution can be determined theoretically. Generally it is necessary to employ experimental methods to this end, among which photoelasticity must rank first.

The development of this branch of experimental mechanics has been retarded by the absence of a suitable material and by a certain mistrust among engineers in the validity of its results.

The researches of Professors Mesnager, Coker, Filon, and others have gone a long way to dispel these doubts, and to build up a confidence in the results obtained by the optical method. It has been proved theoretically and substantiated experimentally that within the elastic limit and in simply connected bodies the stress distribution is independent of the physical constants of the material. Professor Filon has shown that even in the case of multiply connected bodies such as connecting rods, the errors due to the difference between the materials of the model and the corresponding machine part or structural member are very small. The introduction of celluloid as a working material made photoelastic research not only possible but practicable.

In very recent years interesting and promising developments have taken place, and it is the object of this paper to discuss some of these developments and their application. In particular the author will present, first, Dr. Tuzi's fringe method for the determination of the difference between the principal stresses at a point; second, a new experimental method for the determination of the sum of the principal stresses; third, a process for the annealing of bakelite which will restore this excellent material to photoelastic work; fourth, a photoelastic and theoretical investigation of the stress distribution in square plates subjected to diagonal compression; and fifth, photographs of new and inexpensive laboratory equipment which will demonstrate that a photoelastic laboratory is financially within the reach of industrial organizations and engineering schools.

Essentials of Photoelasticity

The fundamental optical phenomenon underlying all photoelastic investigations is that of double refraction. It explains what is transpiring in the crossed Nicols, the quarter-plates, as well as in the stressed model itself.

When a ray of monochromatic light enters a doubly refracting crystal, such as Iceland spar, it emerges transformed in two important respects: first, it splits into two plane polarized rays, the ordinary and extraordinary, which vibrate in mutually perpendicular planes; second, the two rays travel through the crystal with different velocities, and therefore emerge from the crystal with a phase difference which depends on the wave length of the light and the length of the crystal. It is an experimental fact that a stressed element in an isotropic body behaves just like a doubly refracting crystal. To generalize: *Within the elastic limit all isotropic bodies subjected to a two-dimensional stress system are optically equivalent to a set of a large number of doubly refracting crystals shaped so that their lengths at every point are directly proportional to the difference between the principal stresses at that point, and whose principal planes are set parallel to the stress trajectories.* It is a further experimental fact that the relative retardation R between the ordinary and extraordinary rays produced at a point of an isotropic body due to its temporary doubly refracting character is given by the equation

$$R = c\,(P - Q) \qquad [1]$$

where c is an optical constant depending upon the material, and P and Q are the principal stresses at the point. Due to the above-mentioned facts a stressed, transparent model in a field of *white, circularly polarized light* gives a colored image each tint of which is a measure of $(P - Q)$. This phenomenon is the foundation of the prevailing methods in photoelastic laboratories today. It is the basic idea in color matching and compensating. Both of these methods depend upon the color effect to determine the numerical value of $(P - Q)$.

---

[1] Associate Professor of Mechanics, Carnegie Institute of Technology, Pittsburgh, Pa. Dr. Frocht received a B.S. in mechanical engineering at the University of Michigan in 1922, a M.S. in physics at the University of Pittsburgh in 1925, and a Ph.D. in engineering mechanics in June of this year from the University of Michigan. At the expiration of his present leave of absence at the University of Michigan, Dr. Frocht is returning to the Carnegie Institute of Technology with which he has been connected since 1922. From 1912 to 1920 he was associated with various automobile concerns, including the General Motors Research Laboratory at Dayton, Ohio. In 1930 he was on leave of absence from Carnegie at the Autostroy, a U.S.S.R. Corporation for whom he was commissioned to make a study of the functional and structural organization of the Ford Motor Co.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of The American Society of Mechanical Engineers. (From a dissertation for the degree of Doctor of Philosophy in the University of Michigan.)

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The Fringe Method

If instead of white light a monochromatic source be used, then the relative retardation between the ordinary and extraordinary rays caused by the stressed model manifests itself not in color effects but in a change of intensity. Referring now to the rays emerging from the analyzer, let A = amplitude, A_m = maximum amplitude, I = intensity, and I_m = maximum intensity.

It can then be shown[2] that $A = A_m \sin \pi R$ ..... [2]

Since the intensity of light varies as the square of the amplitude,

$$I = A^2 = A_m^2 \sin^2 \pi R$$

But $$A_m^2 = I_m$$

hence $$I = I_m \sin^2 \pi R \quad \text{..... [3]}$$

where R is given by Equation [1].

Inspection of Equation [3] shows that I will be zero for R equal to an integral number of wave lengths. For such values of R the light will be completely extinguished and a dark spot will be obtained on the screen. In this manner the use of monochromatic light results in alternate bright and black fringes, whose number and complexity depend on the material and loading.

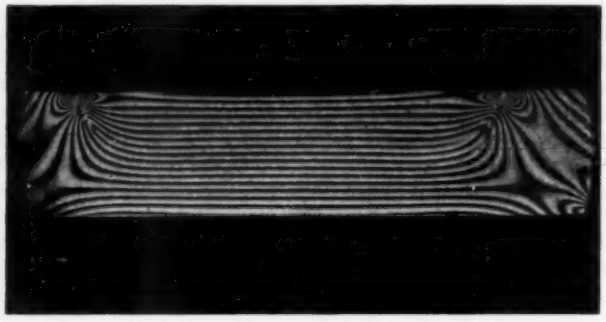

Fig. 1 Fringe Photograph of Bakelite Beam in Pure Bending

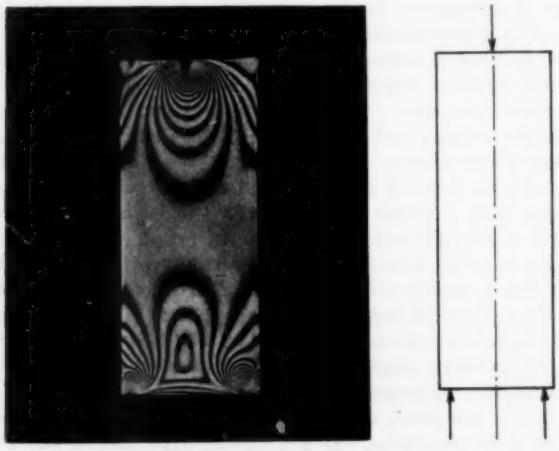

Fig. 2 Fringe Photograph of the Escaping Type

Fig. 1 shows a fringe photograph of a bakelite beam in pure bending. It will be observed that the fringes are straight, parallel, equidistant lines, this being due to the linear distribution of the stress. From the known load conditions and the dimensions of the beam, the stress value of each fringe can be computed.

[2] See article by A. L. Kimball, Jr., on "Stress Determination by Means of the Coker Photo-Elastic Method," *General Electric Review*, January, 1921, pp. 80–81.

The difference between the principal stresses corresponding to each fringe of a stressed model of the same material becomes thus a known quantity, provided we know the number of wave lengths of relative retardation responsible for the particular fringe, that is, provided we know the *fringe order*.

The Formation of Fringes

The formation of fringes is a very interesting, though somewhat complicated phenomenon. Dr. Tuzi classifies fringes into four types: the assembling, the converging, the diverging, and the escaping. The author proposes a simpler classification and will mention only two types of fringes: the escaping and the non-escaping. When all the fringes formed remain in the image, we have the non-escaping type. When some escape from the picture, we have the escaping type. The non-escaping type is best illustrated by pure bending, Fig. 1. The first fringes appear at the extreme fibers and approach the neutral axis as a limit but never reach it, since the stress at the neutral axis always remains zero. The fringes crowd together, but do not escape.

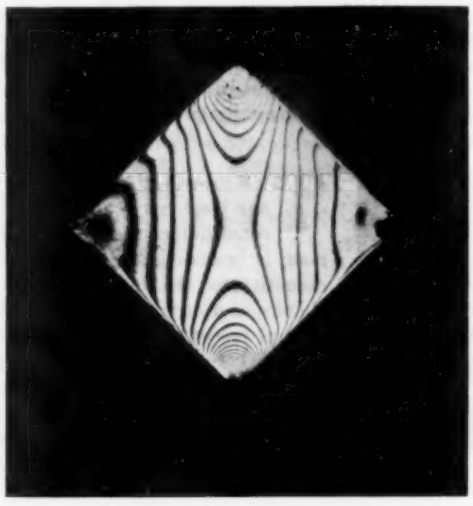

Fig. 3 Phenolite Model Showing Effect of Initial Stresses

The escaping type is the more general of the two. A simple illustration of this type is afforded by the fringes formed in a narrow, rectangular block in compression. Here the fringes are born in the interior, spread toward the edges, and escape, leaving only fragments at the top and bottom. Fringes may escape through the interior as well as the boundary. Fig. 2 shows a fringe photograph of the escaping type.

In the non-escaping type a static picture reveals the fringe order. This is not the case in the escaping type. Here the fringe formation must be studied in order to determine the fringe order. By slow and repeated loading and unloading one can determine the points where the fringes originate and vanish. It is also possible to take moving pictures and thus reproduce the fringe formation on the screen at leisure.

The fringe method for the determination of $(P - Q)$ is simpler than color matching, and more accurate than compensating. The fringes are clearer than isochromatics, and can be traced with accuracy. It eliminates the strain and tediousness that necessarily go with compensating. This method has another important merit. It not only reveals clearly the stresses in the model, but it makes it practicable to photograph them and thereby to secure permanent and convincing evidence of the stress distribution. From a pedagogical point of view the author

considers this of great importance. A picture carries a veracity which a sketch does not, and it is believed that with the help of the fringe method the dissemination of photoelastic knowledge should be materially accelerated.

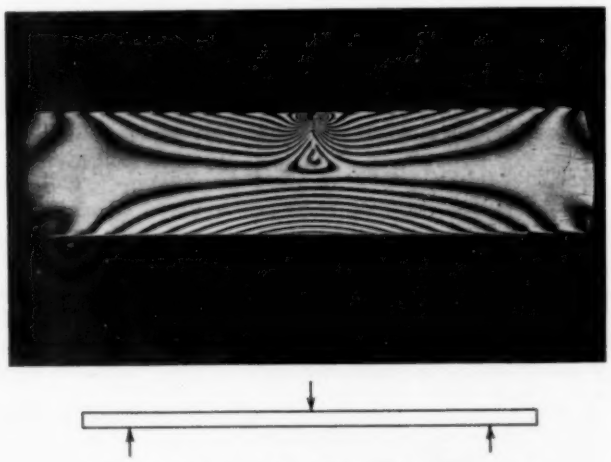

FIG. 4 BAKELITE BEAM UNDER CENTRAL LOAD

ANNEALING OF BAKELITE

The success of the fringe method depends upon having a sensitive material, which will show many fringes under comparatively small loads. Dr. Tuzi used phenolite, which is the invention of Professor Kita and Mr. Matui of the Institute of Physical and Chemical Research, Tokyo, Japan. This material is very sensitive and gives excellent results, but is not obtainable in this country.

Bakelite is a transparent material as sensitive as phenolite, and easily obtainable. Its use as a photoelastic material has been retarded because it shows pronounced initial stresses in its unstrained state. It is therefore of some interest that the author found a method which proved effective in the annealing of bakelite.[3] The main steps of this method are:

1 Heating the models to a temperature of about 70 deg. cent., and

[3] Prof. L. N. G. Filon in his paper "On the Graphical Determination of Stresses From Photo-Elastic Observations," *Engineering*, October 19, 1923, states that a method for the annealing of bakelite was discovered by Mr. Jessop. He does not, however, give an account of it, nor does he give any reference to a publication where such an account might be found.

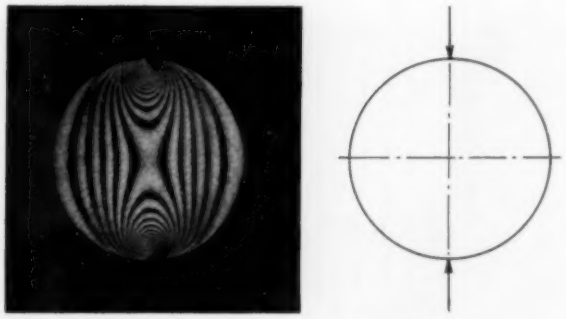

FIG. 7 PHENOLITE DISK

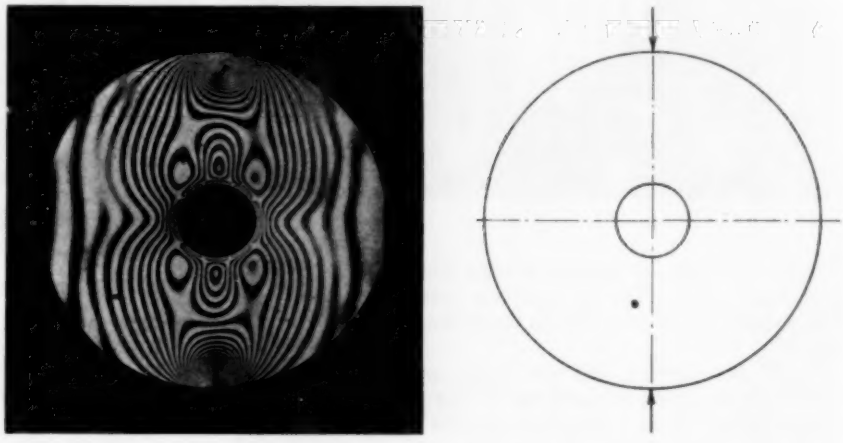

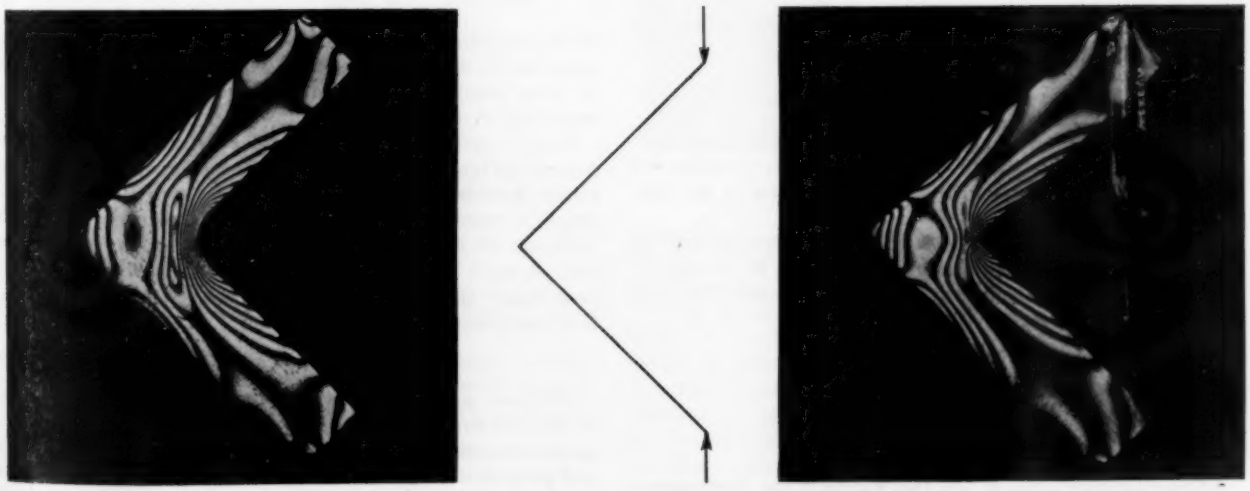

FIG. 8 BAKELITE MODEL

FIGS. 5 AND 6 BAKELITE MODELS SHOWING EFFECT OF FILLET ON STRESS CONCENTRATION, DIMENSIONS AND LOADS IDENTICAL

2 Cooling them very slowly to room temperature.

To procure uniform heating and cooling it is necessary to avoid direct contact between the models and the walls of the furnace. To this end it is advisable to place the models between glass plates and support them on a block.

The amount of time necessary for cooling depends on the furnace. In the author's case it took sixteen hours. Caution must be exercised not to remove the specimen too soon. Good models have been spoiled by premature removal. The heating can be done rapidly. It took the author only fifteen minutes

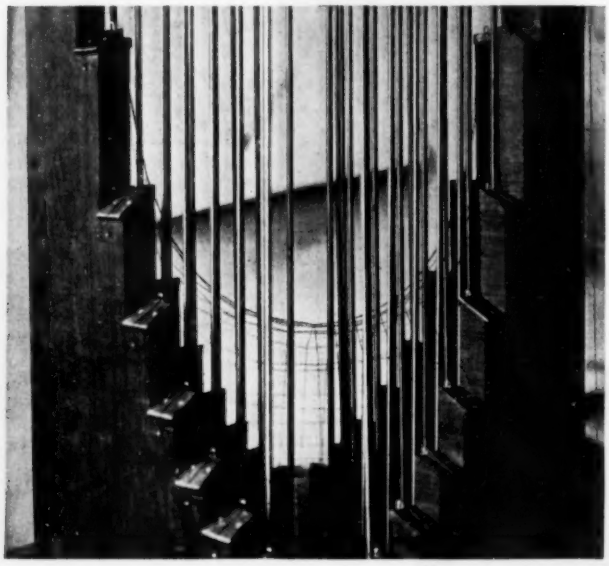

FIG. 9

to do it. In cases of stubborn stresses a second annealing will be found effective. The quality of the annealing obtained from this process can be judged from the photograph reproduced in Fig. 1.

It will be observed that the fringes are straight, parallel, equidistant lines, which would not be the case had there been initial stresses. Fig. 3 shows a phenolite model without annealing. It will be observed that there is marked absence of symmetry in the fringes, and also that they meet the boundary in directions almost parallel to them. An annealed model is shown in Fig. 16 in which the fringes are symmetrical and normal to the boundaries. Figs. 4–8 show fringe photographs of different models annealed by the aforementioned process.

A New Method for the Determination of $(P + Q)$

A method giving the same data as the lateral extensometers of Mesnager and Coker but radically different in principle and construction is being developed in the laboratories of the University of Michigan.

The sum of the principal stresses $(P + Q)$ in a two-dimensional system lends itself to representation by means of a surface.[4] This can be shown in the following way: The continuity equation of a two-dimensional system is

$$\nabla^4\phi = 0 \quad \ldots\ldots [4]$$

where ϕ represents the stress function.

This can be put in the modified form as follows:

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) \times \left(\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2}\right) = 0 \quad \ldots\ldots [5]$$

The second factor of this equation represents the sum of the normal component streases, i.e.,

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = \sigma_x + \sigma_y \quad \ldots\ldots [6]$$

which sum will be designated by the letter S.

The continuity equation then assumes the form:

$$\frac{\partial^2 S}{\partial x^2} + \frac{\partial^2 S}{\partial y^2} = 0 \quad \ldots\ldots [7]$$

and this is the equation of a membrane of small deflections whose boundary is subjected to uniform tension.

At a free boundary one of the principal stresses vanishes, so that the sum of the principal stresses on such boundaries equals the difference, and can therefore be determined photoelastically. If now a surface be constructed with boundary ordinates equal

to the boundary values of $(P + Q)$, then the ordinates at all other points would represent the sum of the principal stresses at those points. This affords an experimental means of determining $(P + Q)$.

Several methods can be used to construct such a surface. A soap film is one possibility; a membrane formed by a stretched rubber sheet is another. Fig. 9 shows a rough attempt to construct a woven surface. The uniform boundary tension is produced by means of small weights attached to the ends of each string. The shape of the curves thus obtained follows very closely the actual $(P + Q)$ curves. Work is in progress to obtain quantitative results.

The Main Problem

The main problem of which this paper is the outgrowth was to find the stress distribution in a square plate subjected to diagonal compression. The problem was investigated theoretically and photoelastically, and, as will be seen later, good agreement was obtained between the two sets of results. The photoelastic

[4] This suggestion is due to Mr. Den Hartog of the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

investigation will be first presented. The apparatus used and its arrangement are shown in Figs. 10 and 11.

The optical solution of a problem consists of four steps:

1 Determination of isoclinic lines
2 Determination of stress trajectories
3 Evaluation of $(P - Q)$
4 Evaluation of P and Q separately.

Isoclinics. The locus of points whose principal stresses have the same directions is called an isoclinic line. The simplest and general method to obtain such lines is by removing the quarter-plates from the polariscope and to turn the crossed Nicols 5 or 10 deg. at a time. The image obtained contains the isoclinics for the particular setting of the Nicols. It is of interest that this ingenious method was proposed by Maxwell when he was only nineteen and still a student at Edinburgh.

Glass models, because of their transparency, give the clearest curves, and such models were used in the present investigation. The size of the model does not matter. The glass was $^5/_{16}$ in. thick and could sustain an average compressive stress of nearly one ton per square inch. To sustain that stress the load had to be uniformly distributed. This was attained by the use of soft copper pins which also prevented chipping. The original sketch of isoclinic curves was enlarged, and the final curves shown in Fig. 12 represent the averages of the enlargement.

The author wishes to call attention to a possible source of error in sketching isoclinics. Not all the black curves from plane polarized light are necessarily isoclinics. A point of zero stress or a point of equal principal stresses will also cause a dark spot. To eliminate the possibility of error, one should compare the pictures with and without quarter-plates. The effect of the quarter-plates, among other things, is to remove the isoclinics,

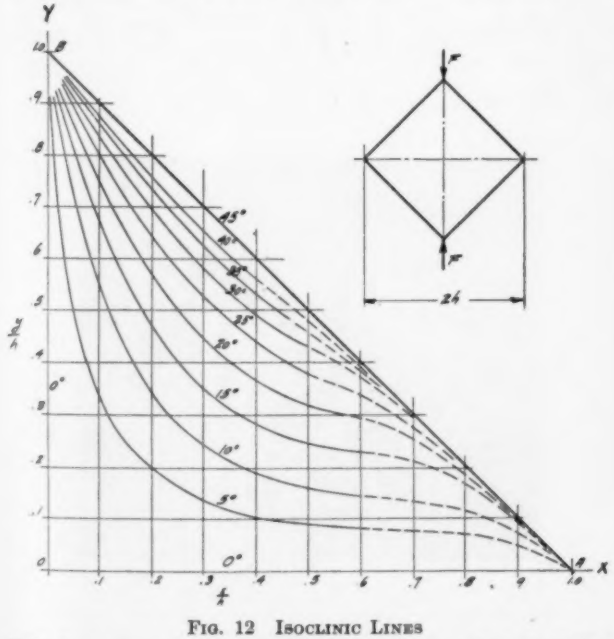

FIG. 12 ISOCLINIC LINES

(Solid lines: from direct observation; broken lines: from theoretical considerations.)

as can be seen from Figs. 13 and 14. The absence of the cross from Fig. 14 shows that it is an isoclinic, and likewise the presence of the circle in the same photograph shows that the circle is not an isoclinic.[5]

[5] Professor Muira includes the circle among the zero isoclinics, but the author believes this to be an error. See the former's "Spannungskurven in rechteckigen und keilförmigen Trägern," p. 87.

An interesting use was made of the cross representing the zero isoclinic in symmetrical models. During the investigation the Ahrens prisms became loose in their mountings and turned about the horizontal axis. They were reset by crossing the

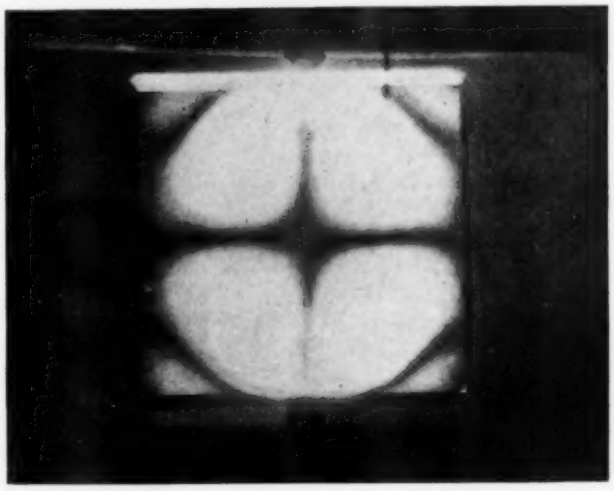

FIG. 13 WITHOUT QUARTER-PLATES

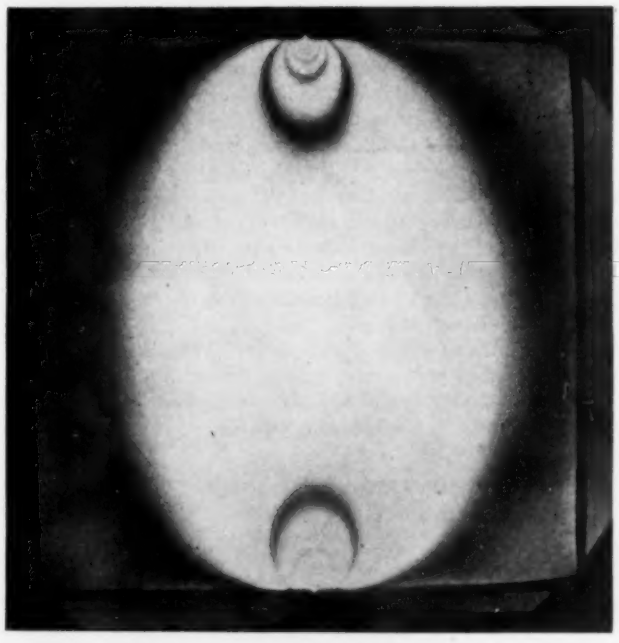

FIG. 14 WITH QUARTER-PLATES

mountings in a vertical and horizontal position, and adjusting the prisms until the isoclinic curve of the symmetrical model gave the cross.

Stress Trajectories. These were mapped in the usual manner and are shown by the full lines of Fig. 15.

Determination of $(P - Q)$. The difference between the principal stresses was determined in several ways. Celluloid, bakelite, and phenolite were used for materials, and color matching, tension compensating, and fringe counting as methods. But the author is so impressed with the simplicity and accuracy of the fringe method that the results will be presented in this form. First, two well-annealed models of the same strip of

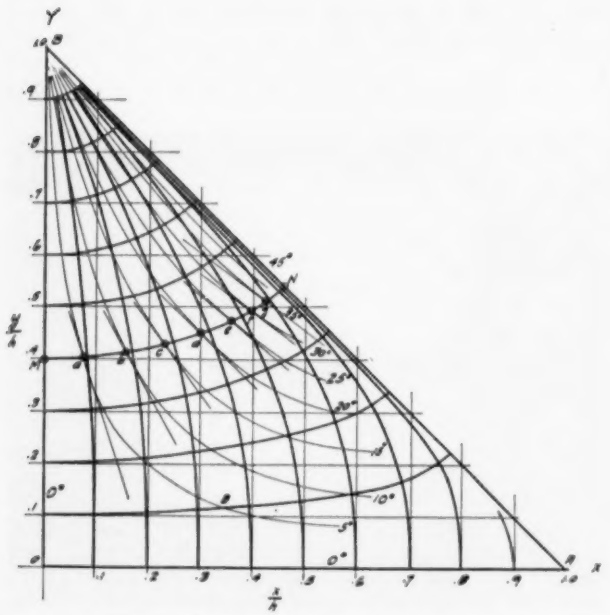

FIG. 15 STRESS TRAJECTORIES (*Heavy Lines*) AND ISOCLINICS (*Light Lines*)

bakelite were secured: a square plate and a beam, Figs. 16 and 17. The sodium lamp which was used for isoclinics was then replaced by the mercury-vapor lamp shown in Fig. 18, and the photographs shown in Figs. 16 and 17 taken. This gave all the optical data necessary to determine $(P - Q)$. As a measure of safety a free-hand sketch of the fringes was made immediately after taking the picture. This took but a few minutes and no optical creep could be observed. The clearness and thinness of the fringes enable one to sketch these with accuracy. The intersections of the fringes with the axes were noted, and curves were plotted with fringes as ordinates and axes as abscissas. Columns 2 in Tables 1 and 2 give the values of $(P - Q)$ in fringe order for the X- and Y-axes.

Determination of P and Q Separately. The principal stresses were determined separately by the use of Professor Filon's graphical-integration method. The equations used in this method are given in the following two forms. For their derivation see Appendix No. 1.

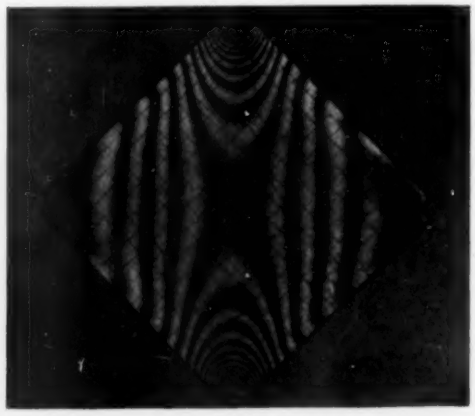

FIG. 16 ANNEALED SQUARE PLATE OF BAKELITE

The principal stresses were first determined along the diagonals, and for these lines Equations [8*a*] and [9*a*] are suitable. The notation is as follows: Referring to Fig. 19, Δx and Δy are the coordinates of any point C on the first curved isoclinic; $\Delta\phi$ is the difference between the parameters of the zero isoclinic and the first curved isoclinic. In the present case $\Delta\phi$ is 5 deg.

In the foregoing equations the directions of s_1 and s_2 are interrelated, s_2 being obtained from s_1 by a counterclockwise rotation of 90 deg.

The steps involved in the determination of P and Q will be best understood by a study of Tables 1 and 2. The mean values given in columns 6 and 12, Table 1, were taken from curves.

P was calculated first. The starting point was taken at A where P_0 is zero, Fig. 15, and integrated toward the origin 0. For s_1 positive to the left, s_2 is positive downward. It follows that Δy in Equation [8a] is negative for the 5-deg. isoclinic. In the calculations Δs_1 was taken as 0.5 in., as the author was working from an image with a diagonal of 10 in. divided into twenty equal intervals. Having determined P and knowing $(P - Q)$ at the same points, it was a simple matter to find Q.

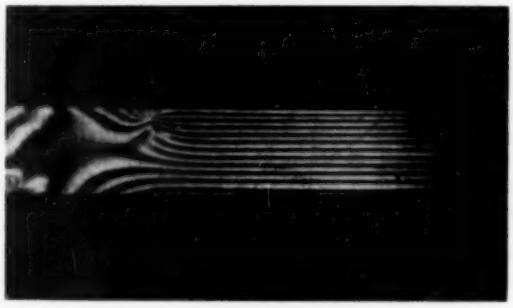

FIG. 17 ANNEALED BEAM OF BAKELITE

The stresses along the Y-axis were determined in a similar manner. The starting point was taken at 0, at which point both principal stresses were now known. Using Equation [9a] and starting with Q_o, values of Q were determined up to $0.82h$, which represents the limit of the experimental results. All the steps and the final results are given in Table 2.

The results thus far obtained are in terms of fringes. It is, however, a simple matter to convert these into pounds per square inch. The photograph of the comparison beam, Fig. 17, shows six fringes corresponding to a bending moment of 10.125 in-lb. For a loading as shown in Fig. 20, the ordinary beam equation $S = Mv/I$ is applicable and gives $S_{max.} = 1703.28$ lb. per sq. in., or 283.88 lb. per sq. in., for fringe No. 1.

By multiplying the fringe value of the principal stresses by 283.88 we obtain these stresses in pounds per square inch.

Verification of Results. The external load on the model was

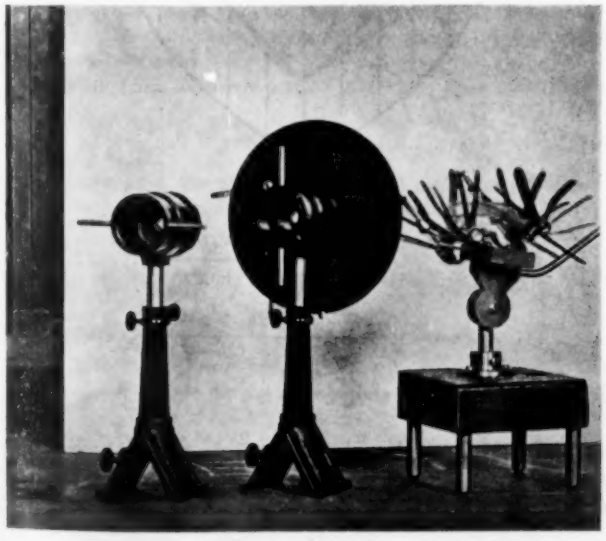

FIG. 18 SHOWING MERCURY-VAPOR LAMP AND CROSSED AHRENS PRISMS

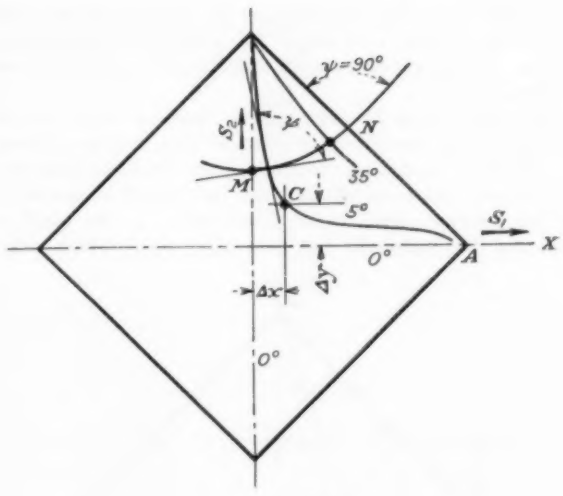

FIG. 19

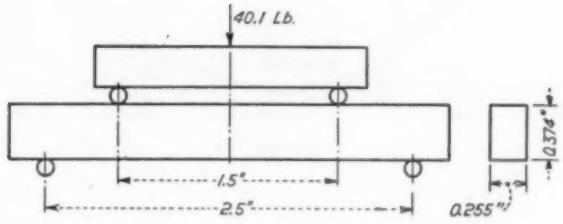

FIG. 20

179.66 lb. If, therefore, a section be made through the horizontal diagonal and one half of the block be considered as a free body, a static check of the work can be obtained. For equilibrium

$$\Sigma Y = 0$$

or

$$179.66 = \int_{-h}^{h} Qtdx \qquad [10]$$

where $2h$ is the diagonal and t the thickness of the model. For $2h = 1.855$, $t = 0.255$, and the mean values of Q as given in Table 1 the right side of Equation [10] works out to be 191 lb., which gives a check within 5.7 per cent. A portion of the discrepancy is probably due to the small initial stresses at the edges of the comparison beam.

DETERMINATION OF PRINCIPAL STRESSES ON A GENERAL STRESS TRAJECTORY

To show the generality of the photoelastic method, the principal stresses were also computed along the stress trajectory MN, Fig. 15. An enlargement of the photograph shown in Fig. 16 was made and the stress trajectory MN superimposed upon it. The intersections of the fringes with this trajectory were noted and a curve plotted giving $(P - Q)$ as a function of MN. The intersections of the isoclinics with MN are marked by the small letters a, b, c, d, e, f, and g, Fig. 15.

To determine P and Q separately, Equation [8b] was used. $\Delta\phi$ in this case is the difference between the parameters of two successive isoclinics. Thus in going from N to g, $\Delta\phi$ is -10 deg., Fig. 15.

ψ for any point on the stress trajectory is the angle between the tangents to the stress trajectory and the intersecting isoclinic measured counterclockwise. These were determined from Fig. 15.

The stress trajectory was followed in the direction of NM, starting from N where P_o is zero. This made $\Delta\phi$ negative and P positive. The details of the work and the final results are given in Table 3.

Check From Stress Trajectory MN. Another check of the correctness of the work from a point of view entirely different from statics is afforded by the results from the stress trajectory MN, Fig. 15. At point M there are two sets of values of the principal stresses. One set of these values is the result of integrating first along $A0$ and then along $0M$. These values

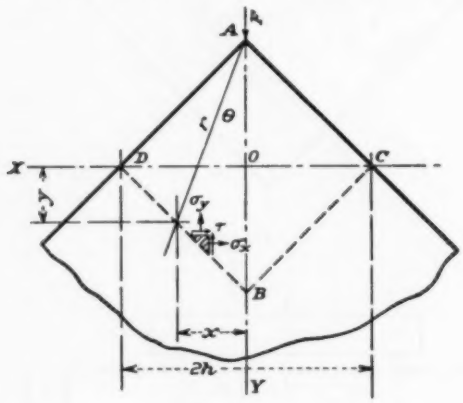

FIG. 21

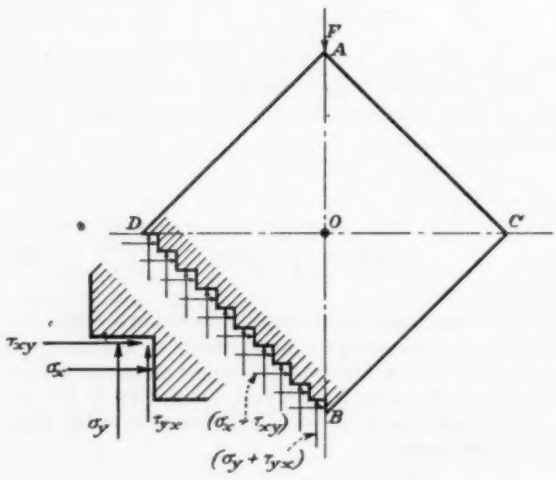

FIG. 22

in fringe order are: $P = 0.8020$, and $Q = -3.988$, see Table 2. The other set of values is the result of integrating along the path NM, which gave $P = 0.824$, and $Q = -3.976$ in fringe order, see Table 3.

The P's agree within 2.8 per cent and the Q's within 0.5 per cent. This agreement between the values of the principal stresses at a point obtained from different paths of integration constitutes the best proof of the correctness of the work.

SUMMARY OF APPROXIMATE THEORETICAL SOLUTION OF PROBLEM

The problem discussed is approached from the point of view of an infinite wedge, and the author assumes the stress function:[6]

[6] It is shown in texts on elasticity that this function satisfies the boundary conditions and the continuity equation.

TABLE 3 COMPUTATIONS OF P AND Q ALONG STRESS TRAJECTORY MN

$P = P_0 + \int_{\phi_0}^{\phi} (P - Q) \cot\psi d\phi$. In going from N to M, $\Delta\phi$ is negative, and $P_0 = 0$. $\therefore P = \int_{\phi_0}^{\phi} (P - Q) \cot\psi d\phi$, a positive number

45	2.00	0.0	0	...	...	0.0	—2.000

NOTE: $\Delta\phi = 5° = 0.0873$ radian everywhere except at 45°, where $\Delta\phi = 10°$ or 0.1646 rad.

$$\phi = Ar\,\theta \sin\theta \quad [11]$$

If from the infinite wedge we cut a square plate of a diagonal $2h$ as shown in Fig. 21, then the sides BD and BC would be subjected to stress components which in terms of cartesian coordinates and boundary conditions reduce to:

$$\sigma_x = -\frac{F}{(\pi+2)} \frac{(y+h)(h-y)^2}{(h^2+y^2)^2} \quad [12]$$

$$\sigma_y = -\frac{4F}{(\pi+2)} \frac{(2h-x)^3}{[x^2+(2h-x)^2]^2} \quad [13]$$

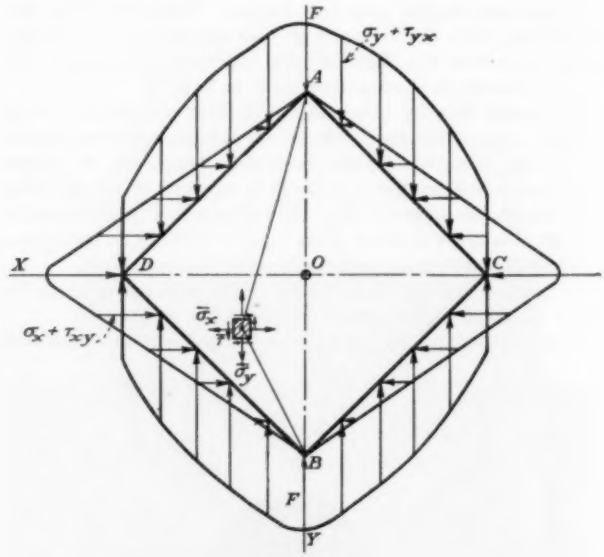

FIG. 23

$$\tau = -\frac{F}{(\pi+2)} \frac{(y+h)^2(h-y)}{(h^2+y^2)^2} \quad [14]$$

$$= -\frac{4F}{(\pi+2)} \frac{(2h-x)^2 x}{[x^2+(2h-x)^2]^2} \quad [15]$$

Combining σ_x with τ_{xy}, and σ_y with τ_{yx}, we obtain

$$\sigma_x + \tau_{xy} = -\frac{F}{(\pi+2)} \frac{2h(h^2-y^2)}{(h^2+y^2)^2} \quad [16]$$

and

$$\sigma_y + \tau_{yx} = -\frac{4F}{(\pi+2)} \frac{(2h-x)^2\,2h}{[x^2+(2h-x)^2]^2} \quad [17]$$

Upon plotting curves for [16] and [17] we find that good approximations can be obtained with simpler and symmetrical functions: namely,

$$\sigma_x + \tau_{xy} = -0.195\left(1 + \cos\frac{\pi x}{h}\right)\frac{F}{h} \quad [18]$$

$$\sigma_y + \tau_{yx} = -\left(0.564 - 0.1945\frac{x^2}{h^2} - 0.1031\cos\frac{\pi x}{h} - 0.0564\cos\frac{2\pi x}{h} - 0.01556\cos\frac{4\pi x}{h}\right)\frac{F}{h} \quad [19]$$

Returning now to the infinite wedge, a square plate *ABCD* is cut from it whose free-body diagram is shown in Fig. 22. Suppose now that to the system of forces in Fig. 22 there is added a symmetrical system and boundary forces are obtained as shown in Fig. 23. The stress components for the combined system are:

$$\bar{\sigma}_x = -\frac{4Fx^2}{(\pi+2)}\left\{\frac{(h+y)}{[x^2+(h+y)^2]^2} + \frac{(h-y)}{[x^2+(h-y)^2]^2}\right\} \quad [20]$$

$$\bar{\sigma}_y = -\frac{4F}{(\pi+2)}\left\{\frac{(h+y)^3}{[x^2+(h+y)^2]^2} + \frac{(h-y)^3}{[x^2+(h-y)^2]^2}\right\} \quad [21]$$

and

$$\bar{\tau}_{xy} = \bar{\tau}_{yx} = \frac{4Fx}{(\pi+2)}\left\{\frac{(h-y)^2}{[x^2+(h-y)^2]^2} - \frac{(h+y)^2}{[x^2+(h+y)^2]^2}\right\} \quad [22]$$

If to $\bar{\sigma}_x$, $\bar{\sigma}_y$, and $\bar{\tau}$ are added the stress components due to a system of boundary forces equal and opposite to those shown in Fig. 23 the required stress distribution will be obtained, that is, the stress system in a square plate subjected to diagonal compression. This will be done by the use of Professor Timoshenko's Approximate Strain-Energy Method.[7]

The required stress function is assumed in the form of a series, thus

$$\Phi = \Phi_0 + \alpha_1\phi_1 + \alpha_2\phi_2 + \ldots\ldots\ldots\alpha_n\phi_n \quad [23]$$

where Φ_0 is a function so chosen that its corresponding stress system satisfies the boundary conditions, ϕ_1, ϕ_2.....ϕ_n are functions whose corresponding stress systems vanish on the boundary, and $\alpha_1, \alpha_2 \ldots\ldots \alpha_n$ are constant coefficients determined by the conditions that the strain energy at equilibrium must be a minimum.

We shall limit ourselves to the first two terms of the series [23], i.e.,

$$\Phi = \Phi_0 + \alpha_1\phi_1 \quad [24]$$

The expression for the strain-energy V, assuming Poisson's ratio $\mu = 0$, and the modulus of elasticity equal E is

$$V = \frac{1}{2E}\int\int(\sigma_x^2 + \sigma_y^2 + 2\tau_{xy}^2) \times dxdy \quad [25]$$

and for equilibrium

$$\frac{\partial V}{\partial\alpha_1} = 0 = \int\int\left(\sigma_x\frac{\partial\sigma_x}{\partial\alpha_1} + \sigma_y\frac{\partial\sigma_y}{\partial\alpha_1} + \frac{2\tau\partial\tau_{xy}}{\partial\alpha_1}\right)dxdy \quad [26]$$

It is proved in the theory of elasticity that in terms of a stress function F the stress components are:

$$\sigma_x = \frac{\partial^2 F}{\partial y^2}; \qquad \sigma_y = \frac{\partial^2 F}{\partial x^2} \quad \text{and} \quad \tau = -\frac{\partial^2 F}{\partial x\partial y}$$

[7] See his article in *Phil. Mag.*, vol. XLVII, June, 1924.

It follows that the stress components in terms of our approximate stress function Φ are:

$$\sigma_x = \frac{\partial^2\Phi_0}{\partial y^2} + \alpha_1\frac{\partial^2\phi_1}{\partial y^2} \quad [27]$$

$$\sigma_y = \frac{\partial\Phi_0}{\partial x^2} + \alpha_1\frac{\partial^2\phi_1}{\partial x^2} \quad [28]$$

$$\tau = -\left(\frac{\partial^2\Phi_0}{\partial x\partial y} + \alpha_1\frac{\partial^2\phi_1}{\partial x\partial y}\right) \quad [29]$$

It will be found that

$$\phi_1 = \frac{1}{16}[(x+y)^2 - h^2]^2[(y-x)^2 - h^2]^2 \quad [30]$$

gives a stress system which vanishes on the given boundaries whose equations are

$$x + y = \pm h \quad [31]$$

$$y - x = \pm h \quad [32]$$

and therefore satisfies the conditions imposed upon it.

Upon substitution of Equations [27], [28], and [29] and their respective derivatives with respect to α_1 in Equation [26] and upon collecting terms in α_1 we get

$$\int\int\left\{\frac{\partial^2\Phi_0}{\partial y^2}\times\frac{\partial^3\phi_1}{\partial y^3} + \frac{\partial^2\Phi_0}{\partial x^2}\times\frac{\partial^3\phi_1}{\partial x^3} + 2\frac{\partial^2\Phi_0}{\partial x\partial y}\frac{\partial^3\Phi_1}{\partial x\partial y} + \alpha_1\left[\left(\frac{\partial^2\phi_1}{\partial y^2}\right)^2 + \left(\frac{\partial^2\phi_1}{\partial x^2}\right)^2 + 2\left(\frac{\partial^2\phi_1}{\partial x\partial y}\right)^2\right]\right\}dxdy = 0 \quad [33]$$

Letting X and Y stand for $-(\sigma_x + \tau_{xy})$ and $-(\sigma_y + \tau_{yx})$, respectively, we remove first the boundary forces defined by Y. In this case Φ_0 is a function of X only. It will also be found that within the given limits of integration

$$\int_0^h\int_0^{h-y}\frac{\partial^2\phi_1}{\partial x^2}dxdy = \int_0^h\int_0^{h-y}\frac{\partial^2\phi_1}{\partial y^2}dxdy \quad [34]$$

Taking these into consideration, Equation [33] reduces to

$$2\alpha_1\int_0^h\int_0^{h-y}\left[\left(\frac{\partial^2\phi_1}{\partial x^2}\right)^2 + \left(\frac{\partial^2\phi_1}{\partial x\partial y}\right)^2\right]\times dxdy = -\int_0^h\int_0^{h-y}\frac{\partial^2\Phi_0}{\partial x^2}\frac{\partial^2\phi_1}{\partial x^2}dxdy \quad [35]$$

It is from this equation that we determine α_1. The left side of Equation [35] contains about eighty integrals of the type

$$\int\int x^m y^n dxdy$$

These have been reduced to only sixteen by observing that within the given limits of integration

$$\int\int x^m y^n dxdy = \int\int x^n y^m dxdy \quad [36]$$

With this simplification

$$2\int_0^h\int_0^{h-y}\left[\left(\frac{\partial^2\phi_1}{\partial x^2}\right)^2 + \left(\frac{\partial^2\phi_1}{\partial x\partial y}\right)^2\right]dxdy = \int_0^h\int_0^{h-y}$$

$$(25x^{12} - 78x^{10}y^2 - 106h^2x^{10} + 222h^2x^8y^2 + 87x^8y^4 + 175h^4x^8 - 116h^2x^6y^4 - 220h^4x^6y^2 - 34x^6y^6 - 140h^6x^6 + 109h^4x^4y^4 + 55h^2x^4 + 76h^6x^4y^2 + 5h^2x^2y^2 - 10h^{10}x^2 + 0.5h^{12})dxdy = 0.1044997h^{14}. \quad [37]$$

The right side of Equation [35] is

$$-\int_0^h\int_0^{h-y}\frac{\partial^2\Phi_0}{\partial x^2}\frac{\partial^2\phi_1}{\partial x^2}\,dxdy = -\int_0^h\int_0^{h-y}(3.5x^6+4.5x^2y^4 + 4.5h^4x^2 - 7.5x^4y^2 - 7.5h^2x^4 - 0.5y^6 + 3h^2x^2y^2 + 0.5h^2y^4 + 0.5h^4y^2 - 0.5h^6) \times \left(0.564 - 0.1945\frac{x^2}{h^2} - 0.1031\cos\frac{\pi x}{h} - 0.0564\cos\frac{2\pi x}{h} - 0.01556\cos\frac{4\pi x}{h}\right)\frac{F}{h}\,dxdy = -0.0070967\,Fh^7. \quad [38]$$

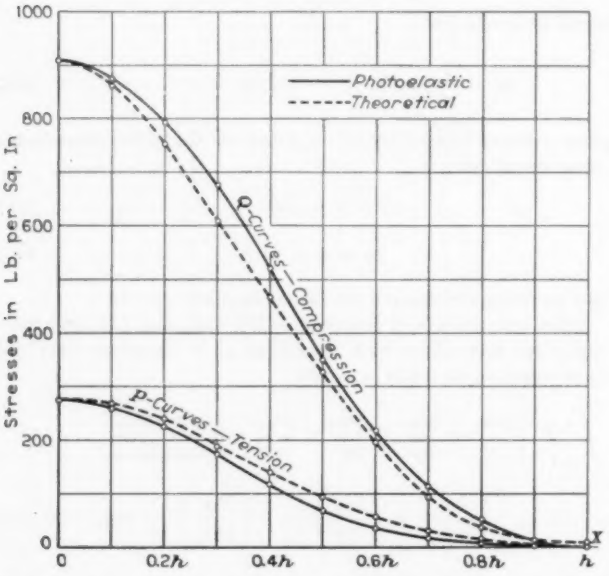

FIG. 24 COMPARATIVE CURVES OF THEORETICAL AND PHOTOELASTIC VALUES OF P AND Q ALONG OX

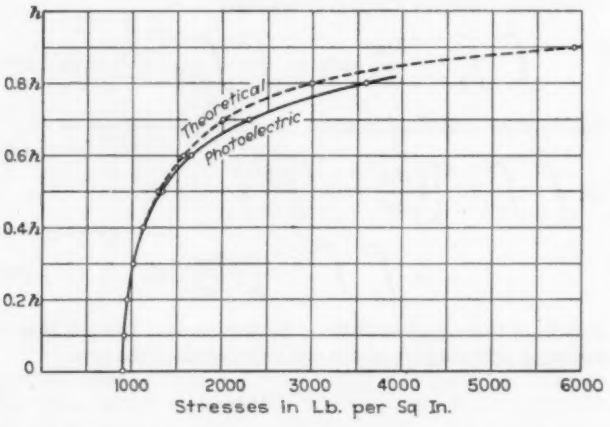

FIG. 25 COMPARATIVE CURVES OF THEORETICAL AND PHOTOELASTIC VALUES OF P ALONG OY

Solving for α_1

$$\alpha_1 = -\frac{0.0070967\,Fh^7}{0.1044997\,h^{14}} = -0.06788\,\frac{F}{h^7} \quad [39]$$

The approximate stress function for the Y boundary forces thus becomes

$$\Phi = \Phi_0 - 0.06788\,\frac{F}{h^7} \times \frac{1}{16}\,[(x+y)^2 - h^2]^2 \times [(y-x)^2 - h^2]^2 \quad [40]$$

In precisely the same way the approximate stress function for the X boundary forces is found to be

$$\psi = \psi_0 + 0.114249\,\frac{F}{h^7} \times \frac{1}{16}\,[(x+y)^2 - h^2]^2 \times [(y-x)^2 - h^2]^2 \quad [41]$$

where ψ and ψ_0 replace Φ and Φ_0, respectively. Upon combining the two stress systems Φ and ψ and designating the resultant stress components by P_0, Q_0, and S_0, we obtain

$$P_0 = \frac{\partial^2\psi_0}{\partial y^2} + 0.04637\,\frac{F}{h^7}\frac{\partial\phi_1}{\partial y^2} \quad [42]$$

and

$$Q_0 = \frac{\partial^2\Phi_0}{\partial x^2} + 0.04637\,\frac{F}{h^7}\frac{\partial\phi_1}{\partial x^2} \quad [43]$$

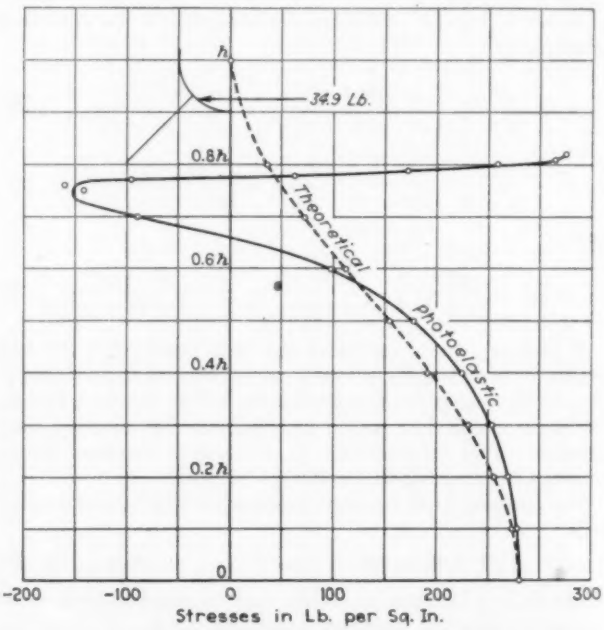

FIG. 26 COMPARATIVE CURVES OF THEORETICAL AND PHOTOELASTIC VALUES OF Q ALONG OY

Denoting the resultant stress components in the square block by P, Q, and S, respectively, we obtain

$$P = P_0 + \bar{\sigma}_x \quad [44]$$

$$Q = Q_0 + \bar{\sigma}_y \quad [45]$$

Table 4 gives the values of P and Q for the axes of symmetry; $r = x/h$ or y/h.

DISCUSSION OF RESULTS

The extent to which the theoretical results substantiate the

experimental ones is graphically represented by the curves of Figs. 24–26, inclusive. The only marked divergence is shown by the curve of Fig. 26 beyond $0.6h$. The explanation for this discrepancy is found in the approximate character of the stress functions Φ and ψ. It is felt that if more terms of the series [23] were taken this divergence would be minimized. All the other curves substantiate the photoelastic results. At the center and the extremities of the horizontal diagonal the agreement is almost perfect. It is therefore considered that the results from the photoelastic investigation represent a correct picture of the stress distribution in the square block.

Referring now to this stress distribution it is observed first of all that fairly large tensile stresses are produced as a result of the diagonal compression. From an engineering point of view this is perhaps the most interesting aspect of the problem. The large tensile stress could hardly have been predicted on the basis of the ordinary theories of mechanics. At the center the maximum tension is 278.6 lb. per sq. in., or nearly one-third of the corresponding compressive stress. The maximum value of the tension, however, is at least 350 lb. per sq. in., this being the value obtained on the Y-axis at $0.82h$. Square blocks weak in tension and subjected to diagonal compression should therefore show signs of failure at points on the loaded diagonal about $h/5$ from the corners.

It may also be worth noting that the P-stresses are all tensile along what might be called the horizontal stress trajectories, but are of variable signs on the vertical stress trajectories. Thus on the Y-axis the P is positive from 0 to $0.655h$, negative from this point to $0.775h$, and again positive from there on to at least $0.82h$. No computations were made beyond this point due to the inaccuracies in the measurements of the very small values of Δx. It is of interest that $(P - Q)$ in fringe order could be distinctly read even at $0.9h$.

The P-curve cannot rise much beyond the value of 350 lb. per sq. in. without having to make a sudden return and cross the axis again to assume compressive values. Assuming that the P-curve stays positive to $0.9h$, and that the stress distribution in the tip beyond $0.9h$ is essentially that of an infinite wedge, we get a static check on the loaded diagonal from horizontal summation of the forces, first, however, cutting out the loaded tips up to a radius of $0.1h$, and replacing them by the horizontal thrusts which they exert, and which for our loads were found to be 34.9 lb.

$$\Sigma X = 0, \text{ or } 34.9 = \int_0^h Ptdy \ldots\ldots\ldots [46]$$

Taking $2h$ again as 1.855 in., t as 0.255 in., and the mean values of P from Table 2, we get for the right side of Equation [46] 33.96 lb., or a static check within 2.7 per cent.

Photoelastic Equipment

The main equipment of a photoelastic laboratory consists of

1 A polariscope
2 A compensator
3 A loading frame
4 A camera
5 A monochromatic lamp
6 An electric furnace, and
7 A special table for drawing isoclinics.

Fig. 10 shows a photograph of the polariscope used in the Photoelastic Laboratory of the Mechanics Department at the University of Michigan. It is imported from the Winkel-Zeiss firm at Göttingen. It uses Ahren prisms instead of Nicols, and gives satisfactory results.

Fig. 27 shows a photograph of a compensator developed at the laboratory. The carriage of the compensator was designed by Dr. Donnell, formerly of the Mechanics Department of the University of Michigan. It is capable of a vertical, horizontal, and rotary motion. The spring, the beam compensator (Fig. 28), the setting-up fixture, and other features were designed by the author. Considerable difficulty was encountered in the design of a spring which would be free from energy losses. The adopted design gives a linear relation between load and deflection, and is the same during loading and unloading. In the fringe method the compensator is not used to determine $(P - Q)$. It is used, however, to determine the sign of the stress.

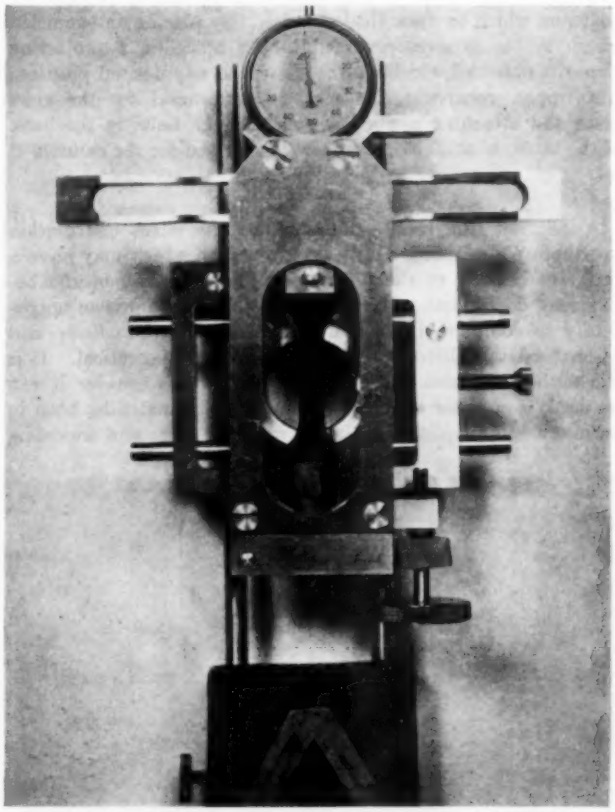

Fig. 27 Tension Compensator

It also makes an excellent tension machine, and the one shown could produce a tension of 150 lb., the accuracy of the reading being $^1/_4$ lb. The spring constant is 1615 lb.

The Loading Frame. The frame shown in Fig. 29 can produce tension, compression, and bending. The central frame is capable of a vertical and a horizontal motion. It can accommodate many sizes of models and has means to produce perfect alignment of the supporting pins. When producing bending provision is made for self-centering, which automatically gives equal moment arms and loads. By means of a small eccentric operated by a wooden handle visible in the picture, the load can be quickly removed from the model. The springs reduce impact forces and absorb vibrations. The main lever rests against a knife edge.

Camera. An ordinary Eastman 5 × 7-in. camera was used. The lens was removed, the front of the camera opened, and the image projected directly upon the film. To retain the use of the shutter it was mounted on a special pedestal and placed close to the analyzer. In selecting a camera for the fringe

method special attention should be paid to the provisions for adjusting the focal plane, as it is of utmost importance to secure good focusing of every part of the image.

Lamp. For the fringe method a monochromatic lamp must be had. The one used was a mercury-vapor lamp, shown in Fig. 18. With the aid of a No. 77 Wratten filter, the yellow rays were stopped and a fairly pure green light obtained. Orthochromatic Eastman films were found suitable for the author's purpose.

Furnace and Isoclinic Table. The annealing work was done in a small electric furnace working at $12^1/_2$ amperes and 220 volts. Fig. 30 shows a three-in-one piece of equipment. The main function of this table was to provide a vertical glass drawing board on which to draw the isoclinics. By placing an enameled screen in the grooves provided in the uprights, a projecting screen is obtained which can be moved to any desired position. Also, upon removing the special frame used for the glass plate and attaching a wooden shelf through bolts in the back of the table, a satisfactory support is obtained for the camera.

Conclusion

Aside from the results obtained for the stress distribution in square plates under diagonal compression which may have a practical bearing in the design and understanding of the behavior of double knife edges, this investigation affords an opportunity to compare the several methods in photoelasticity and to contrast the photoelastic method with the theoretical. It is the author's opinion that the fringe method, whenever it can be used, is superior to compensating or color matching both in accuracy and simplicity, and that with the successful annealing of bakelite a suitable material is made available for this method.

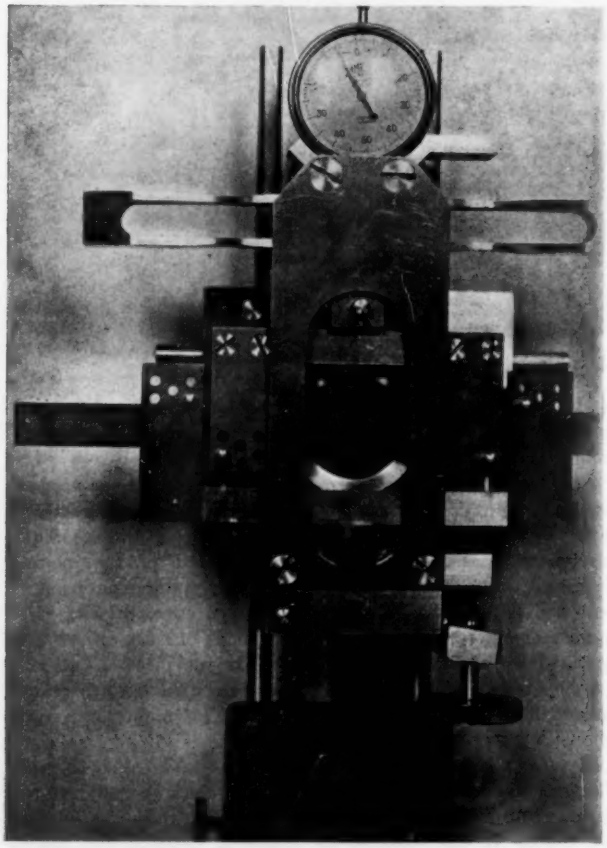

Fig. 28 Beam Compensator

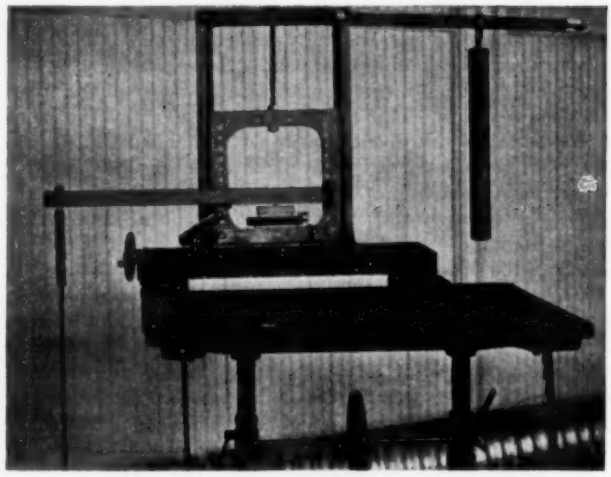

Fig. 29 Loading Frame Showing Arrangement for Bending (See Fig. 10 for compression.)

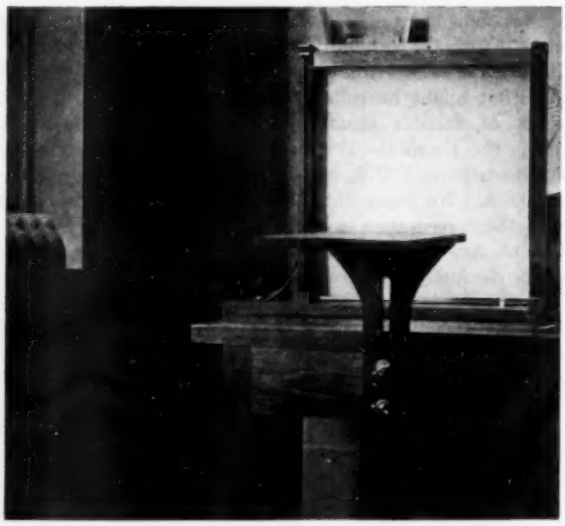

Fig. 30 Combined Projecting Screen, Vertical Drawing Board, and Camera Support

That the photoelastic results are reliable and agree with those from the mathematical theory of elasticity has been proved long before this. It is only desired to call attention to the vast difference in time and labor between the two methods. The summary of the approximate theoretical solution submitted fails to convey the amount of work necessary to get the results. Special tables of integrals have to be constructed, and many laborious and tedious computations have to be made which increase the danger of errors. It has been the author's experience that the photoelastic method takes about as many weeks as the theoretical method takes months.

The prevailing impression seems to be that the cost of a photoelastic laboratory is too high for the average engineering college or industrial organization. It may therefore be of interest to note that all the equipment described in this paper cost less than $1500, and it is believed that $2000 is sufficient to equip a moderate but efficient laboratory for quantitative work.

The main problem of this paper was suggested by Professor Timoshenko, who has kept in constant touch with this investi-

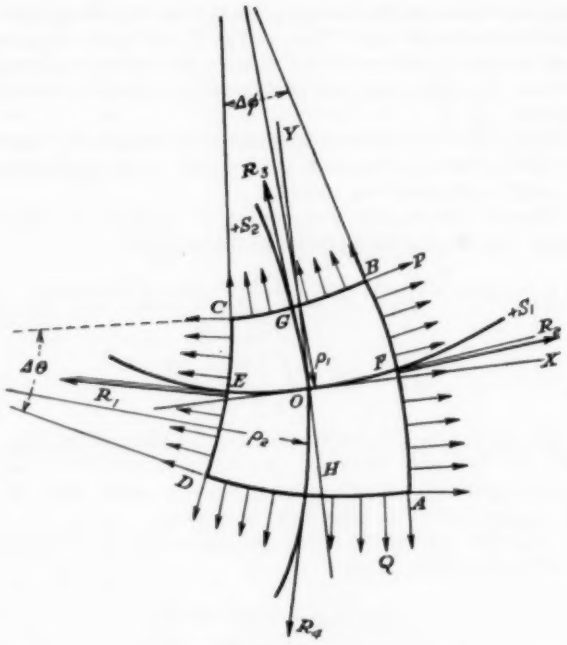

FIG. 31

gation and to whom the author is indebted for valuable advice. He also wishes to thank Dr. Tuzi for the sample of phenolite used in the investigation, and the Research Department of the Westinghouse Electric & Manufacturing Company for the bakelite which they were good enough to supply for the research.

Appendix No. 1

DERIVATION OF FUNDAMENTAL EQUATIONS FOR THE METHOD OF GRAPHICAL INTEGRATION

Let s_1 and s_2 denote two stress trajectories meeting at point O, Fig. 31.

Let s_1 be measured positive to the right of O and s_2 upward.

Let ρ_1 and ρ_2 be radii of curvature of s_1 and s_2, respectively, being measured positive if the tangent to the curve rotates counterclockwise as s_1 and s_2 increase.

In the element of Fig. 31 $OE = OF = \Delta s_1$, and $OG = OH = \Delta s_2$; also the boundary consists of arcs of the stress trajectories passing through points H, F, and G, and E.

Let P and Q represent average boundary stresses, and let R_1, R_2, R_3, and R_4 represent the resultant forces on the four sides of the element.

Lastly, let P_0 and Q_0 represent the resultant forces on GOH and EOF, respectively.

If $\Delta\phi$ is a small angle, the resultants R_1 and R_2 may be treated as tangents to EOF at E and F, respectively. Similarly R_3 and R_4 may be taken as tangent to GOH at G and H, respectively, the errors being infinitesimals of higher order. It follows that R_1 and R_2 make angles with the X-axis equal to $\Delta\phi/2$.

The Y-component of R_1 is $R_1 \sin \frac{\Delta\phi}{2}$

The Y-component of R_2 is $R_2 \sin \frac{\Delta\phi}{2}$

and the sum, which will be designated by R_y, is

$$R_y = (R_1 + R_2) \sin \frac{\Delta\phi}{2} = (R_1 + R_2) \frac{\Delta\phi}{2} \quad \ldots\ldots [47]$$

$\Delta\phi$ being a small angle.

For ρ_1 a positive radius of curvature R_y is positive that is upward, as can be seen from the figure. For equilibrium it is necessary that

$$\Sigma Y = 0 \quad \ldots\ldots [48]$$

Hence

$$(R_4 - R_3) = R_y \quad \ldots\ldots [49]$$

$$\therefore (R_4 - R_3) = (R_1 + R_2) \frac{\Delta\phi}{2} \quad \ldots\ldots [50]$$

Now

$$R_1 = \left(P_0 - \frac{\partial P_0}{\partial s_1} \Delta s_1\right) \quad \ldots\ldots [51]$$

and

$$R_2 = \left(P_0 + \frac{\partial P_0}{\partial s_1} \Delta s_1\right) \quad \ldots\ldots [52]$$

hence

$$R_1 + R_2 = 2P_0 \quad \ldots\ldots [53]$$

and [47] becomes

$$(R_1 + R_2) \frac{\Delta\phi}{2} = 2P_0 \frac{\Delta\phi}{2} = P_0 \Delta\phi \quad \ldots\ldots [54]$$

Also

$$R_3 = Q_0 + \frac{\partial Q_0}{\partial s_2} \Delta s_2 \quad \ldots\ldots [55]$$

and

$$R_4 = Q_0 - \frac{\partial Q_0}{\partial s_2} \Delta s_2 \quad \ldots\ldots [56]$$

$$\therefore R_4 - R_3 = -2 \frac{\partial Q_0}{\partial s_2} \Delta s_2 \quad \ldots\ldots [57]$$

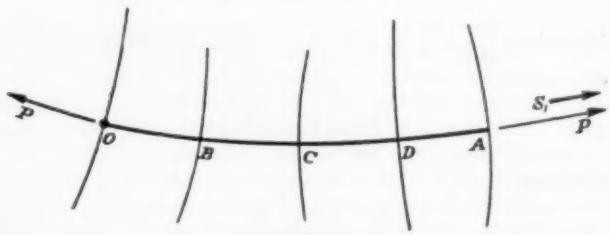

FIG. 32

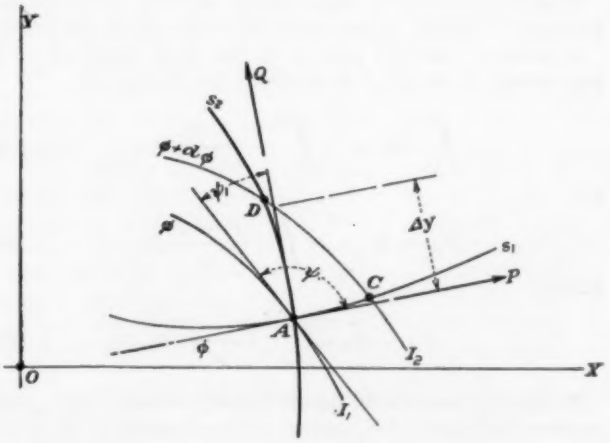

FIG. 33

Combining with [53],

$$-2\frac{\partial Q_0}{\partial s_2}\Delta s_2 = P_0\Delta\phi \quad [58]$$

or

$$\frac{\partial Q_0}{\partial s_2}\Delta s_2 = -\frac{P_0}{2}\Delta\phi \quad [59]$$

But as a first approximation

$$Q_0 = 2\Delta s_1 Q \quad [60]$$

and

$$P_0 = 2\Delta s_2 P \quad [61]$$

On substitution in [59],

$$2\frac{\partial}{\partial s_2}(\Delta s_1 Q)\Delta s_2 = -2\Delta s_2 P\frac{\Delta\phi}{2} \quad [62]$$

but

$$\Delta s_1 = \rho_1\frac{\Delta\phi}{2}$$

hence [62] becomes

$$2\frac{\partial}{\partial s_2}\left[\left(\rho_1\frac{\Delta\phi}{2}\right)Q\right]\Delta s_2 = -\Delta s_2 P\Delta\phi \quad [63]$$

But $\Delta\phi$ may be taken as a constant, so that [63] becomes

$$\frac{\partial}{\partial s_2}(\rho_1 Q)\Delta s_2\Delta\phi = -\Delta s_2 P\Delta\phi \quad [64]$$

or

$$\frac{\partial}{\partial s_2}(\rho_1 Q) = -P \quad [65]$$

$$\therefore \rho_1\frac{\partial Q}{\partial s_2} + Q\frac{\partial \rho_1}{\partial s_2} = -P \quad [66]$$

In the limit $\frac{\partial \rho_1}{\partial s_2} = -1$, since $\Delta\rho_1 = -\Delta s_2$ and we have $\rho_1\frac{\partial Q}{\partial s_2} - Q = -P$

$$\therefore \frac{\partial Q}{\partial s_2} + \frac{P-Q}{\rho_1} = 0 \quad [67]$$

Similarly,

$$\frac{\partial P}{\partial s_1} + \frac{P-Q}{\rho_2} = 0 \quad [68]$$

It will be observed that Equations [67] and [68] do not contain the elastic constants. Therefore they hold beyond the elastic limit.

If we start from any point O on the stress trajectory of P and follow it to any point A we obtain upon integration

$$\int_{P_0}^{P_A} dP = -\int_0^A \frac{(P-Q)}{\rho_2}ds_1 \quad [69]$$

or

$$P_A - P_0 = -\int_0^A \frac{(P-Q)}{\rho_2}ds_1 \quad [70]$$

Hence

$$P_A = P_0 - \int_0^A \frac{(P-Q)}{\rho_2}ds_1 \quad [71]$$

It must be remembered that in this derivation ρ_1 and ρ_2 were assumed positive if the rotation of the tangent to the curve is counterclockwise as the curves s_1 and s_2 increase and that s_2 and s_1 are interrelated, s_2 being obtained from s_1 by counterclockwise rotation of 90 deg. Thus in Fig. 32 if O is the origin and s_1 is measured positive to the right, ρ_1 is positive at all points between O and A, and ρ_2 is positive at O, B, and A, and negative at C and D.

In Fig. 32 if A is taken as an origin and s_1 is measured positive toward O, then ρ_1 is negative at all points; ρ_2 is negative at A, B, and O and is positive at D and C.

Professor Filon[8] gives two methods to evaluate the integrals on the right-hand sides of Equations [71] and [72]:

$$P_A = P_0 - \int_0^A \frac{(P-Q)}{\rho_2}ds_1 \quad [71]$$

$$Q_A = Q_0 - \int_0^A \frac{(P-Q)}{\rho_1}ds_2 \quad [72]$$

Let point A be a point in a body under plane stress, Fig. 33. Through this point there are two stress trajectories s_1 and s_2 and an isoclinic I_1 of parameter ϕ, where ϕ is the angle which the tangent to s_1 at A makes with the X-axis.

Let I_2 be a nearby isoclinic of parameter $\phi + d\phi$, intersecting s_1 at C and s_2 at D. Then

$$AD = \rho_2 d\phi; \text{ and } \frac{1}{\rho_2} = \frac{d\phi}{AD} \quad [73]$$

Also

$$ds_1 = AC$$

hence

$$\frac{1}{\rho_2}ds_1 = d\phi\frac{AC}{AD} \quad [74]$$

If ψ be the angle through which the stress trajectory of P has to be rotated (counterclockwise) in order to bring it upon the isoclinic I_1, then

$$\frac{AD}{AC} = -\tan\psi \quad [75]$$

the negative sign being necessary because tan ψ is negative and AD/AC is positive.

Upon substitution in [74], we have

$$\frac{ds_1}{\rho_2} = \frac{-d\phi}{\tan\psi} = -\cot\psi\, d\phi \quad [76]$$

Substituting in [71]

$$P_A = P_0 + \int_{\phi_0}^{\phi}(P-Q)\cot\psi\, d\phi \quad [77]$$

Also

$$\rho_1 d\phi = AC, \text{ and } \frac{1}{\rho_1} = \frac{d\phi}{AC}$$

$$\therefore \frac{ds_2}{\rho_1} = d\phi\frac{AD}{AC} = d\phi\cot\psi_1 \quad [78]$$

Upon substitution in [72],

$$Q_A = Q_0 - \int_{\phi_0}^{\phi}(P-Q)\cot\psi_1\, d\phi \quad [79]$$

The equations just discussed give good results when the angles ψ are large. For small values of ψ, Equations [77] and [79]

[8] L. N. G. Filon, "On the Graphical Determination of Stress From Photo-Elastic Observation," *Engineering*, Oct., 1923, p. 511.

become inaccurate as a small error in ψ makes a large error in cot ψ. In such case the intervals between successive isoclinics become large, and this adds to the inaccuracy of the method.

Professor Filon therefore gives another treatment for such cases. Let Δy, Fig. 33, be the intercept measured perpendicular to the path of integration between two near isoclinics in the neighborhood of the point considered whose parameters differ by $\Delta\phi$. Then

$$\frac{1}{\rho_2} = \frac{\Delta\phi}{\Delta y} \text{ (approximately)} \quad [80]$$

The isoclinics are usually drawn for constant differences of say, 5 or 10 deg., so that $\Delta\phi$ is a constant.

Substituting this in [67] and [68],

$$P = P_0 - \Delta\phi \int_0^A \frac{(P - Q)}{\Delta y}\, ds_1 \quad [81]$$

which again enables us by graphical integration to determine P and Q.

This last method is especially useful in cases of symmetry, in which the straight lines of symmetry are also isoclinics. Δy is then the intercept between this line and the nearest isoclinic, measured perpendicular to the path of integration.

Discussion

T. McLean Jasper.[9] The writer is grateful to know that some one has extended the work with polarized light and has developed its use with bakelite, which offers a material much more suitable than celluloid. Glass, which is probably the most suitable material from the optical standpoint, is so difficult to shape and therefore is not likely to yield answers to the most difficult problems in two-dimensional stress.

Most of our complicated machinery problems are three-dimensional in degree. It would be very gratifying if the photoelastic method could be applied to such problems. The photoelastic method is attractive and elegant and should draw very good support. However, its limitations should be carefully stated and understood.

The writer would like to suggest that the effect when using polarized light should be given by the following formula:

$$R = c\,(P - Q)\,t$$

in which the thickness of the material t is not considered as a part of the constant c. In this way corrections for the thickness change due to stress or variation in the thickness of models can be considered.

The writer also believes that a compensator such as the Babinet should be considered as part of the equipment of measurement and not trust to a tension specimen of the material for the work of evaluating the stress differential. In this way a much more refined gradation of stress measurement can be obtained.

[9] Director of Research, A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

J. N. Goodier.[10] The writer would like to add his congratulations to the author on his achievements in obtaining such excellent fringe pictures and on his convincing demonstration of the virtues of this method of interpreting the photoelastic images.

Criticism of the method can hardly be directed toward the determination of maximum shear stress, a quantity so important in practice and so readily revealed by the apparatus. But in the isolation of the principal stresses, as the author points out, the same accuracy may not be preserved, especially on account of the difficulties of graphical integration. This may conceivably be the cause of the discrepancy between the theoretical and photoelastic curves in Fig. 26. It is true that if the actual distribution were similar to the photoelastic version, the theoretical approximation (Fig. 24) would be by no means adequate to represent it, but on the other hand experience of similar stress systems leads one to regard the photoelastic curve, representing the tensions across the vertical diagonal of the square, improbable as a consequence of the boundary tractions represented in Fig. 23, and therefore to doubt the conclusions based on it, particularly those regarding the situation and magnitude of the maximum tension. It would be very interesting to have an estimate of the possible error of the photoelastic results in the region $0.6h$ to $0.8h$ in Fig. 26.

Arshag G. Solakian.[11] The paper is an important contribution to the science of the optical-mechanical method of stress determination. It is very encouraging that during the last ten years important research work along this line has been carried on in different institutions of the United States. However, based on his experiences and observations in the Photoelastic Laboratories of Dr. E. G. Coker, of University College, London, and of Prof. A. Mesnager, of L'École des Ponts et Chaussees, Paris, and also including the considerable amount of research work in and publications about photoelasticity contributed by other European institutions, the writer is of the opinion that this interesting field should deserve more importance than is given to it by our physicists and engineers

Some time last November, Prof. G. B. Karelitz and the writer built up a simple optical set at the Physics Laboratories of Columbia University for the study of shearing stresses in keys and keyways of different types. Bakelite was adopted as the material used for the models, on account of its high optical sensitiveness in producing several color fringes for stresses within the elastic limit of the material. The method adopted for measuring the shearing stresses was exactly the same as that used by the author, the only difference being that a white source of light was used which produced color fringes of yellow, red, and green of several repeating orders. The author's method of black-and-white fringes due to the use of monochromatic light undoubtedly has the advantage of the formation of an image that can be easily and cheaply photographed and printed. On the other hand, the color fringe method has the following merits:

(*a*) With the black-and-white-fringe method it is very difficult to determine the order of a certain fringe for the evaluation of its corresponding stress value. It requires slow and repeated loading and unloading of the material and counting of the number of the fringes passing a certain point. Tension tests run by the writer at the Materials Testing Laboratories of Columbia University have revealed the fact that bakelite under repeated loading and unloading is not free from the influences of permanent set and of creep phenomena, both of which are functions of time and intensity of stress. Hence, stress conditions of the elements in a bakelite model under such loading are of a constantly changing nature.

[10] Commonwealth Fund Fellow, University of Michigan, Ann Arbor, Mich.

[11] Engineering Department, Columbia University, New York, N. Y.

With color fringes, the first-order yellow, red, and green bands are easily recognized by their brightness, relatively larger width of bands, and their location in the specimen. Hence the order of the others can be quickly determined by starting to count from the respective colors of the first order.

(*b*) The use of color fringes with three-color bands for each order against two bands in the black-and-white-fringe method has the advantage of increasing the optical sensitivity of bakelite in the ratio of 3 to 2.

(*c*) Another difficulty encountered in the use of the black-and-white-fringe method is due to the presence of black bands corresponding to $P - Q = 0$, which, intermixing with the stress fringes, cause certain confusion in their determination. The use of quarter-wave mica plates to produce circular polarized light eliminates only the direction bands called isoclinics. In color fringes the black bands corresponding to $P - Q = 0$ are easily recognized and eliminated.

The method of heat-treating bakelite, as adopted by the author to free the model from the effects of initial stresses, is similar to that used by the writer. Several trials at different temperatures have shown that a heating temperature of 75 to 85 deg. cent., with a heating time of at least one hour and uniform cooling down to room temperature during a period of about 12 to 14 hours, is very satisfactory to obtain the desired results. The writer is of the opinion that the presence of stubborn stresses requiring a second heat treatment for their removal, as suggested by the author, is greatly due to the very short time allowed for heating (15 minutes) and the lower value of temperature used (70 deg. cent.). In this connection it might be of interest to point out that under no circumstances should one try a temperature of 110 deg. cent. or above this value during the annealing process of bakelite on account of the change of transparency of the material. At temperatures above 180 deg. cent. a piece of perfectly transparent bakelite became red and non-transparent.

Both mechanical and optical tests run in the laboratories of Columbia University have indicated that the properties of bakelite are affected by annealing. Hence the stress-fringe order relations will no more be the same for the material in its initial and heat-treated stages. However, by annealing the calibrating beam under the same temperature and time conditions as that of the model, any discrepancy of this nature will be eliminated.

Observations of the stress fringes in the problem studied by the author give the impression to the writer that their very close spacing at points of stress concentrations might have produced stresses very close to the elastic limit of the material. Although bakelite, like most brittle materials, possesses neither a true elastic limit nor a distinct yield point, however time-creep tests of specimens of bakelite, both annealed and non-annealed, show that stresses within about 35 per cent of the maximum strength of the material do not produce an appreciable permanent set.

H. F. Moore.[12] At the University of Illinois a photoelastic apparatus has been developed using a petrographic microscope fitted with a Babinet compensator. The general appearance of the set up is shown in Fig. 34. The microscope is attached to the framework of a milling machine, and the specimen to be stressed and studied is mounted on the table of the milling machine and

[12] Research Professor of Engineering Materials, University of Illinois, Urbana, Ill. Mem. A.S.M.E.

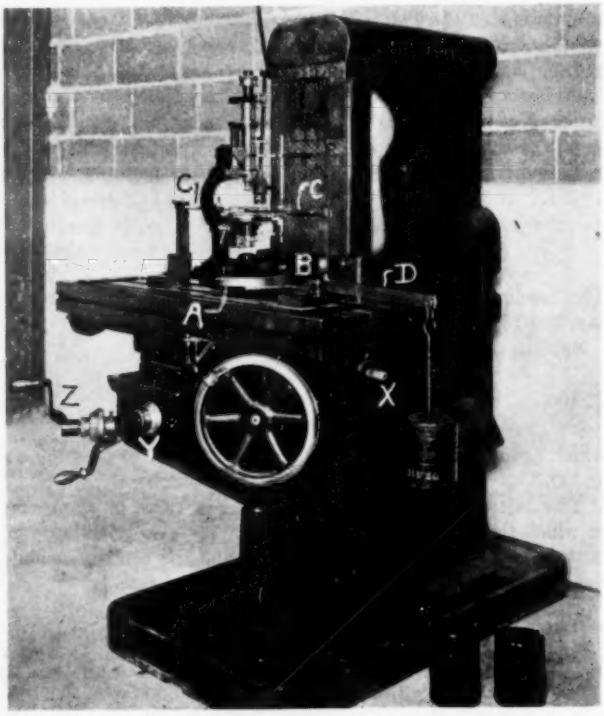

Fig. 34 (Right Top) Petrographic Microscope Mounted on Milling-Machine Frame
(Loading apparatus shown at *D*, grips for specimen at *C*.)

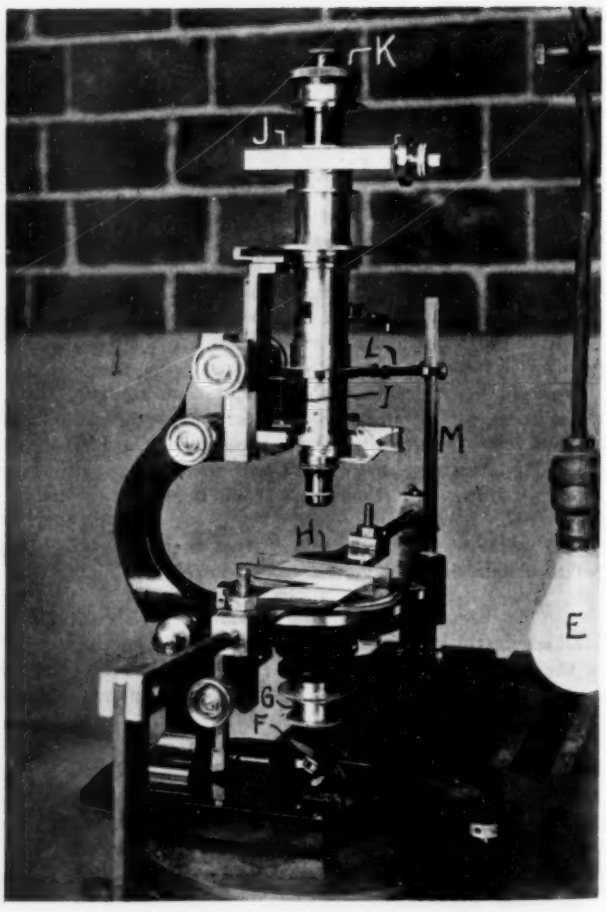

Fig. 35 (Right Bottom) Petrographic Microscope With Babinet Compensator *J* and Cap Nicol *K*
(Specimen shown at *H*.)

can thus be moved in three directions by micrometer control. Fig. 35 shows the microscope in somewhat greater detail. The polarizer is located at G, and at I is the ordinary analyzer, which can be moved out of the way. The Babinet compensator, which consists of two quartz wedges which can be slid over each other by a micrometer screw, is shown at J. In use the specimen is placed under the microscope, and the microscope is focused with the cross-hairs intersecting on the point at which the stress is to be determined. The Babinet compensator is not in place when this is done, and the ordinary eyepiece is used. A general notion of stress distribution can be obtained by the use of the analyzer I, noting the color bands (or if monocromatic light is used, the fringes). After the microscope is thus focused, the analyzer I is moved out of the way, and the Babinet compensator J is put in place, as is a cap Nicol K which is put in place of the eyepiece of the microscope. Looking through K and J, cross-hairs are seen and bands of colored light with a dark line about in the middle. Using the micrometer on J, this dark line is brought to the intersection of the cross-hairs. A definite load is then put in the specimen. The position of the dark line shifts, and it is again brought to the cross-hairs by means of the micrometer. The difference of micrometer readings with and without load is a measure of the difference of principal stresses at the point studied. The stress constant of the micrometer is obtained by a test on a simple tension specimen made of the same material and of the same thickness as that in which the stress is determined, and the direction in which *tensile* stresses cause the black line to move is also determined in this calibration test. The Babinet compensator was used for stress-distribution study some years ago by Mesnager. The testing rig used at Illinois has been developed by Prof. T. M. Jasper and later by Prof. R. Michel and Mr. S. G. Hall.

M. F. Sayre.[13] Great credit is due to Professor Kita and Mr. Matui in Japan and to the Westinghouse Research Laboratory and to Professor Frocht of the University of Michigan, in this country, for the development of satisfactory methods of preparing phenolite and bakelite for use in photoelasticity studies. Professor Frocht in his fringe photographs has admirably brought out the advantages of these materials; for it is only the high sensitivity of these materials which has made possible the fringe method. With celluloid or glass the photoelastic sensitivity is so much less that two or possibly three fringes represent the maximum that can be obtained without exceeding the elastic limit. It is this fact which in practice has compelled the use of the color rather than the fringe method to date.

One word of caution might be here interpolated for the benefit of novices. When dealing either with celluloid or bakelite, stresses must be kept within the elastic limit of the material to obtain accurate results. It is therefore desirable when starting work to find out experimentally the unit stress and the number of fringes corresponding to the elastic limit for one's particular material, and to avoid going beyond that number of fringes, regardless of the temptation to do so in order to obtain an attractive picture.

G. B. Karelitz.[14] The difficulty of an analytical solution of complicated cases of a stressed state makes all methods facilitating a visual study of stress distribution rather valuable. A number of analogies, such as the famous membrane analogy of twist, have been developed recently. Investigations of stresses in structures by the use of models have been also employed with success. However, the photoelastic method has given to date the most powerful and illuminating presentation of stress distribution in loaded members, provided that cases of two-dimensional stress are considered.

By the introduction of bakelite as a working material, the author has made a notable contribution to the art and should be congratulated on his achievement. The writer, together with Mr. A. Solakian, has been working at Columbia University on questions of photoelasticity, and they have also used bakelite as their material. Our observations regarding the ease of annealing, procedure, and temperatures coincide with those of the author, which is highly gratifying.

It seems to the writer that the author has not brought out with sufficient force the point that the fringe method, as described by him, is a powerful tool for designers. The main value of the photoelastic method is not in the possibility of determining the exact values of the principal stresses, but in obtaining at a glance the stress concentrations caused by irregularities in cross-section or loading. It helps also to form a correct idea about stress distribution in loaded members, which makes it an indispensable aid to instruction. From the standpoint of "practical" use the isoclinics are of no particular value, once bakelite is employed, the fringe picture itself giving sufficient information.

It also may be added that there is some justification for the use of colored images instead of monochromatics. When a complicated fringe diagram is analyzed, there may be regions where a monochromatic (such as Fig. 8) does not show whether a valley or a hill is encountered in the shearing stress. With a colored image, the succession of colors gives this information. The colors of the fringes change, with increase of shearing stress, from red to yellow, green, gray, red, yellow, etc. It is therefore clear that stress increases in the direction from yellow to green and decreases in the direction from yellow to red.

In conclusion, the writer wishes to express his admiration for the perfect photographs produced by the author.

Author's Closure

The author has read with interest and appreciation the discussions of T. McL. Jasper, J. N. Goodier, A. G. Solakian, H. F. Moore, M. F. Sayre, and G. B. Karelitz.

Mr. Jasper's suggestion to write the stress-optic formula in the form $R = c(P - Q)t$ so that the thickness of the material would be shown explicitly would be of benefit in models of variable thickness. In models of constant thickness the variation due to stress can be neglected for all engineering purposes. In such cases it is simpler to include the thickness in the constant of proportionality.

The author agrees that a Babinet compensator would be a valuable addition to a well-equipped photoelastic laboratory and also that it is not desirable to trust the tension-strip compensator. He wishes, however, to emphasize that in the fringe or monochromatic method employed by him the difference between the principal stresses is determined without resort to such a tension compensator (see Fig. 1). The accuracy of this method is good, the procedure simple, and there is considerably less labor involved then either with the Babinet or the tension compensator.

The author shares Mr. Goodier's opinion that it would be desirable to check the values of the normal stresses on the vertical diagonal beyond $0.6h$ by a method other than that of graphical integration, and he plans to do so when suitable equipment is available. The 5-deg. isoclinic is asymptotic to the vertical axis of symmetry, Fig. 19. The distances marked ΔX thus become very small beyond $0.5h$, thereby increasing the per cent error in the values of the normal stresses the accuracy of which depends on the degree of precision with which these distances are measured.

The author was very much interested in the comments made by

[13] Associate Professor of Mechanical Engineering, Union College, Schenectady, N. Y. Mem. A.S.M.E.

[14] Associate Professor, Columbia University, New York, N. Y. Mem. A.S.M.E.

Mr. Solakian, as he raises the fundamental question of the superiority of the fringe or monochromatic method over that of white light. In paragraph (*a*) Mr. Solakian states: "With the black-and-white-fringe method it is very difficult to determine the order of a certain fringe for the evaluation of its corresponding stress value. It requires slow and repeated loading and unloading of the material and counting of the number of the fringes passing a certain point." Leaving for the moment the question of difficulty involved in determining the fringe order, the author wishes to point out that even in the white-light method essentially the same difficulties exit. The process of counting is as necessary with white light as it is with monochromatic light, since the order of a color band must be known before a numerical value can be attached to it. The same is true about the need for slow loading. If the fringe pattern is of the escaping type, so is the color pattern, and to determine the number of escaping isochromatics, one has to watch their formation during slow loading. The determination of fringe No. 1, as well as of the whole fringe order, presents in reality no difficulties.

It is the author's opinion that the existence of optical creep is really a strong point against the white-light method and in favor of the fringe or monochromatic method. It takes only a fraction of a second to take an accurate fringe photograph, and it may take an hour or more to sketch isochromatics with even a partial degree of accuracy. The existence of creep is therefore bound to affect the drawing of isochromatics vastly more than it does a picture. As a matter of fact the sharpness of the fringe photographs is evidence of the absence of effect of creep. For best results the fringe photograph should be taken immediately after the load is applied, and the determination of the fringe order

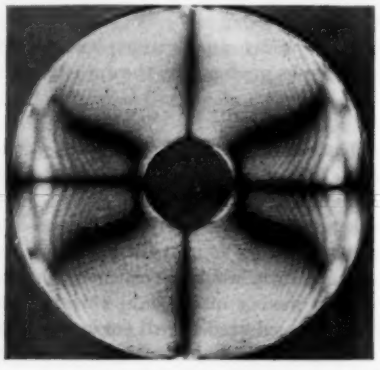

FIG. 36 BAKELITE-MODEL WHITE-LIGHT PHOTOGRAPH
(Showing the vagueness of isochromatics of higher order. Compare with Fig. 8. The black curves represent the zero isoclinic.)

should be carried out later. The presence of creep during the determination of the fringe order is evidently of no importance.

In paragraph (*b*) Mr. Solakian concludes that the use of white light increases the optical sensitivity of bakelite in the ratio of 3 to 2 by furnishing three bands of yellow, red, and green to two bands of black and white. It seems to the author that it would be more correct to say that the fringe method increases the optical sensitivity rather than the white-light method. Mr. Solakian has undoubtedly observed that isochromatics become narrower and narrower as their order increases. In fact, beyond the fifth green the colors become so crowded and washed out as to be of little value. Assuming that all isochromatics can be traced with accuracy (a task not always easy to perform, especially in the presence of creep), and taking as a practical limit the sixth green, we have a total of 18 isochromatic bands. With the fringe method the patterns are distinct even beyond the 15th fringe, which represents approximately the elastic limit of bakelite. We thus have within the elastic limit 30 bands with the fringe method, against 18 with white light, or an effect equivalent to an increase in optical sensitivity of more than 3 to 2 (see Fig. 36).

The author agrees with Mr. Solakian that the use of white light brings out very clearly the points of $P - Q = 0$ by providing a colored background for the dark points or bands. A little experience, however, enables one to tell these points with relative ease when a mercury-vapor lamp is used. All one needs to do is to remove the color filter, and the dark bands come into relief.

The author has had few occasions to go to temperatures higher than 70 deg. cent. to obtain well-annealed models, and because the changes produced in the bakelite increase with the temperatures, he prefers to anneal at 70 deg. cent., and only in exceptional cases to go a few degrees above that.

The points at which the loads were acting in the problem studied by the author were undoubtedly stressed beyond the elastic limit. That, however, is inevitable if an appreciable optical effect is to be produced on the horizontal diagonal. Before closing, the author wishes to point out an aspect of the monochromatic method which has thus far been neglected—i.e., the directional effect of stress when white light is used.

Consider two elements A and B in a body subjected to a two-dimensional stress system (see Fig. 37). Let us assume that the

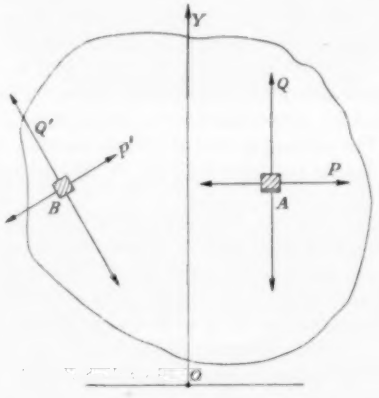

FIG. 37

principal stresses on these elements are equal in magnitude but differ in direction; i.e., $P = P'$; $Q = Q'$. If a ray of plane polarized light be transmitted through this body, it will be resolved into rectilinear components in directions of the principal stresses the magnitudes of which will depend on the direction of the plane of vibration of the impinging ray. The character of the emerging ray will thus depend on the direction of the principal stresses. If, for concreteness, the impinging-plane polarized ray be vibrating in a vertical plane, then the emerging ray would still be plane polarized at point A, while the one at B would generally be elliptic. In such cases the optical effect of a stress system acting upon an element would depend on the direction of the stresses as well as their magnitudes. To obviate such a condition the plane-polarized ray is replaced by a circularly polarized one, which breaks up into equal components regardless of the directions of the principal stresses. Such a condition is implied in the stress-optic law $R = c\,(P - Q)$, which does not contain the directions of the stress system. Now, the most effective way to produce circular polarization is by means of a quarter-plate. But this quarter-plate has meaning only when used with monochromatic light. There can evidently be no quarter-plate for white light. If white light be merely the combined effect of the fundamental colors having different wave lengths, then obviously a quarter-plate can be made to fit one but not all of the colors

simultaneously. So that white light gives elliptic polarization and not circular, with a consequent result that there is a directional effect of the stresses at a point.

The author has made some experiments to verify this theory. Strips of celluloid and bakelite were subjected to tension and placed in the path of plane and circular rays, respectively. They were then rotated in the plane normal to the axis of propagation of the ray of white light, and the changes of color were observed.

In the plane-polarized field, both the celluloid and the bakelite showed marked changes in brightness, the maximum brilliance being at an inclination of 45 deg. to the plane of vibration. In the circularly polarized field the celluloid strip seemed to hold its color, but the bakelite strip showed pronounced changes. Starting with a deep green in the vertical position, the color changed and showed a clear tinge of red in the horizontal position, indicating a possible error of approximately 20 per cent. What seemed to be evidence of circular polarization with celluloid thus proved to be evidence of its small optical sensitivity. There is therefore a directional effect when white light is used. Such, however, is not the case with monochromatic light. Here a quarter-plate can be made to produce true circular polarization and thereby to eliminate directional effect and to increase the accuracy of the work.

The fringe or monochromatic method has also the advantage that it makes the taking of clear moving pictures practicable, and thereby contributes an effective tool for many fields of investigation, especially for the study of impact stresses.

The author was glad to learn from H. F. Moore and M. F. Sayer of the photoelastic work which is being done at their respective institutions. He also wishes to thank G. B. Karelitz for emphasizing the practical value of the fringe method for designers. While the author champions the fringe or monochromatic method, believing that it has genuine merits and that it will facilitate the dissemination of knowledge of photoelasticity, there are two occasions on which he uses white light as a source: one of these is when sketching isoclinics and the other when investigating the signs of boundary stresses.

APM-53-12

Influence of Damping in the Elastic Mounting of Vibrating Machines

By E. H. HULL,[1] SCHENECTADY, N. Y.

This paper considers the elastic material for, and design of, elastic mountings intended for the prevention of transmission of vibration from electrical apparatus into the structure of buildings in which comparative quiet is desired. The effectiveness of such a support depends on the square of the ratio of the frequency of the impressed disturbance to the natural frequency of the machine on its mounting. Thus the natural frequency of the machine on its mounting must be made low in comparison with the impressed frequency. It is shown analytically that damping, or internal friction, in an elastic mounting causes additional transmission through the mounting. An apparatus was built to compare directly the effectiveness of materials proposed for elastic support. The detrimental effect of damping is clearly shown at high ratios of impressed frequency to natural frequency, causing the transmission to be doubled in the case of some samples. Therefore when choosing the elastic material for a support it is necessary to consider the damping present in the substance. Drift tests were also made to aid in determining the best material for this work. In several ways rubber appears to be well suited to use as an elastic support material. As an example, its incorporation in a mounting for a 15-hp. induction motor is described.

THE present tendency toward lighter building construction creates structures which transmit noise and vibrations throughout their framework more readily than do buildings of the older types. Recently, elastic mountings have been placed under apparatus which creates objectionable disturbances in these modern buildings. Excellent results are obtained in preventing the transmission of vibration to the building by the use of such mountings, provided that these supports are correctly designed and applied.

Elastic supports may be divided into two types: (1) Mountings intended for isolation from disturbances of any frequency or from shocks, and (2) mountings designed for isolation from vibration of one, or several, known and constant frequencies. Mountings of the first type are exemplified by the automobile suspension in which damping of some sort is known to be beneficial since road shocks may occur at the natural frequency of the vehicle on its springs. The present investigation deals with the effect of damping in the elastic material of mountings of the second type. A mounting constructed to prevent the transmission of electromagnetic noise from a three-phase induction motor to its foundation is described as an example of this second type.

Demonstration

An apparatus sketched in Fig. 1 gives an idea of the function of an elastic support. The mass M is supported through a spring k from a crosshead P moving with constant amplitude in approximately simple harmonic motion. At a very low cranking speed M moves through the same amplitude and in phase with P. As the speed increases the amplitude of M increases to a maximum at the resonant speed.

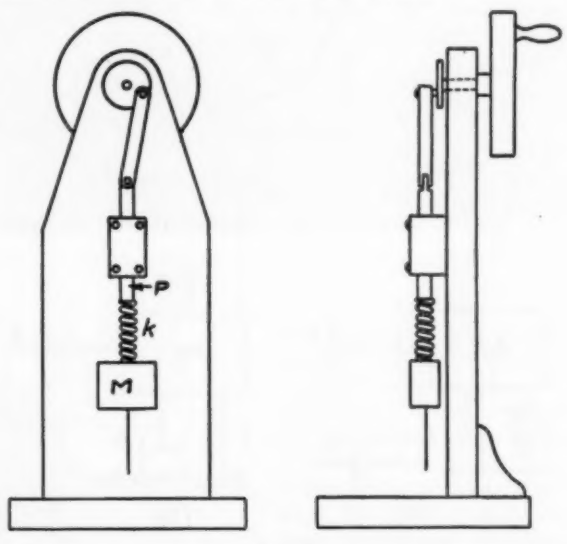

Fig. 1 Apparatus for Demonstrating the Effect of Elastic Mounting

In this range the motions of P and M, which have been in phase, shift through 180 deg. and continue out of phase at higher speeds. Any increase in speed above the resonant speed tends to decrease the amplitude of M until it is found, at a speed several times the resonant speed, that the mass remains practically stationary in space.

The curve marked $\delta = 0$ in Fig. 2 indicates the relation between speed and amplitude, showing clearly that the elastic support of M is harmful until a speed of 1.41 times the resonant speed is reached, but becomes increasingly effective as the frequency is raised above that speed. At a speed of several times that at which resonance occurs, M moves with a small fraction of the impressed amplitude.

Simple Theory

Fig. 3(*a*) shows schematically the essentials of the demonstration apparatus with damping added. k is the stiffness constant of the spring in force per unit deflection, the mass $M = W/g$,

---

[1] General Electric Co. Jun. A.S.M.E. Edwin H. Hull was born at Derby, Conn., in 1902; was graduated from the Sheffield Scientific School of Yale University in 1924, and since then has been in the Research Laboratory of the General Electric Company.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

and the damping, assumed to follow the viscous-friction law, contains a constant b having the dimensions force per unit linear velocity. The disturbing force of frequency ω and the resulting motions are assumed to be sinusoidal.

If the transmissibility ϵ of the system is defined as the ratio of the maximum amplitude of M to the maximum impressed amplitude, then the Appendix gives

$$\epsilon = \sqrt{\frac{b^2\omega^2 + k^2}{b^2\omega^2 + (k - M\omega^2)^2}} \quad \ldots\ldots [6]$$

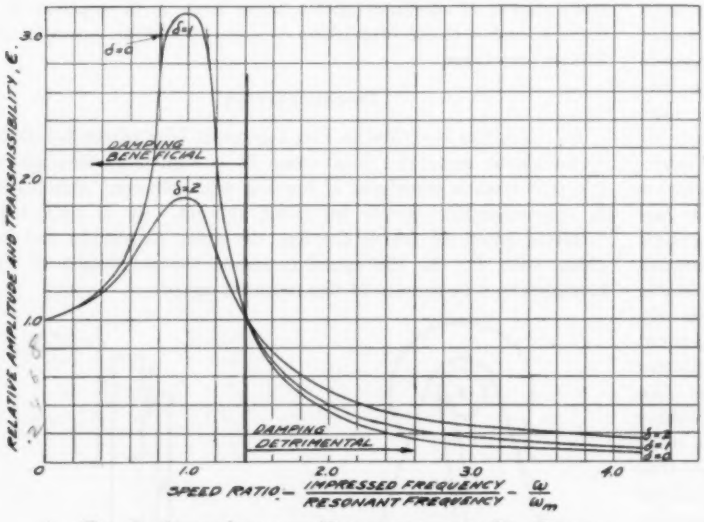

FIG. 2 AMPLITUDE AND TRANSMISSIBILITY VS. SPEED

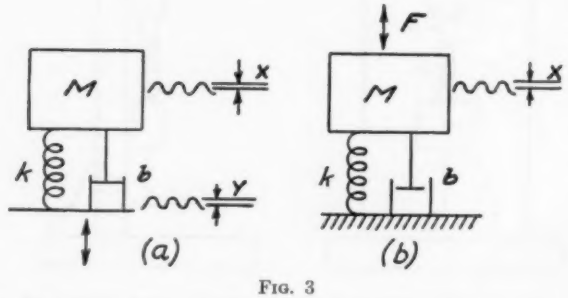

FIG. 3

When $b = 0$,

$$\epsilon = \frac{1}{1 - \left(\frac{\omega}{\omega_e}\right)^2}$$

or, since we are not interested in phase,

$$\epsilon = \frac{1}{\left(\frac{\omega}{\omega_e}\right)^2 - 1} \quad \ldots\ldots [7]$$

where $\omega_e = \sqrt{(k/M)}$, the resonant speed of the system.

Elastic mountings of the second type are usually represented by the system shown in Fig. 3(b). This case includes vibrating machines isolated from buildings by an elastic suspension. Here the transmissibility will be given by the ratio of the maximum value of the force transmitted to the foundation to the maximum value of the impressed force. In the Appendix it is shown that Equations [6] and [7] hold in this case as well as in the former.

In order to obtain comparisons between various systems it is convenient to have the damping term given by a dimensionless quantity. For the cases in which the viscous-friction law holds (frictional resistance proportional to velocity) it is easily shown[1] that the logarithmic decrement, $\delta = \pi b/\sqrt{(Mk)}$. Substituting in [6],

$$\epsilon = \sqrt{\frac{1 + \frac{\delta^2}{\pi^2}\left(\frac{\omega}{\omega_e}\right)^2}{\left(1 - \left(\frac{\omega}{\omega_e}\right)^2\right)^2 + \frac{\delta^2}{\pi^2}\left(\frac{\omega}{\omega_e}\right)^2}} \quad \ldots\ldots [8]$$

Fig. 2 shows that the transmissibility in the range from $\omega/\omega_e = 3$ and up may be more than doubled by common values of δ. Thus damping is beneficial in suspensions of the first type in which the speed ratio ω/ω_e may vary over an unknown range and hence be less than 1.41. On the other hand, damping is detrimental in supports of the second type, in which with proper design the speed ratio will never be near unity.

APPARATUS AND EXPERIMENTS

Since it is not known what law is followed by the friction in the various materials available for elastic support, or whether the stiffness of the material remains constant, it was thought advisable to make tests measuring the transmissibility directly. The usual troublesome frequency encountered in electrical machinery is twice the fundamental electrical frequency or 120 cycles per second for 60-cycle power supply. By experience we have found that a speed ratio ω/ω_e of 6 or 8 is desirable in isolating this vibration. In order to make the test results as applicable as possible to practical problems, it was decided to make measurements over this range. Unit pressure and thickness of the tested materials were to be kept equal or near to those used in practice.

In directly determining transmissibility in a system similar to that in Fig. 3(a), three measurements are necessary, namely, two amplitudes and a speed. Likewise, in the system of Fig. 3(b) two forces and speed are necessary. Since for this case it is easier to measure small amplitudes than small alternating forces, the former system was chosen for test purposes. It has been shown in the Appendix that both systems give the same expressions for transmissibility.

Figs. 4 and 5 give some idea of the construction and arrangement of the test apparatus. The horizontal shaft S, motor driven through a belt and pulley at one end, carries a flywheel F at the other. Sunk in the face of F is a circular hole, eccentric with the shaft S. A disk D is held in this hole by the nut N. D carries a ball-bearing support at a distance from the disk center equal to the eccentricity of the hole in F. Hence, by changing the angular position of D, the eccentricity of its ball-bearing support may be varied from zero to twice the eccentricity of the support in D. A connecting rod R leads to a crosshead carrying a table T. Any slight rotation of T is prevented by the horizontal phosphor-bronze strip Q.

Samples of isolating material O are placed on the table T, and support the $48^1/_2$-lb. weight W which is prevented from tipping by six horizontal wires. Speed is measured by an electric tachometer U having a range up to 10,000 r.p.m. The two cathetometers, C_1 and C_2, supported at points some distance from the apparatus, measure the amplitudes of the table and weight, respectively, by reading the apparent width of a point against a calibrated eyepiece scale. Distinct points were best

[1] A. L. Kimball, Trans. A.S.M.E., 1929, APM-51-21.

obtained by strongly illuminating the surface tangentially and selecting one of a number of minute, brilliant points of light reflected by dust or metal particles adhering to the surface. A dial indicator (not shown) was used to read the weight amplitude near resonant speed.

In performing the tests, the eccentricity was adjusted to produce a double amplitude of the platform of 12–15 mils. The thickness of the sample was initially chosen as that recommended by the manufacturer of the material and the area adjusted to conform with his recommended loading pressure. Readjustments of these dimensions were often necessary to give proper isolation. The prepared sample was placed centrally on the platform and the weight lowered upon it.

As the speed was slowly raised, the platform and weight amplitudes and speed were read at frequent intervals. The first occurrence of interest was the maximum-amplitude point of the weight, which was carefully determined. Readings were taken at frequent intervals from this point up to the highest speed which would produce a readable amplitude of the weight, or until vibration in the microscope supports made further reading impossible. In certain cases the energy dissipation due to friction in the sample raised its temperature sufficiently to change its stiffness and friction coefficient. When this occurred the sample was run at a high speed until a temperature equilibrium was reached, the readings then being taken as the speed was decreased.

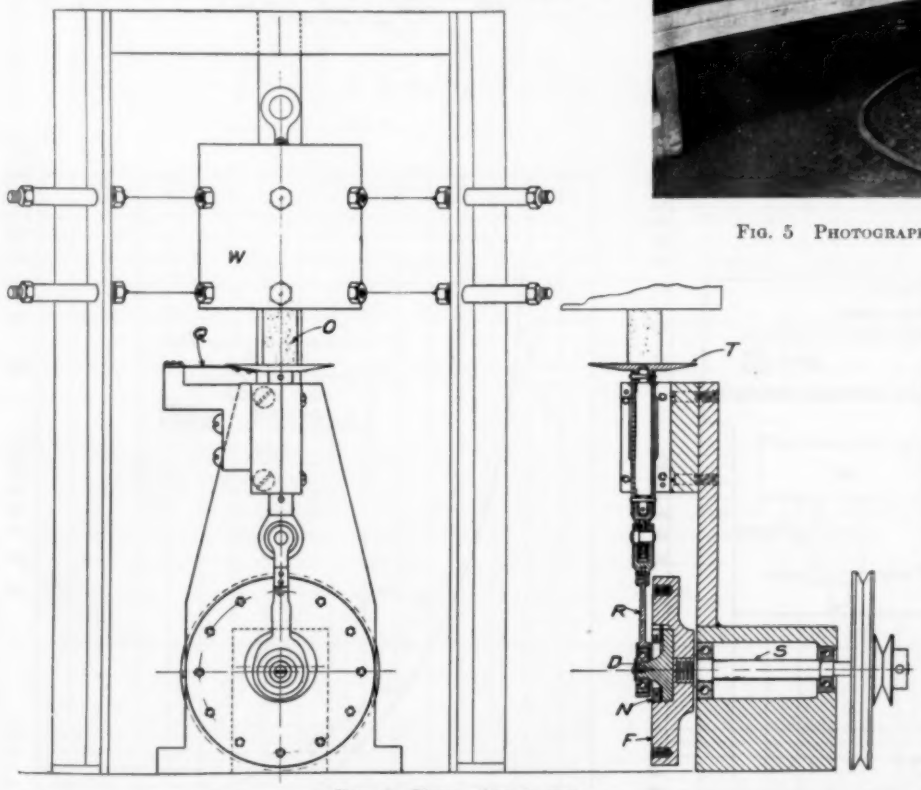

FIG. 4 TEST APPARATUS

RESULTS AND DISCUSSION

Results were plotted as shown in Figs. 6–11. The transmissibility ϵ is, as before, the ratio of the amplitude of the weight to the platform amplitude and is plotted on a logarithmic scale in order to magnify the situation at high ratios of impressed frequency to frequency of maximum amplitude of the weight, ω/ω_m. f_m, noted on each set of curves, is the frequency in vibrations per second corresponding with ω_m, an angular frequency. The solid line on each of the plots is the $\delta = 0$ curve from Fig. 2 representing the transmissibility which should be obtained with constant stiffness and no damping in the material. Steel springs follow the latter curve very closely.

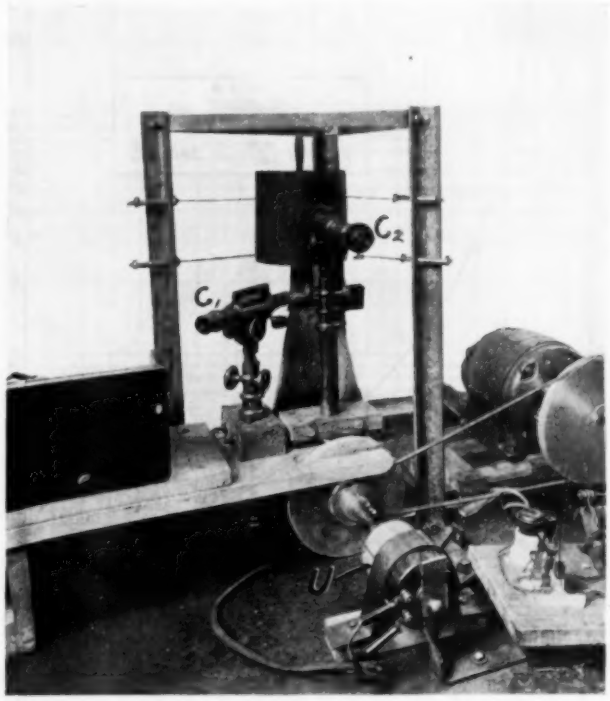

FIG. 5 PHOTOGRAPH OF TEST ARRANGEMENT

Experimental results from a high-quality rubber compound, containing about 90 per cent pure rubber, are given in Fig. 6. Damping in the material is low, as is shown by the large amplitude at resonance; therefore the increase in transmissibility due to damping is small.

Fig. 7 indicates the results obtained from coarsely ground, compressed cork, and also disproves the popular fallacy that interfaces of unlike materials reflect "vibration waves" analogous to the partial reflection of light on passing between bodies of different refractive indices. Data taken with and without the steel plate between the cork samples fall along the same curve.

The broken line of Fig. 8 shows results obtained from a natural cork, intended for isolation purposes, loaded in accordance with the manufacturer's recommendations. Amplification occurs at frequencies up to 2900 r.p.m. Tripling the load per unit area gave isolation at frequencies above 2000 r.p.m. as shown by the solid curve. Fig. 9 shows the latter data plotted for comparison with the transmissibility which could be obtained for the same stiffness with no damping.

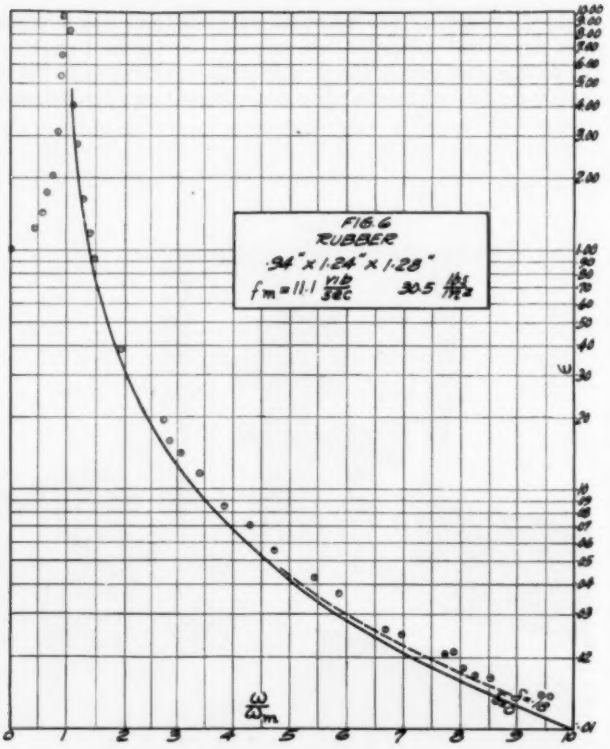

FIG. 6

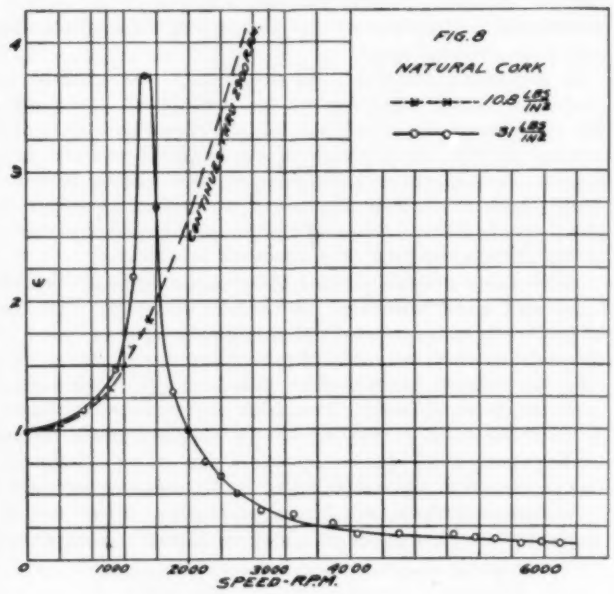

FIG. 8

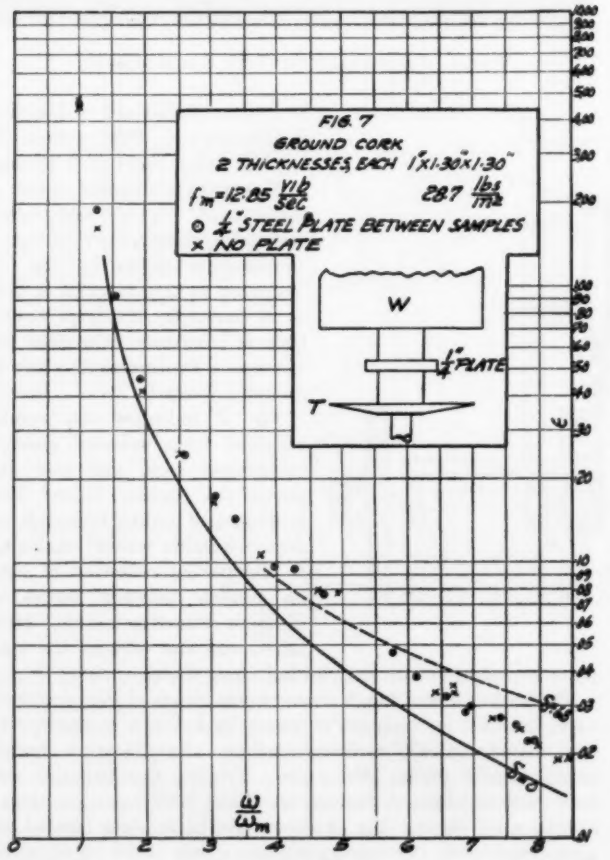

FIG. 7

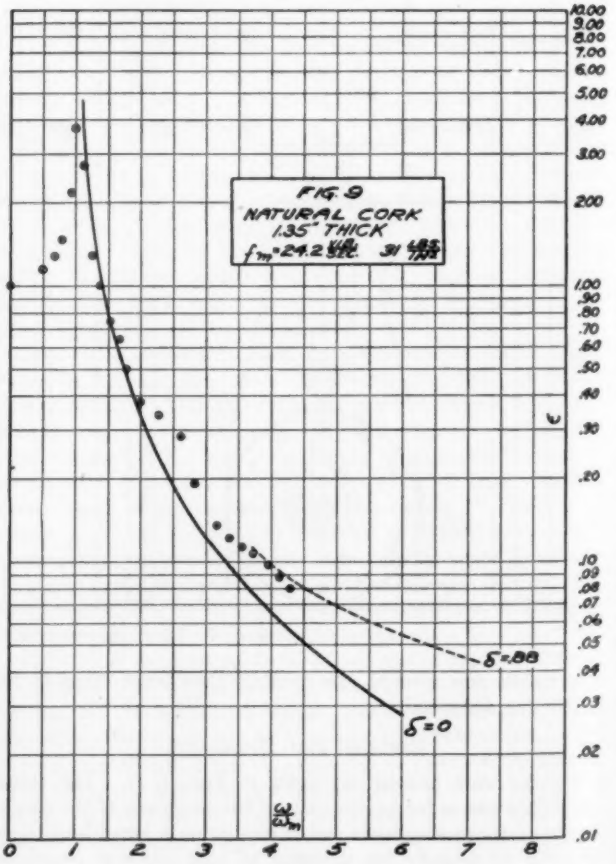

FIG. 9

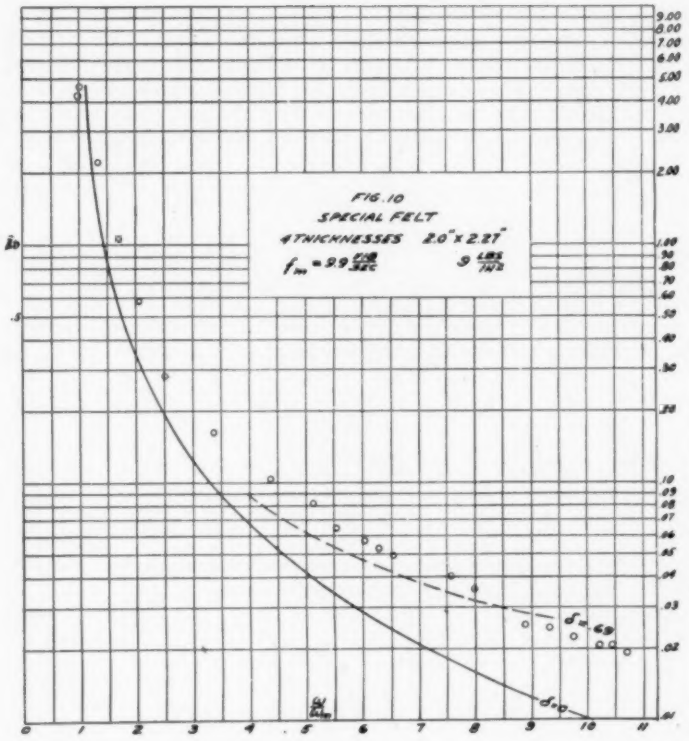

FIG. 10

A material similar to hektograph-pad gel required four thicknesses at 30 lb. per sq. in., rather than the maker's recommendations of one thickness, to produce satisfactory isolation (see Fig. 11).

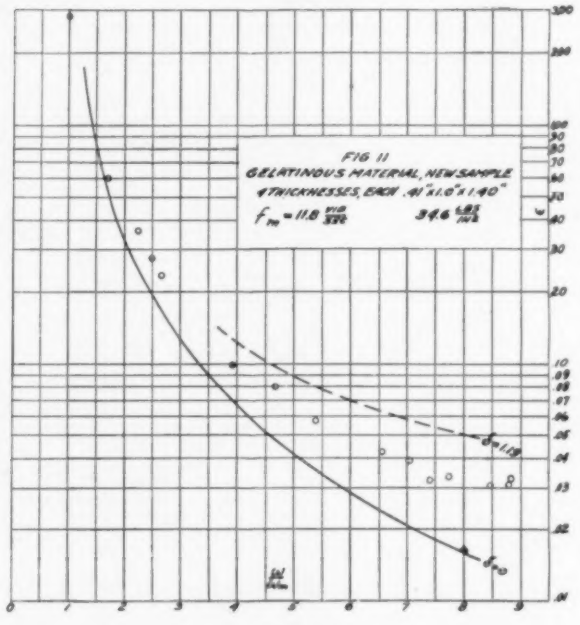

FIG. 11

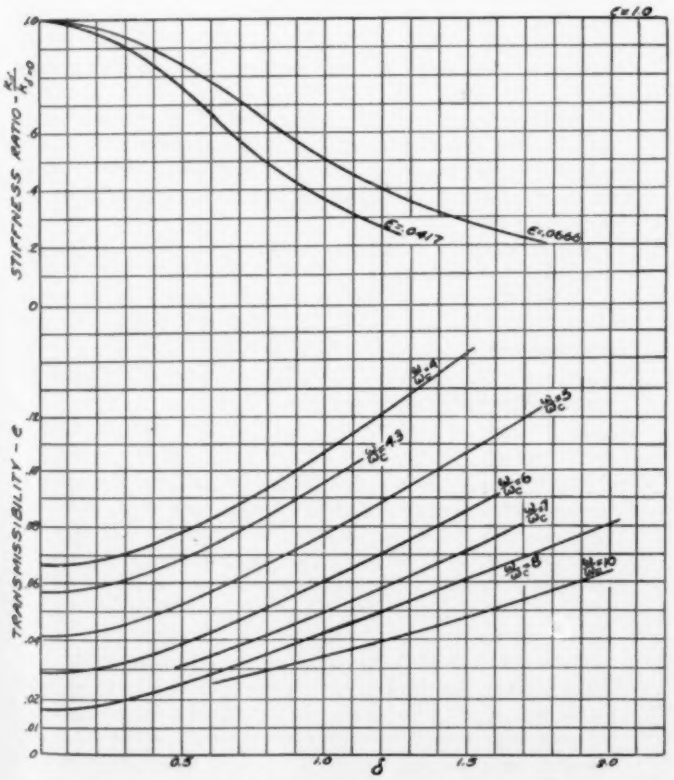

FIG. 12 COMPARISON OF MOUNTINGS FOR VARIOUS DECREMENTS

In the case of a special hair felt made for isolation purposes, Fig. 10 shows that the transmissibility is doubled at a speed ratio of 8.

In the analyses given in the Appendix, friction was assumed proportional to the velocity of extension and compression in the material. Some idea of the degree of approximation in this assumption may now be obtained.

When there is considerable damping present in a vibrating system of one degree of freedom, maximum amplitude does not occur at the value of speed given by $\omega_c = \sqrt{(k/M)}$, but is displaced in a direction and amount dependent on the type of system considered.

In this case Equation [6] gives

$$\frac{x}{y} = \sqrt{\frac{b^2\omega^2 + k^2}{b^2\omega^2 + (k - M\omega^2)^2}} \quad \ldots\ldots\ldots\ldots [6]$$

Solving for x, differentiating with respect to ω, and simplifying,

$$\omega_c^2 = \omega_m^2 + \frac{b^2\omega_m^4}{2k^2} \quad \ldots\ldots\ldots\ldots [9]$$

Thus, for this case, friction reduces the speed at which maximum amplitude occurs.

A first approximation of k and b may be obtained by assuming that $\omega_c^2 = \omega_m^2$. Then

$$k = M\omega_m^2$$

Equation [6] may now be solved for b, using the measured value of x/y at ω_m. Substituting these approximate values of k and b in [9] gives a value for ω_c^2, from which more exact values of k and b may be obtained by repeating the above process. It is found that this second determination of b is sufficiently accurate. The logarithmic decrement for the material may now be found using the previously given expression

$$\delta = \frac{\pi b}{\sqrt{Mk}}$$

Values for some of the substances tested are given in Table 1.

TABLE 1 VALUES OF δ FOR VARIOUS SUBSTANCES

Material	δ
Rubber	0.18
Special felt for supporting purposes	0.69
Cork, coarse ground and compressed	0.68
Gelatinous material similar to hektograph pad { 6 mo. old	1.93
Gelatinous material similar to hektograph pad { new	1.19
Natural cork loaded perpendicular to grain	0.88

The broken-line curves in Figs. 6–11, excluding Fig. 8, show the values of transmissibility which would be obtained from these various materials based on the calculated δ at ω_m, if these materials obeyed the viscous-friction law.

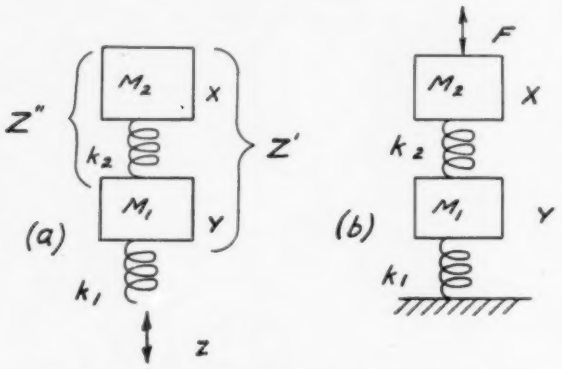

FIG. 13 TWO-DEGREE-OF-FREEDOM SYSTEMS

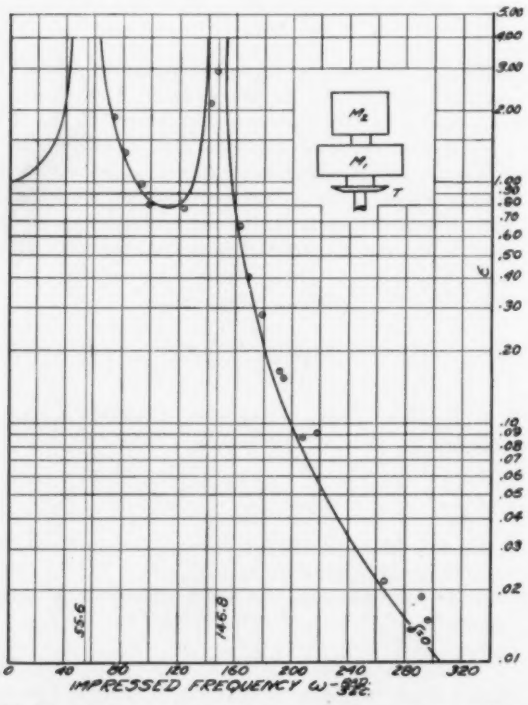

FIG. 14 TEST RESULTS IN A SYSTEM OF TWO DEGREES OF FREEDOM

Apparently this law gives a general idea of the increased transmissibility for an average case in the frequency range of $\omega/\omega_m = 6$ to 8, but may vary somewhat for particular cases.

A comparison may be made on the basis of this theory between two mountings, one in which $\delta = 0$ and the other in which $\delta = 1$.

The lower set of curves given in Fig. 12 shows the increase in transmissibility with increasing δ for constant speed ratios, and brings out the fact that δ has an increasingly greater effect as the speed ratio is raised. The upper group of two curves shows the amount by which the stiffness of a system having a certain δ must be reduced below the stiffness of a system in which $\delta = 0$, in order to maintain a constant transmissibility. When elastically mounted machines are required to transmit torque to apparatus on a separate base, the mounting stiffness should be as high as possible, consistent with good isolation, thus requiring a low value of δ.

Other damping laws might be considered, the solid-friction law,[3] for instance, in which the friction loss per cycle is independent of frequency but proportional to the square of the maximum stress in the material. Kimball[3] has shown in this case that for a sustained vibration

$$b' = \frac{\xi E k}{\pi \omega}$$

and that $\delta = \xi E$. Combining,

$$b' = \frac{\delta k}{\pi \omega}$$

This value when substituted for b in Equation [6], after dividing numerator and denominator by k^2, gives

$$\epsilon = \frac{x}{y} = \sqrt{\frac{\frac{\delta^2}{\pi^2} + 1}{\frac{\delta^2}{\pi^2} + \left(1 - \frac{\omega^2}{\omega_c^2}\right)^2}} \quad \ldots\ldots [10]$$

The values of δ computed by this expression and that of Equation [8] from values of x and y at ω_m will be very nearly the same since $(\omega_m/\omega_c)^2$ is close to unity. On the other hand, a large difference in the value of ϵ does occur at speeds well away from resonance.

The point marked with a triangle at $\omega/\omega_m = 8$ on Fig. 11 indicates the expected increase in transmissibility according to this law. The predicted increase is negligible, hence the law should be rejected for substances such as cork, gelatinous material, and felt.

The damping law for each material tested is probably different. Assuming that the stiffness for each material remained constant, these laws for the particular conditions of the test could be discovered from the data presented. This is not thought worth while since the assumption of the viscous-friction law gives an indication of the amount which friction raises the transmissibility in the most important range.

SYSTEM OF TWO DEGREES OF FREEDOM

Elastic mountings in the form of systems of two degrees of freedom offer interesting possibilities. Such a system was set up on the test apparatus using an additional elasticity and mass arranged as sketched in Fig. 13(*a*), rubber being used as the elastic medium. Fig. 14 shows the test points as well as a curve indicating the expected result when $b = 0$, obtained from Equation [14] developed in the Appendix.

The steep slope of the curve above the second resonant speed indicates that the support is very effective at a short distance above this speed. For instance, the two-degree system gives a calculated ϵ of 0.02 at 266 radians per sec. A one-degree-of-freedom system would require a resonant speed of 38 radians per sec., which is less than either of the two-degree-of-freedom resonant speeds, to produce the same transmissibility.

[3] A. L. Kimball and D. E. Lovell, *Phys. Rev.*, vol. 30 (1927), pp. 948–959.

Drift Tests

Drift tests to determine the loss in thickness with time under load were made on samples of materials used in the above experiments. A simple apparatus was used (see Fig. 15) consisting of a 112-lb. weight, held in a vertical position by horizontal wires, under which the sample S is placed. The dial indicator I gives the drift in mils. Variation in stiffness with drift is obtained from measurements of the resonant frequency of the weight on the sample at several times as the test progressed.

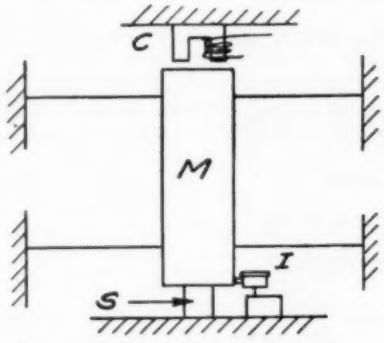

Fig. 15 Drift-Testing Apparatus

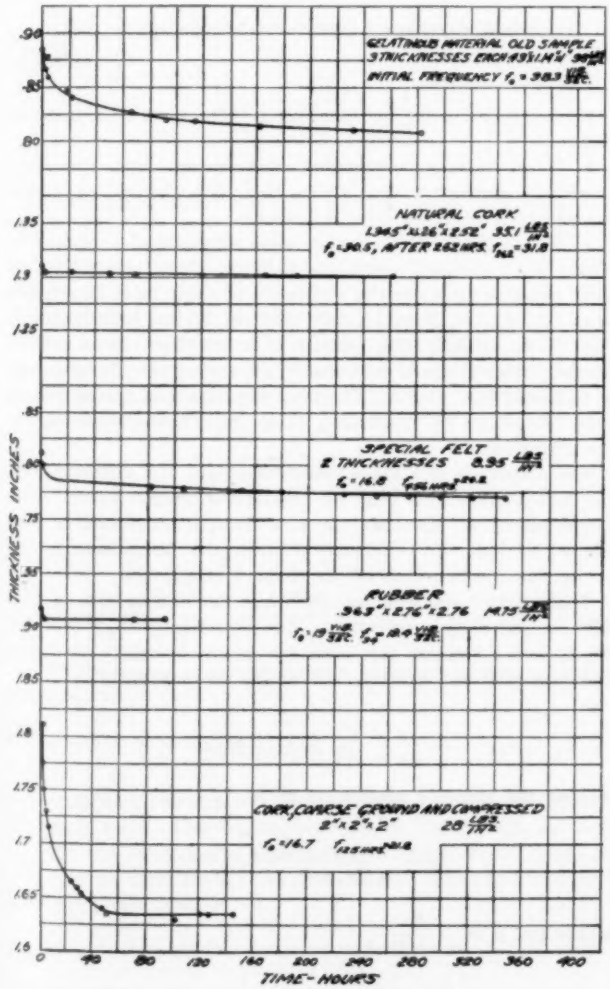

Fig. 16 Drift-Test Results

Samples were proportioned to give about the same load per unit area as was found necessary for satisfactory transmissibility.

The upper curve of Fig. 16 shows the loss in thickness with time for a six-months-old sample of the gelatinous material, which had become 1.6 times as stiff as the newer sample. Even at this high loading and consequent rapid drift, the resonant frequency is too high for proper isolation.

Natural cork shows a small drift, but the resonant frequency is high. Two thicknesses should be used to reduce this frequency and obtain better isolation, in spite of the fact that the drift would be doubled in so doing.

Two thicknesses only of the special felt were tested. Even with this low loading, the drift is great and the stiffening with time fairly large. If the test had been made with four thicknesses the drift would have been twice as large and the percentage change in stiffness the same.

Rubber, at this low loading, shows practically no drift, although at higher loadings some loss in thickness would begin to appear.

Ground cork, when loaded to a value just below the manufacturer's recommended range, shows a very large initial drift. The frequency increase is considerable also.

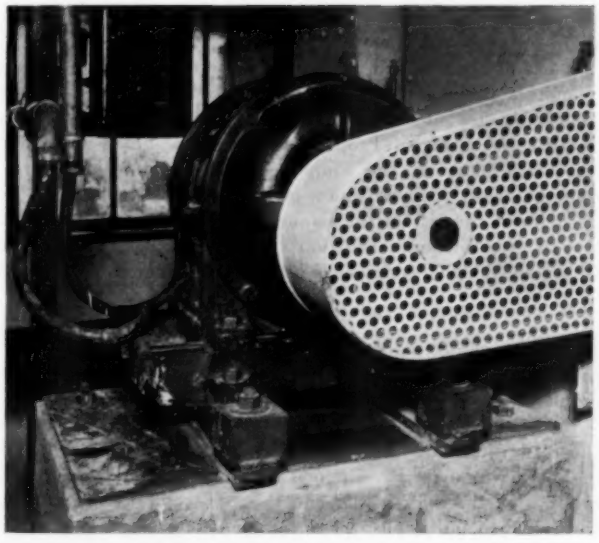

Fig. 17 Photograph of an Installation

Rubber in a Motor Support

In choosing the elastic material for mountings several considerations point to rubber as the most advantageous. Its damping is low, much energy may be stored in a small volume, protection from oil can be arranged, stiffness in various directions may be controlled by shape, drift is small at low pressures, and finally, its life, when compounded with antioxidants, is fairly long.

As an example of the use of rubber, Fig. 17 shows a three-phase induction motor driving a ventilating fan in an office building. The sliding base under the motor is isolated from the foundation by rubber placed in the four symmetrically disposed metal boxes, two of which are visible in the foreground. An induction motor may have vibration components along each of its three coordinate axes, therefore the mounting must be elastic in all directions. A motor on such a mounting has six modes of vibration, and hence six natural frequencies, all of which should fall outside the running range of the motor. Since a floor is most sensitive to vibration in a vertical direction, the natural frequency of the motor on its mounting must be low in that direction. The fundamental frequency of the impressed force is 120 cycles per sec. for a 60-cycle power supply, hence the vertical natural frequency referred to above should be about 15–20 cycles per sec. The mounting shown isolated

the motor very satisfactorily, and also appeared sufficiently stable for good belt operation.

It has not been found possible to make the mounting stiffness of motors transmitting torque to apparatus on separate bases sufficiently low to isolate from unbalance vibration unless the motor speed is high. Proper mechanical balancing will nullify this disturbance at the source. In machines which share a common base, such as motor-generator sets, the natural frequencies of the set on the mounting may be made sufficiently low to give adequate isolation from the unbalance vibration. Of course all higher frequencies are isolated even more effectively.

Summary

Supports can be made to prevent the transmission of vibration to or from the mounted machine through its base, but cannot reduce the noise radiated directly to the air from the machine.

In an elastically supported machine the speed ratio, that is, the ratio of the disturbing frequency to the natural frequency of the machine on its support, must be greater than 1.41 in order that the support be effective. For vibrations, such as those due to unbalance, having a frequency below the audible range, a speed ratio of 2 or 3 is sufficient. Vibration occurring at frequencies in the audible range, due to electrical disturbances for instance, requires a speed ratio of 6 or 8 for proper isolation.

Damping has been shown, both by theory and experiment, to be detrimental to this type of support. For comparison purposes, damping has been assumed to follow the viscous-friction law. A table of δ, the logarithmic decrement of the material, is given for several substances in order that such comparisons may be made. All tests were carried out at values of pressure and frequency approximating service conditions.

Several considerations point to rubber as the material best suited to supports of the type described.

In conclusion the author wishes to acknowledge the suggestions and assistance given by Messrs. A. L. Kimball and W. C. Stewart of the Research Laboratory of the General Electric Company.

Appendix

TRANSMISSIBILITY OF VARIOUS SYSTEMS OBTAINED BY THE MECHANICAL-IMPEDANCE METHOD

MECHANICAL vibration problems may be solved for the steady-state conditions by a complex quantity method analogous to that used in solving electrical circuits.[4,5,6] The electrical equivalents of mechanical quantities are tabulated below.

Electromechanical Equivalents

Mechanical		Electrical	
v	velocity	i	current
F	force	E	voltage
Z	velocity impedance	Z	impedance
x	amplitude	q	charge
k	stiffness	$\frac{1}{C}$	$\frac{1}{\text{capacity}}$
b	friction coefficient	R	resistance
Z_m	mechanical impedance	$j\omega Z$	

$$j = \sqrt{-1}$$

Ohm's law states that

$$i = \frac{E}{Z} \qquad [1]$$

and analogously

$$v = \frac{F}{Z} \qquad [2]$$

In our problem the instantaneous values[7] of displacement and velocity are

$$x_i = x \sin \omega t$$

and

$$v_i = \frac{dx}{dt} = x\omega \cos \omega t$$

Returning to maximum values,

$$v = j\omega x$$

Substituting in [2] and solving for x,

$$x = \frac{F}{j\omega Z} = \frac{F}{Z_m} \qquad [3]$$

Mechanical impedance, Z_m, is found from the following known constants of the system in question:

Frictional impedance (proportional to velocity)	$= jwb$
Mass impedance	$= -M\omega^2$
Elastic impedance	$= k$

Three general rules for combining these quantities may be given:

1 When various components of a system have the same amplitude impressed upon them, their impedances are added directly to obtain the total impedance.

2 If it is possible for two or more elements of a system to divide an impressed amplitude between them, depending on their impedances, then the reciprocal of their total impedance equals the sum of the reciprocals of the individual impedances.

3 When dealing with systems of more than one degree of freedom, impedances of each part of the system are first obtained as indicated in 1 and 2. The total impedance of the system is then discovered by combining these impedances according to the above rules.

The amplitude of a mass means, of course, the distance from the mid-position to a peak on the time vibration curve. The amplitude of an elasticity, or of a damping medium, is considered as half the difference between the displacements impressed on the two ends of the element in question.

This method will first be applied to the simple case of Fig. 3(*b*) by way of demonstration. The sinusoidal force F vibrates M, k, and b through the same amplitude, therefore their impedances will add directly. From [3] we may write

$$x = \frac{F}{jb\omega + k - M\omega^2} \qquad [4]$$

Taking the absolute magnitude gives

$$x = \frac{F}{\sqrt{b^2\omega^2 + (k - M\omega^2)^2}}$$

where $\tan \phi = \dfrac{b\omega}{k - M\omega^2}$

Returning to the problem of the paper, the transmissibility ϵ of this system will be given by the ratio of the maximum force passing through to the rigid foundation to the maximum value of the impressed force f/F.

[4] A. G. Webster, Proc. Am. Acad. of Science, vol. 5 (1919), p. 275.

[5] A. E. Kennelly and Nukiyama, Trans. A.I.E.E., vol. 38 (1919), pp. 651–699.

[6] C. A. Nickle, Trans. A.I.E.E., vol. 44 (1925), p. 1277.

[7] I. B. Crandall, "Theory of Vibrating Systems and Sound," 1926, p. 9.

$$f = x(j\omega b + k)$$

Solving [4] for F and taking the ratio f/F gives

$$\epsilon = \frac{f}{F} = \frac{x(j\omega b + k)}{x(j\omega b + k - M\omega^2)} = \sqrt{\frac{b^2\omega^2 + k^2}{b^2\omega^2 + (k - M\omega^2)^2}}. \quad [5]$$

In the system of Fig. 3(a) in which the foundation is moved through a constant amplitude y, causing a certain amplitude x to appear in M, the transmissibility will be given by the ratio x/y. A certain force F is required to move the foundation ends of k and b through the amplitude y. This same force is applied to M through k and b. Therefore from [3] we may write

$$x = \frac{F}{Z_m(\text{mass})}, \quad y = \frac{F}{Z_m(\text{total})}$$

$$\epsilon = \frac{x}{y} = \frac{Z_m(\text{total})}{Z_m(\text{mass})}$$

$$Z_m(\text{mass}) = -M\omega^2$$

From rule 2,

$$\frac{1}{Z_m\ (\text{total})} = \frac{1}{-M\omega^2} + \frac{1}{k + j\omega b}$$

whence

$$\epsilon = \frac{x}{y} = \frac{\dfrac{-M\omega^2(k + j\omega b)}{j\omega b + k - M\omega^2}}{-M\omega^2}$$

Canceling and taking the ratio of the magnitude of the vectors,

$$\epsilon = \frac{x}{y} = \sqrt{\frac{b^2\omega^2 + k^2}{b^2\omega^2 + (k - M\omega^2)^2}} \quad \ldots\ldots [6]$$

Equations [5] and [6] are identical.[8]

The transmissibility of the two-degree-of-freedom system shown in Fig. 13(a) is x/z. Assuming the displacements x, y, and z positive, also that $x > y > z$, and, for brevity, that $b = 0$, we have from [3],

$$x = \frac{-k_2(x - y)}{-M_2\omega^2} \quad \ldots\ldots [11]$$

$$y = \frac{-k_1(y - z)}{Z'} \quad \ldots\ldots [12]$$

$$Z'' = \frac{-k_2M_2\omega^2}{k_2 - M_2\omega^2}, \qquad Z' = \frac{M_1M_2\omega^4 - k_2M_1\omega^2 - k_2M_2\omega^2}{k_2 - M_2\omega^2}$$

Solving [12] for y, substituting in [11] and bringing z to the left-hand side,

$$\epsilon = \frac{x}{z} = \frac{k_1k_2}{k_1k_2 - \omega^2(k_1M_2 + k_2M_1 + k_2M_2) + M_1M_2\omega^4}. \quad [13]$$

To simplify, the expression may be divided through by the constants k_1k_2. The resonant speeds of the system, ω_c' and ω_c'', are the roots of the denominator when it is set equal to zero. Then breaking up the denominator, using the sum and product of the roots, gives

$$\epsilon = \frac{1}{\left[\left(\frac{\omega}{\omega_c'}\right)^2 - 1\right]\left[\left(\frac{\omega}{\omega_c''}\right)^2 - 1\right]} \quad \ldots\ldots [14]$$

An identical expression may be obtained for the transmissibility of the system shown in Fig. 13(b). Damping will increase the transmissibility in either case.

Discussion

STUART H. HAHN.[9] The writer is much interested in hearing of the investigation that the author has been making, especially so because this work appears to antedate a somewhat similar investigation with which he has been connected for some months past. Thus the user of a material has, as often before, anticipated its manufacturer in a study of some of its properties.

The author is to be congratulated upon having designed and built a machine for general testing of elastic materials as mountings for the isolation of vibrating machines. The design is simple and the method of use is quite direct. So far as may be judged from the paper itself, however, the author appears to have neglected to consider entirely what we may term the form factor for comparatively incompressible materials which plays an important part in determining the properties of an elastic mounting. It is well known that rubber and more or less similar elastic materials, such as the gelatinous substance tested by the author, are only slightly compressible, so that when subjected to compression, as in a machine mounting, the material must bulge at the sides, undergoing tensile strains in planes perpendicular to the axis of compression. The elastic properties of a block of such material are thus dependent on more than the two factors of unit loading and thickness mentioned by the author; they depend very markedly upon the configuration and extent of the surface area. This discussion, of course, leaves out reference to other than solid elastic soft bodies with sides perpendicular to the loaded face.

Thus the author's figure of about 14 lb. per sq. in. for rubber may be applied only to blocks of such shape and composition as that used by him in his test set-up. In general, however, our work has pointed to loading figures for the various materials tested by the author, of about the same order of magnitude as the values he found most suitable for isolation of high-frequency vibrations. Our work, although so far performed on an entirely different scale from that adopted by the author, also indicates that damping factors of the various materials may be arranged in the same order as he has shown in his Table 1. Our work also corroborates his findings on the so-called gelatinous substance, which is, it is believed, a vulcanized vegetable oil. This material shows exceptionally high hysteresis and was of practically no use as an elastic mounting in the thickness recommended by its manufacturers.

Rubber has been used as an elastic support in many forms for at least the past hundred years. It has long had a few special uses such as for the rubber buffers and springs in European railroad equipment (in which it is said to have longer life than steel springs) and for the landing gears of aeroplanes. This use has been developed widely in the past ten years with its general adoption as an elastic mounting for motors and other parts of automobiles. Its application to motor supports has been studied only by somewhat empirical methods, and as a result there are almost as many rubber mounting designs as there are manufacturers. One of the most important types of motor mounts is that in which the rubber is stressed in shear. The shear mounting often has a considerable advantage of compactness for a given value of the elastic constant.

The damping factor given by the author in Table 1 is of course a characteristic only of the particular rubber compounds which he tested. Both the damping factor and the elastic properties of rubber compounds may, as most engineers realize, be adjusted over quite a wide range by selection of compound. The writer's company has, for instance, made rubber balls for incorporation into a rubber-metal combination universal joint and torsional vibration damper which had such high damping characteristics that they would rebound to a height of only about 10 per cent

[9] Physical Research Laboratory, B. F. Goodrich Company, Akron, Ohio. Jun. A.S.M.E.

of the fall when dropped on a hard surface, as contrasted to a rebound of about 50 per cent for a solid ball of pure rubber composition. The elastic properties of soft rubber may also be varied over almost as wide a range.

The method of studying elastic supports used in the writer's own laboratory has been to apply the support to a fairly large special machine weighing about four tons which is used for punching out small pieces from a wide web of rubber-fabric composition and to measure the building vibrations set up by the heavy impact, in several locations with a sensitive vibrograph of his own design and construction. Other full-scale tests have been and will be run, and laboratory studies on general properties of elastic supports are contemplated.

FRANK M. LEWIS.[10] The author has brought to attention the very interesting and important problem of the elastic mounting of generators. He divides elastic supports into two classes; those designed to protect against shock and those designed to isolate against a single frequency or a relatively small number of frequencies all higher than a certain fundamental.

The author concludes that for mountings of the second type the transmission will be increased with damping and that the best type of elastic support would be one entirely without damping.

The writer is rather hesitant to draw such a conclusion.

The dynamic system which actually exists in the case of a generator or other machine transmitting vibration to a structure is in actuality much more complicated than the simple system postulated by the author in Fig. 3 (*a*) or (*b*). It is assumed in Fig. 3 (*b*) that the structure on which the generator is mounted is of infinite rigidity or mass. If such were actually the case, there would be no need to solve the problem, for no vibration would be transmitted to the structure.

The essence of the problem is the elasticity of the structure and the resonant conditions which may exist in it due to this elasticity.

The actual set-up more nearly resembles that of the author's Fig. 13 (*b*). In this let M_1k_1 represent the elastic system of the building on which the motor M_2 is mounted by the spring k_2. In practice the frequency of the M_1k_1 system alone will be in the vicinity of the disturbing periodic force and is not under control. The frequency of M_2k_2 can be made low as compared with that of the disturbing force.

Assume for the moment no damping in k_1.

If the damping in k_2 were made to approach infinity, it is evident that M_2 and M_1 would vibrate together as a single mass and that a condition of synchronism between the periodic forces and the natural frequency of the elastic system would exist, resulting in excessive vibration. If the damping in k_2 were made zero, the system would now have two natural frequencies. One of these would be relatively low, but the other might be in the vicinity of the frequency of the periodic force, and excessive vibration might again exist. Excessive vibration could then occur if the damping in the machine support was either very large or very small. There must exist, then, some optimum value of damping in the machine support for which a minimum amplitude of vibration would exist in the structure.

This optimum value of damping may be found by setting up the equations for a system of two degrees of freedom, with damping, and finding the damping for minimum vibration in M_1 or the structure. The resulting equations will be, to be sure, rather cumbersome.

In an actual case we will rarely know either the natural frequency or rather frequencies, for there are usually many, or the damping characteristics of the structure on which the generator is mounted. It may therefore not be possible in an actual case to determine the optimum damping, but such an optimum nevertheless exists.

In actual practice the writer believes that the difference in the results obtained with various mounting substances, provided that the elasticities of the mountings are the same, may be very small.

From the viewpoint of the suppression of noise directly from the machine frame, the writer believes that the mounting having a relatively high damping might prove superior.

The question of the merits of damping in machine mountings is by no means settled, and it is hoped that it will continue to receive the author's attention.

J. ORMONDROYD.[11] Spring mounting for the elimination of the evil effects of vibration has been a thing very attractive to engineers over a long period of time. Mr. Akimoff discussed spring mounting in general terms in papers published by the A.S.M.E. before the war. The condition of the art at that time was such that spring mounting made the job worse as often as it made it better.

Mr. C. R. Soderberg brought spring mounting under scientific control by work done in 1923 and 1924, published in *The Electric Journal* at that time. In these papers he has defined the transmission factor ϵ and pointed out the fact that, above a certain speed, ratio damping was harmful rather than good. His definitions of transmission factor were the same as those given in this paper. The author's valuable contribution lies in the laboratory test equipment and in the test curves from this equipment.

The drift test is especially valuable in choosing material for flexible mounting, as it is very important that the material should not become progressively stiffer. It would be interesting to find from the author how the drift characteristics, changing thickness, and changing natural frequencies vary with the specific weights of the materials tested. Several years ago the writer had many static tests made on felts, corks, and rubber in which hysteresis loops were found. It was found that the results could be classified best for a given type of material by using the specific weight of the material. Since the specific weight of the material must be intimately connected with the internal structure, it must play an important role in the elastic, plastic, and damping properties of the material.

The author's test measurements were of such a nature that he should be able to give the energy dissipation per cycle for the materials tested. This should be given supplementing the logarithmic decrement figures given by him.

AUTHOR'S CLOSURE

The behavior of rubber is as Mr. Hahn has stated; that is, the stiffness of a pad of given thickness does not increase as the first power of the area, but at some higher power. A very short discussion of this phenomena, including two curves, has been included in a previously presented paper.[12] Discussion of this phase of rubber in elastic supports was purposely omitted as being outside the field of the present paper. The 14 lb. per sq. in. must not be taken as a recommended loading for rubber. It is merely the pressure on 1-in.-thick rubber of a certain grade necessary to give the mass used in the reported experiments a desired frequency. Under other conditions the loading required to give the proper frequency may run to over 100 lb. per sq. in.

Mr. Lewis states that in a system of two degrees of freedom

[10] Consulting Engineer, Webb Institute of Naval Architecture, New York, N. Y. Mem. A.S.M.E.

[11] Experimental Division Engineer, Westinghouse Elec. & Mfg. Co., South Philadelphia Works, Philadelphia, Pa.

[12] "Elastic Supports for Isolating Rotating Machinery," Hull and Stewart, presented before the A.I.E.E., Rochester, N. Y., April 29 to May 2, 1931.

an optimum value of damping may be found. In order to investigate this point a fairly typical arrangement was studied, and calculations were made from the result. An induction motor, M_2 of Fig. 13(*b*), weighing about 600 lb., was elastically mounted with a vertical natural frequency at 15 vibrations per

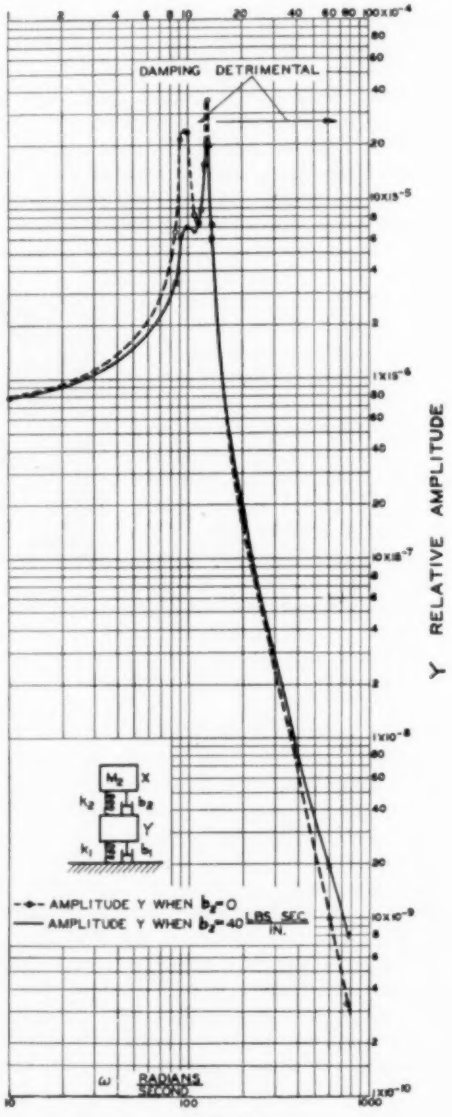

FIG. 18

second on a concrete building floor 9 in. thick having a vertical natural frequency at 20 vibrations per second. The following constants were obtained for the system:

$$M_1 = 80\frac{\text{lb-sec.}^2}{\text{in.}}, \qquad k_1 = 1.3 \times 10^6\frac{\text{lb.}}{\text{in.}}, \qquad b_1 = 250\frac{\text{lb-sec.}}{\text{in.}}$$

$$M_2 = 1.5\frac{\text{lb-sec.}^2}{\text{in.}}, \qquad k_2 = 1.4 \times 10^4\frac{\text{lb.}}{\text{in.}}, \qquad b_2 = 0 \text{ or } 40\frac{\text{lb-sec.}}{\text{in.}}$$

The damping constant for the floor, b_1, was obtained from the value of reinforced concrete, $\delta = 0.075$. That for the support, b_2, is taken for comparison purposes first as zero and then as that due to an elastic foundation constructed of a material having $\delta = 0.8$, such as cork.

Expressions for the motion of the mass M_1, the floor in the foregoing case, were worked out following the method given in the Appendix, and in the last part of the Appendix in particular.

In Fig. 18 the relative amplitude of the floor, M_1, is plotted against impressed frequency for the two values chosen for b_2. These results show that damping is beneficial in two frequency ranges only; from zero up to a point above the first resonant speed, and at the second resonant speed. Damping is detrimental between the two resonant speeds and from a point just above the second resonant speed on up. In this case the base was designed to isolate a vibration of 120 vibrations per second or 753 radians per second from the floor. At this frequency the specified amount of damping in the motor support would cause the floor to vibrate through 2.5 times the amplitude that it would experience with no damping in the motor support.

This effect of damping in a two-degree system is as its action in one-degree systems would indicate; beneficial below the first resonance and at resonance, detrimental at other times. In a closely coupled two-degree system such as the one cited, the frequency of the disturbing force will never be on or below the first resonant frequency of the system, and the second resonant frequency of the system should never be allowed to correspond with the frequency of the disturbing force.

In a loosely coupled system containing, for example, an elastically mounted motor and a wall considerably removed from the motor, the amount of damping in the motor supports will affect the magnitude of the disturbing force transmitted to the structure and hence the amplitude of the wall, but could not affect the motion of the wall, as it would be far removed and small in comparison with other damping forces acting on the wall.

Regarding Mr. Ormondroyd's discussion, the author makes no claim to priority in the theory of elastic supports in systems of one degree of freedom. Mr. Soderberg's work is included in the references.

Referring to the suggestion that similar materials may be classified by density with regard to drift and changing stiffness under load, rubber and the gelatinous material may be taken as an example. The specific weight of this sample of rubber is 0.0381 lb. per cu. in. and that of the gelatinous substance 0.0482 lb. per cu. in., which would indicate that the latter material would drift less under similar conditions, thus leading to an erroneous result.

In some cases the more dense samples of rubber have been found to give greater drift under load than those having a smaller density.

On the sixth page of the paper is a short discussion showing that the solid friction law, in which the internal friction loss per cycle is independent of frequency, does not hold for the type of substance tested. However, the viscous friction law in which the friction loss is proportional to velocity does give a fair idea of the damping effect. In this case the energy dissipation per cycle depends, among other factors, on velocity, so that it cannot be stated as a constant for the material.

APM-53-13

Thermal Stresses in Thin-Walled Cylinders

By CLARENCE H. KENT,[1] FAYETTEVILLE, ARK.

The author, using Föppl's method, investigates the stresses in (1) a cast-iron cylinder 30 in. long, 20 in. mean diameter, and 1 in. in wall thickness, with the temperature 100 deg. fahr. higher inside than outside; (2) the same cylinder and temperature conditions, but with cylinder supported at the ends; and (3) a steel cylinder of same size with flat heads rigidly attached and subjected to 500 lb. per sq. in. internal pressure. Constant and variable temperature gradients are considered, both in axial and radial directions.

THE problem of the stresses in a long, hollow cylinder caused by a temperature gradient in the radial direction was first solved by T. M. C. Duhamel (1)[2] in 1838. The solution was presented in a memoir which laid the foundation for future study of thermal stresses. Later writers have brought the problem to its present-day form (5), (6), (10). The method is exact for an infinitely long cylinder of any thickness and any temperature distribution in the radial direction only. It finds the principal planes of stress in such a cylinder to be in the radial, axial, and tangential directions with normal stresses acting on each, and shows that stresses on a plane perpendicular to the axis are independent of the position of this plane.

In order that the solution may be exact when a cylinder of finite length is chosen, boundary conditions require that external forces equal in value and distribution to the stresses in the axial direction act on the ends. In the usual case such forces will not be present, so that the stresses near the ends will be very different from those calculated by this method. The effect diminishes as we recede from the ends, and practically disappears at a point sufficiently far away. Some writers have assumed that this point was located at a distance from the ends equal to the thickness of the cylinder wall, but its location really depends on the ratio of this thickness to the cylinder diameter. For such examples as the liner of a Diesel-engine cylinder this effect does not disappear until we have moved from the ends a distance equal to about twelve times the wall thickness. Since the tangential stresses at the ends may be as much as 35 per cent higher than those near the middle, it becomes important to investigate them.

For determining the value of these stresses in thin cylinders Dr. August Föppl (21) turned to a method which had been in use for some time in the case of cylinders subjected to internal or external pressure. This was to treat an element cut from the cylinder wall as a beam on an elastic foundation. The method is not exact because it disregards radial stress, but it is sufficiently accurate for cases in which the cylinder diameter is at least ten times the wall thickness.

Applying the method first to a cylindrical shell of finite length in which a temperature gradient exists in the direction of the radius only, it is found that the maximum tangential stress at the ends is 30 per cent higher than the similar stress in an infinite cylinder. In a cast-iron cylinder of 1 in. thickness, 20 in. mean diameter, and 30 in. length, the tangential stress at the ends produced by a temperature difference between inner and outer surfaces of 100 deg. fahr. is 7850 lb. per sq. in. Away from the ends the value of both the tangential and axial stresses is 6000 lb. per sq. in., which is the same as that in a thin plate subjected to the same temperature gradient through its thickness and prevented from bending. This stress is independent of the thickness of the plate, which seems to contradict experience, as it is usually considered that a thicker plate will be subjected to higher thermal stresses. For the same rate of *heat flow* this is true, but in that case the temperature difference will be higher across a thick plate than across a thin one, and thus give rise to higher stress. The cylinder walls are deflected outward 0.0022 in. at the ends, which is the cause of the increase in tangential stress at this point. Fig. 6 shows the deflection of the walls and the distribution of tangential and axial stresses in the exterior surface.

The actual curve assumed by the cylinder walls has the form of a damped wave which is identical with that of a beam on an elastic foundation acted upon by a moment at the ends. In the case of the cylinder a small longitudinal strip of the walls represents the beam, and its elastic support is furnished by the resistance of the wall as a whole to expansion or contraction. Fig. 6 shows clearly how the moment produced by the thermal stresses has bent the end of the wall outward, and how this effect is damped out as one moves away from the ends.

If the deflection at the ends of such a shell is prevented by rigid supports such as those shown in Fig. 8, tangential stresses will be reduced. In the case of the shell just considered this reduction amounts to 43 per cent, as the curves in Fig. 9 indicate. It is noticed that the axial and tangential stresses reach a constant value of 6000 lb. per sq. in. at a point about 12 in. from the ends in both Figs. 6 and 9.

The supports at the ends do not entirely eliminate deflection, but they reduce its maximum value to less than 0.001 in. As the maximum axial stress is only 7 per cent above the normal "thin plate" value, one may conclude that for all practical purposes a cylinder so supported may be treated as of infinite length. The stresses in the wall will then be the same as those in the thin plate. Although the method does not apply to a thick cylinder, we may reason by analogy that the usual stress formulas for an infinite cylinder may be used with an equal degree of accuracy for a finite cylinder provided with similar end supports.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of The American Society of Mechanical Engineers. [Selected from a dissertation prepared under the direction of Prof. S. Timoshenko for presentation to the Faculty of the University of Michigan in partial fulfilment of the requirements for the degree of Doctor of Philosophy.]

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The stress will be reduced, of course, by any support whether or not it is rigid, and its effect can be computed if its elastic properties are known. Obviously the stress at the ends under such conditions will fall somewhere between the 7850 lb. per sq. in. value of Fig. 6 and that of 4500 lb. per sq. in. of Fig. 9, with the values for the middle portion of the cylinder remaining at 6000 lb.

In Example 3 the method is applied to a steel cylinder of the same dimensions and having the same temperature difference as the cast-iron cylinders considered. We now assume that heads of the same material as the walls are rigidly attached; that is, there is no bending in the joint between the head and the walls. An internal fluid pressure of 500 lb. per sq. in. is now introduced, though to avoid unnecessary complications in the calculations no opening is assumed. Such an opening should be placed somewhere within the middle 10 in. of the wall, where the cylindrical form is not interfered with by the application of heat or pressure.

The head applies both a moment and a shear to the wall whose value is calculated from the slope of the head at the joint and its expansion in a radial direction under load. The head tends to be deflected outward by the pressure, but inward by the temperature strain and action of the walls. The tensile stress along any radius in the exterior of the head reaches a maximum of 28,000 lb. per sq. in. at the center for a flat head $1^1/_2$ in. thick.

The curves of Fig. 11 indicate a complex stress distribution in the walls. The internal axial stress which normally is compression is changed to tension at the ends by the moment of the cylinder heads and reaches a maximum value of 26,550 lb. per sq. in. The tangential stresses at the ends are kept low by the action of the heads in limiting deflection.

At the middle of the cylinder the tangential tension reaches a maximum of 20,300 lb. per sq. in. on the exterior, 5000 lb. of which is produced by the internal pressure and the rest is due to the temperature difference. Axial stresses here are lower since the internal pressure has a smaller effect on them. The deflection curve is a damped wave shifted from its normal position by the action of the moment and shear at the origin. At the middle the effect of the internal pressure is to prevent the deflection returning to zero as it did in previous cases.

This example is intended to illustrate the fact that a great variety of end conditions may be successfully handled by this method, as long as there is a means of arriving at an expression for the moment and shear exerted on the cylinder walls at the ends. A flanged connection at the ends would also afford a good example of this.

So far the discussion has been concerned with shells having a temperature gradient in the radial direction only. It happens in many applications that temperature gradients also exist in the axial direction. In an internal-combustion-engine cylinder, for example, heat is flowing radially through the walls, but the temperature of the interior varies at the same time in the axial direction.

A case of very localized heating, such as that which is produced in welding pipe, develops a large gradient in the axial direction. The method used in this paper is quite easily extended to cases where the temperature along the axis varies with integral powers of the axial coordinate. This gives sufficient latitude for handling most practical cases.

Suppose in the cast-iron cylinder of the first example, the interior temperature varies linearly along the axis from zero to 100 deg. fahr., while the exterior is held at zero. Since the cylinder walls are thin, a linear distribution can still be assumed along the radius. Fig. 15 shows the deflection and the stress distribution for this case. The maximum stress at the warmer end is slightly less than that of Fig. 6, and the maximum axial stress is some 1400 lb. per sq. in. less.

Any constant temperature difference may be superposed directly on the curves of Fig. 15 to find the combined effect. If, for example, the internal temperature varies linearly over the length from 100 deg. fahr. to 200 deg. fahr. while the exterior is kept at zero, the stress and deflection curves are obtained by adding the curves of Fig. 6 to those of Fig. 15.

If the temperature varies with the second power of the axial coordinate instead of the first, the problem may be handled in the same way. The stress curves obtained would differ but little from those of Fig. 15 at the end sections. The middle portion would be represented by a parabola instead of a straight line.

A case of this type of temperature distribution occurs in the cylinder liner of a Diesel engine. From experimental measurements of temperatures obtained by Dr. Eichelberg (11) and Dr. Letson (12) the temperature curves of Fig. 16 were drawn. The measurements were made in each case by thermocouples embedded in the liner at a distance of 5 mm. from each surface. The equations of the curves are of the second degree in x, and the stresses produced may be calculated by this method. In Fig. 16 the liner is shown pressed into its casing, which is assumed to exert a sufficient moment and shear on the liner to bring the deflection and slope at this end to zero.

The maximum stress of approximately 6500 lb. per sq. in. occurs at the end. As we have seen before, when the deflection of the end is prevented the cylinder behaves much as if it were infinite in length. The stresses obtained by the usual formulas applying to infinite cylinders are about 150 lb. per sq. in. below the value just given. The actual stress will depend upon the exact amount of the deflection permitted at the end. The assumptions, first of free ends and then of fixed ends, establish the limits between which any particular case might fall. Normally the end conditions will be much nearer to the fixed case.

In the example chosen the sharp peak of stress at the origin could be much reduced by designing the press fit of the liner in its casing to permit an outward slope of about 0.001 in. per inch at the origin and to keep the deflection of the wall beyond its normal position as low as possible. To see the effect of this, imagine that the maximum tangential stress in Fig. 15 is reduced to about that at the origin in Fig. 9. If the moment is removed the axial stresses will be reduced to zero at the end.

Notation

a = linear expansion coefficient
c = mean radius of cylindrical shell
E = modulus of elasticity
e_t = unit tangential deformation
h = thickness of cylindrical shell
I = moment of inertia of strip of unit width and depth h
K = modulus of foundation
l = length of cylinder
M = moment
p = pressure, lb. per sq. in.
r = radius of curvature
σ_r = stress in radial direction
σ_t = stress in circumferential direction
σ_x = stress in axial direction
T = temperature
ΔT = temperature difference between interior and exterior surfaces of cylinder
η = distance from neutral axis
μ = Poisson's ratio
$\phi; \psi; \theta; \alpha$ = functions of x, see Appendix No. 1.

Heat Flow

If the interior surface of a hollow cylinder be maintained at a temperature T_1, and the exterior at a temperature T_2, flow of heat takes place through the walls which after a sufficient time becomes a steady flow. The temperature of any point in the wall is then given by the solution of the differential equation:[3]

$$\frac{\partial^2 T}{\partial r^2} + \frac{1}{r}\frac{\partial T}{\partial r} = 0$$

where T is the temperature of any point whose distance from the axis is r.

The solution is:

$$T = \frac{(T_2 - T_1)\log r + T_1 \log r_2 - T_2 \log r_1}{\log r_2 - \log r_1}$$

r_1 and r_2 being the inner and outer radii.

This discussion is confined to thin-walled cylinders in which the logarithmic distribution above becomes practically linear and is given by:

$$T = \frac{(T_2 - T_1)r + T_1 r_2 - T_2 r_1}{r_2 - r_1}$$

Let $r_2 - r_1 = h$, and $(r_1 + r_2)/2 = c$ = radius of mid-plane of cylinder wall. Let $\eta = r - c$; thus η is measured from the mid-plane and positive outward.

Let $T_2 - T_1 = \Delta T$, $T_1 = -\Delta T/2$, and $T_2 = +\Delta T/2$; thus the temperature is also measured from the mid-plane and positive outward. Since a uniform heating or cooling of the entire cylinder will have no effect on stresses, we may choose the temperature of the mid-plane as we like. For convenience let its temperature be zero. By these substitutions the temperature equation becomes:

$$T = \frac{\eta}{h}\Delta T$$

when the temperature of the external surface is higher than that of the internal. When this condition is reversed and the heat flow is away from the center the temperature of any point is given by:

$$T = -\frac{\eta}{h}\Delta T \qquad [1]$$

This expression is the same as that for a flat plate of thickness h subjected to a constant temperature difference ΔT.

It is to be noted that neither the coefficient of linear expansion a nor the modulus of elasticity E remains constant when the temperature varies. For temperature differences not exceeding 200 deg. fahr., however, this variation will not seriously affect the result. One may express a as a function of the temperature and thus take care of its variation for temperature differences exceeding that mentioned (9). It is questionable whether the introduction of this complexity is warranted in view of the fact that an error of the same order, due to the variation of E, is still present. For purposes of this work it will be assumed that a and E are constant, choosing an average value for the temperature range dealt with.

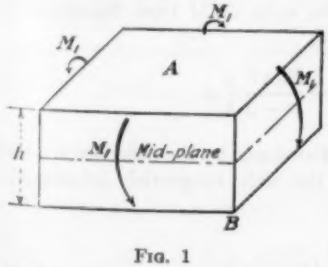

Fig. 1

[3] Carslaw, p. 114.

Constant Temperature Gradient in Radial Direction Only

Consider an element of a flat plate of thickness h and sides unity, shown in Fig. 1. Let a constant temperature difference ΔT be applied to the surfaces A and B so that the temperature of any point is a function of its distance from the mid-plane and is given by Equation [1]. The element will then be bent to a spherical surface of radius:[4]

$$\frac{1}{r} = \frac{a\Delta T}{h} \qquad [2]$$

This curvature will be removed by the application of the moments M_1 in Fig. 1, whose value is:

$$M_1 = -\frac{EI}{1-\mu}\frac{a\Delta T}{h} \qquad [3]$$

The stresses produced by these moments are:

$$\sigma_x = \sigma_y = \frac{Ea\Delta T}{1-\mu}\frac{\eta}{h} \qquad [4]$$

If a similar element is cut from a thin cylindrical shell and heated in the same manner, Equation [2] represents the *change* in curvature which it will experience. The moments required to remove this change and the stresses resulting are given by Equations [3] and [4], except that in the cylinder σ_y is replaced by σ_t.

In order that we may have such a stress distribution in a cylinder of finite length we must assume that at the ends are applied uniformly distributed moments of value M_1 per inch of circumference, as shown in Fig. 2(*a*). In such a cylinder or in one of infinite length the stress distribution due to the application of the temperature difference ΔT is given by Equation [4].

In the usual case the ends of the cylinder are free. To accomplish this we shall have to apply to the cylinder ends a moment equal and opposite to M_1 as shown in Fig. 2(*b*). On the temperature stresses given by Equation [4] we must superpose the stresses produced by the application of the moment $-M_1$, whose value we shall now determine.

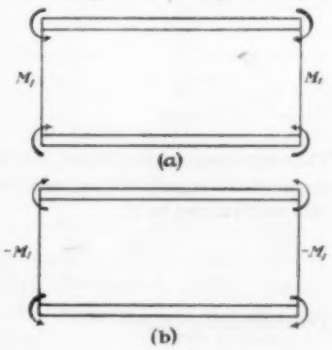

Fig. 2

Consider the cylinder at a uniform temperature which we may take as zero. Let a strip of unit width of the thickness of the cylinder wall be cut from it as in Fig. 3. The moment $-M_1$ acts on the ends of this strip producing a deflection y, which is resisted by the radial component of tangential stresses set up by such movement, as shown in Fig. 4. Since all the strips composing the cylindrical shell are affected alike, there can be no shear between them.

The value of the radial component of these tangential stresses produced by a deflection y, is $(Eh/c^2)y$ per unit length of strip. The moment at any point x in the strip due to these forces can be computed from Fig. 5. If $K = Eh/c^2$, the force acting on the element of length du is $Kydu$ and its lever arm about the point x is $(x - u)$. The summation of moments about the point x gives:

$$M + M_1 + \int_0^x Ky(x-u)du = 0 \qquad [5]$$

[4] See Timoshenko, p. 487.

where M represents the internal moment at the cross-section mn, and is positive in a beam bent concave upward. The relation between moment and deflection in a thin strip is:

$$M = \frac{EI}{1-\mu^2}\frac{d^2y}{dx^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

This modification of the usual bending formula is caused by the prevention of lateral contraction, since no change can take place in the angle θ of Fig. 3. Substituting the values of M and M_1 in [5]:

$$\frac{EI}{1-\mu^2}\frac{d^2y}{dx^2} - \frac{EI}{1-\mu}\frac{a\,\Delta T}{h} + \int_0^x Ky(x-u)du = 0 \ldots [7]$$

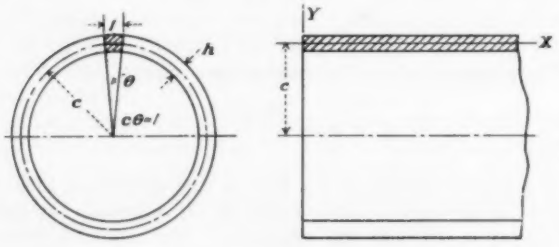

FIG. 3

FIG. 5

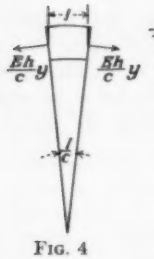

FIG. 4

This equation simply states the law of statics that the sum of moments acting about the point x must be zero. Differentiating this with respect to x:

$$\frac{EI}{1-\mu^2}\frac{d^3y}{dx^3} + \int_0^x Kydx = 0 \quad \ldots\ldots\ldots\ldots [8]$$

Differentiating again:

$$\frac{EI}{1-\mu^2}\frac{d^4y}{dx^4} + Ky = 0 \quad \ldots\ldots\ldots\ldots [9][5]$$

These equations describe a beam on an elastic foundation bent by moments $\frac{EI}{1-\mu}\frac{a\,\Delta T}{h}$ acting on the ends. The solution is:

$$y = e^{\beta x}(C_1 \cos \beta x + C_2 \sin \beta x) + e^{-\beta x}(C_3 \cos \beta x + C_4 \sin \beta x)$$

where $\beta = \sqrt[4]{\frac{K(1-\mu^2)}{4EI}} = \sqrt[4]{\frac{3(1-\mu^2)}{h^2c^2}}$, and C_1, C_2, etc., are constants of integration.

We may dispose of two of these constants at once. As we move away from the ends of the cylinder the deflection of the wall, produced by a moment on the end, should decrease, and when x is large, should be practically zero. Under no circumstances could it show the rapid increase produced by the terms multiplied by $e^{\beta x}$. Therefore we reason: $C_1 = C_2 = 0$. The deflection curve then takes the form:

$$y = e^{-\beta x}(C_3 \cos \beta x + C_4 \sin \beta x) \quad \ldots\ldots\ldots [10]$$

The analysis is valid for a cylinder of any length up to Equation [10]. In placing C_1 and C_2 equal to zero it was assumed that the cylinder was long enough to permit the deflection and slope of the wall to become practically zero at the middle. Specific examples will show what this length must be, but in general a distance equal to $2\pi/\beta$, which is the wave length of the harmonic form assumed by y will be sufficient.

To evaluate the constants C_3 and C_4, we may compute from [10] the values of d^2y/dx^2 and d^3y/dx^3 for $x = 0$ and substitute them in Equations [7] and [8]. By differentiation we find:

$$\frac{d^2y}{dx^2}_{(x=0)} = -2\beta^2 C_4$$

Placing $x = 0$ in [7] and substituting this value for d^2y/dx^2

$$C_4 = -\frac{1+\mu}{2\beta^2}\frac{a\,\Delta T}{h}$$

By differentiation again, we obtain:

$$\frac{d^3y}{dx^3}_{(x=0)} = 2\beta^3(C_3 + C_4)$$

and from Equation [8]:

$$C_3 = \frac{1+\mu}{2\beta^2}\frac{a\,\Delta T}{h}$$

Putting these values in [10],

$$y = \frac{1+\mu}{2\beta^2}\frac{a\,\Delta T}{h}e^{-\beta x}(\cos \beta x - \sin \beta x) = \frac{1+\mu}{2\beta^2}\frac{a\,\Delta T}{h}\psi \quad [11]$$

where $\psi = e^{-\beta x}(\cos \beta x - \sin \beta x)$

and:

$$\frac{d^2y}{dx^2} = (1+\mu)\frac{a\,\Delta T}{h}\phi \quad \ldots\ldots\ldots\ldots [12]$$

where $\phi = e^{-\beta x}(\cos \beta x + \sin \beta x)$.

As noted above, $l/2$ is assumed large enough to permit the effect of the moment on the ends to disappear at the middle of the cylinder. When both ends of the cylinder are free, the deflection, moment, stresses, etc., are symmetrical about the point $x = l/2$.

The axial stress in the shell owing to the deflection y is:

$$\sigma_x' = -\frac{M\eta}{I}$$

We may substitute in this the value of M from Equation [6], and of d^2y/dx^2 from [12], giving

$$\sigma_x' = -\frac{Ea\,\Delta T}{1-\mu}\frac{\eta}{h}\phi$$

To find the tangential stresses produced by the deflection we note that $e_t = y/c$, where e_t is the unit tangential deformation. From Hooke's law,

$$e_t = \frac{1}{E}(\sigma_t' - \mu\,\sigma_x')$$

[5] An alternate derivation of this formula is given in Appendix No. 2.

Substituting the values of y and σ_x':

$$\sigma_t' = \frac{Ea\,\Delta T}{h(1-\mu)}\left[\frac{1-\mu^2}{2\beta^2 c}\,\psi - \eta\mu\phi\right]$$

These stresses are due to the deflection y alone. We may now refer to Equation [4] and superpose the stresses existing in the shell owing to the temperature gradient to obtain the complete expressions for the stresses in a cylindrical shell, heated in the manner assumed and having ends free from external forces:

$$\sigma_x = \frac{Ea\,\Delta T}{1-\mu}\,\frac{\eta}{h}\,(1-\phi) \qquad [13]$$

$$\sigma_t = \frac{Ea\,\Delta T}{1-\mu}\,\frac{\eta}{h}\left[1 - \mu\phi + \frac{1-\mu^2}{2\beta^2 c\eta}\,\psi\right] \qquad [14]$$

Since $\phi = 1$ for $x = 0$, this expression for σ_x satisfies the condition of free ends. When $\eta = h/2$

$$\sigma_x = \frac{Ea\,\Delta T}{2(1-\mu)}\,(1-\phi)$$

$$\sigma_t = \frac{Ea\,\Delta T}{2(1-\mu)}\left[1 - \mu\phi + \frac{1-\mu^2}{\beta^2 hc}\,\psi\right]$$

when $x = 0$, max. $\sigma_t = \dfrac{Ea\,\Delta T}{2}\left(1 + \dfrac{1+\mu}{\sqrt{3(1-\mu^2)}}\right)$ [15]

when x is large, $\phi = \psi = 0$, and

$$\sigma_x = \sigma_t = \frac{Ea\,\Delta T}{2(1-\mu)} \qquad [4]$$

It may be shown in the usual way that the maximum value of σ_t occurs when $x = 0$ and $\eta = h/2$. The absolute value is less for $\eta = -h/2$.

If we assume $\mu = 0.25$, we may compare the value of σ_t at the ends with that for the region near the middle. Equation [4] then gives for the exterior surface, when x is large:

$$\sigma_t = \frac{Ea\,\Delta T}{2}\,(1.333)$$

For a similar point at the ends, Equation [15] gives:

$$\text{max. } \sigma_t = \frac{Ea\,\Delta T}{2}\,(1.744)$$

The peak stress at the ends is thus 30 per cent higher than the value near the middle.

The maximum value of σ_x occurs at $x = \pi/\beta$. Since the minimum value of $\phi = -0.043$, by referring to Fig. 17, the maximum axial stress will be only 4 per cent above the value given by Equation [4].

Example 1. As an illustration of the preceding section, assume a cast-iron cylinder of 20 in. mean diameter, 1 in. thickness, and 30 in. length. Let the inside temperature be 100 deg. fahr. above the outside. Other constants are:

$E = 15 \times 10^6$ lb. per sq. in. $\quad a = 6 \times 10^{-6}$ in. per in. per deg. fahr.

$\mu = 0.25$ $\quad \beta = \sqrt[4]{\dfrac{3(1-\mu^2)}{h^2c^2}} = 0.41$ in.$^{-1}$

The deflection at the ends is:

$$\text{max. } y = \frac{1+\mu}{2\beta^2}\,\frac{a\,\Delta T}{h} = 2.23 \times 10^{-3} \text{ in.}$$

The tangential and axial stresses away from the ends are given by Equation [4] and are: $\sigma_x = \sigma_t = \dfrac{Ea\,\Delta T}{2(1-\mu)} = 6000$ lb. per sq. in. tension and compression on the outer and inner surfaces, respectively. A formula[6] taking into account the true logarithmic temperature distribution in the cylinder walls and applying only to the portion distant from the ends gives, at the outer surface, $\sigma_t = \sigma_x = 5990$ lb. per sq. in.; and at the inner surface, $\sigma_t = \sigma_x = -6100$ lb. per sq. in. Thus for a ratio of $h/c = 0.1$, Equation [4] is very accurate.

The maximum tangential stress is:

$$\text{max. } \sigma_t = \frac{Ea\,\Delta T}{2}\left(1 + \frac{1+\mu}{\sqrt{3(1-\mu^2)}}\right) = 7850 \text{ lb. per sq. in.}$$

tension on the outer surface at the ends. The maximum axial stress occurs at $\pi/\beta = 7.67$ in. from each end, and its value is:

$$\text{max. } \sigma_x = 6270 \text{ lb. per sq. in.}$$

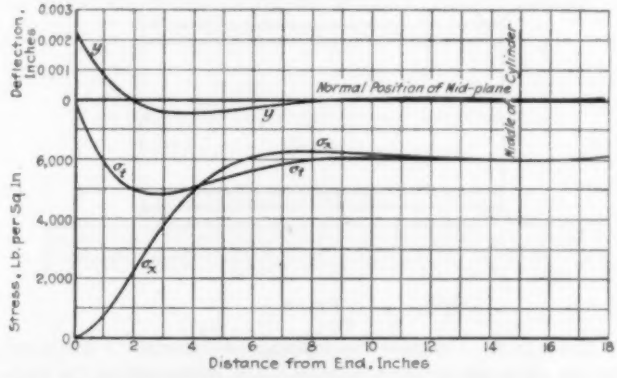

FIG. 6 TENSION IN OUTER FIBERS OF HOLLOW CAST-IRON CYLINDER (Length, 30 in.; diameter, 20 in.; thickness, 1 in. Temperature of internal surface, 100 deg. fahr.; of external surface, 0 deg. fahr.)

Fig. 6 shows the deflection of the cylinder wall from its normal position, and the variation in the tangential and axial stresses in the outer surface over one-half the length of the cylinder.

EFFECT OF CYLINDER HEADS OR OTHER END CONNECTIONS

An advantage of the method given is that it lends itself particularly well to the solution of the problem of the cylinder with end connections or cylinder heads exerting moments and loads on the ends and subjected at the same time to temperature gradients.

Let us again assume the cylindrical shell at a uniform temperature and with the moments and loads M_0 and q_0 per unit of circumference applied at the ends. A unit strip of this shell

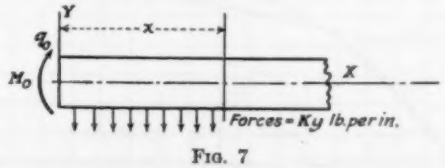

FIG. 7

will then be loaded as in Fig. 7. Equation [10] gives the deflection curve. Evaluating the constants for the end conditions in this case, we have:

$$C_3 = \frac{1-\mu^2}{2\beta^2 EI}\left(M_0 + \frac{q_0}{\beta}\right); \qquad C_4 = -\frac{1-\mu^2}{EI}\,\frac{M_0}{2\beta^2}$$

[6] Timoshenko, p. 554.

and:

$$y = \frac{1-\mu^2}{EI}\frac{1}{2\beta^2}\left(M_0\psi + \frac{q_0}{\beta}\theta\right) \quad \ldots\ldots [16]$$

where, $\theta = e^{-\beta x}\cos\beta x$

From [16] we find:

$$\sigma_x = -\frac{12\eta}{h^3}\left(M_0\phi + \frac{q_0}{\beta}\alpha\right) \quad \ldots\ldots [17]$$

where $\alpha = e^{-\beta x}\sin\beta x$, and

$$\sigma_t = \frac{Ey}{C} + \mu\sigma_x \quad \ldots\ldots [18]$$

On these results will be superposed those in Equations [11], [13], and [14] to obtain the effects of a moment and load M_0 and q_0 combined with temperature difference.

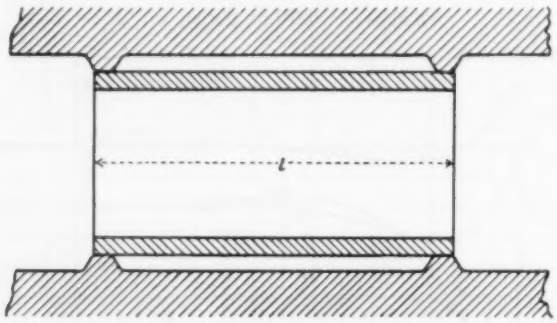

FIG. 8

Example 2. Consider the cylinder of Example 1 subjected to the same temperature difference but supported at the ends as in Fig. 8. Let these supports be sufficiently rigid that we may consider the deflection zero at the ends. Since there is no external moment at the ends, the load q_0 is determined from the fact that the sum of the deflections at the point $x = 0$ given by Equations [11] and [16] is zero:

$$0 = \frac{1+\mu}{2\beta^2}\frac{a\Delta T}{h} + \frac{1-\mu^2}{EI}\frac{q_0}{2\beta^3}$$

and

$$q_0 = -\frac{EI}{1-\mu}\beta\frac{a\Delta T}{h} = -410 \text{ lb. per in. of circumference}$$

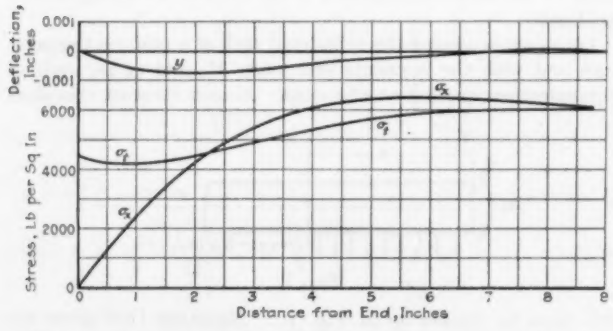

FIG. 9 TENSION IN OUTER FIBERS OF CYLINDER OF FIG. 6 SUPPORTED AS IN FIG. 8

To obtain the complete results for this case we may superpose on the curves of Fig. 6 the results of Equations [16], [17], and [18], in which $M_0 = 0$, and $q_0 = -410$ lb. per in. Fig. 9 shows the deflection and stresses produced in the cylinder walls.

Far from the ends the stresses are the same as those in Fig. 6. At the ends, however, the tangential stress has been reduced by the supports from a maximum of 7850 lb. per sq. in. in Fig. 6 to 4500 lb. per sq. in. in Fig. 9. This reduction depends only on the value of μ, and amounts to 42.7 per cent for $\mu = 0.25$.

Example 3. Assume a steel cylinder of the same dimensions as the cast iron one of Example 1 and heated in the same manner. In addition let it be subjected to an internal pressure of 500 lb. per sq. in. and fitted with flat heads rigidly attached to the walls. The heads are of the same material but h_1 in. thick. The temperature gradient is assumed to exist in the heads as well as the walls. The constants are:

$E = 30 \times 10^6$ lb. per sq. in. $\quad h = 1$ in.
$a = 6.7 \times 10^{-6}$ in. per in. per deg. fahr. $\quad h_1 = 1.5$ in.
$\mu = 0.3$
$\beta = 0.407$ in.$^{-1}$

The deflection and stresses in the cylinder walls owing to the moment and shear at the ends produced by the heads are given in Equations [16], [17], and [18]. To these must be added the effects of the internal pressure, p lb. per sq. in., which produces a constant deflection pc^2/Eh. It increases the axial stress by an amount $pc/2h$, and the tangential stress by double this value. The deflection and stresses due to the temperature gradient may be taken from Equations [11], [13], and [14].

M_0 and q_0 are determined from a consideration of the cylinder head for which the axes are taken as in Fig. 10. The moment

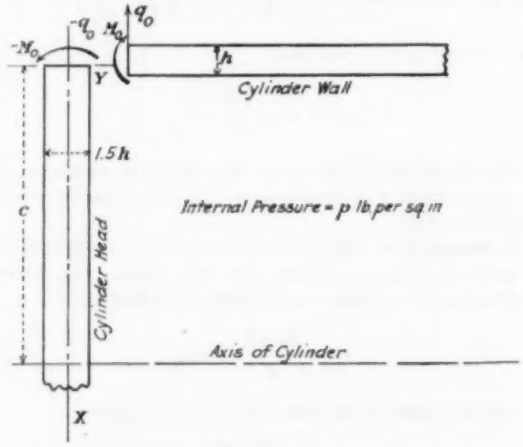

FIG. 10

and load at the edges are equal and opposite to those acting on the wall. The formulas applying to the head, which is treated as a thin plate, may be taken directly from textbooks covering this subject. The extension of the radius of the plate produced by the load $-q$ is $-\frac{q_0 c}{Eh_1}(1-\mu)$, which must be equal to the deflection of the walls at the end when the two are brought together. The wall deflection is given by Equations [11] and [16] plus pc^2/Eh. Equating these two expressions:

$$\frac{1+\mu}{2\beta^2}\frac{a\Delta T}{h} + \frac{pc^2}{Eh} + \frac{1-\mu^2}{EI}\frac{1}{2\beta^3}\left(M_0 + \frac{q_0}{\beta}\right) = -\frac{q_0 c}{Eh_1}(1-\mu) \quad \ldots\ldots [a]$$

The slope of the cylinder head will be influenced by three factors: the internal pressure; the temperature difference; and the moment $-M_0$ at the edges. The slope at the edges owing to the internal pressure is:

$$-\frac{3pc^3(1-\mu)}{2Eh_1^3}$$

That due to the moment is

$$\frac{12\,M_0 c}{Eh_1^3}(1-\mu)$$

That due to the temperature gradient may be determined from the radius of curvature of a thin plate as given in Equation [2] and is: $\frac{a\Delta T}{h_1}c$. The slope of the wall at the ends is determined from the slope of Equations [11] and [16], when $x = 0$:

$$\frac{dy}{dx_{(x=0)}} = -\frac{1-\mu^2}{EI}\frac{1}{2\beta^2}(2\beta M_0 + q_0) - \frac{1+\mu}{\beta}\frac{a\Delta T}{h}$$

When joined, the slope of the wall and the head will be the same:

$$-\frac{1-\mu^2}{EI}\frac{1}{2\beta^2}(2\beta M_0 + q_0) - \frac{1+\mu}{\beta}\frac{a\Delta T}{h} = -\frac{3pc^2(1-\mu)}{2Eh_1^2} + \frac{12M_0 c}{Eh_1^3}(1-\mu) + \frac{a\Delta T}{h_1}c \quad \ldots\ldots [b]$$

Equations [a] and [b] determine M_0 and q_0 as follows:

M_0 = 180 lb-in. per inch of circumference.
q_0 = —1590 lb. per inch of circumference.

These values substituted in Equations [17] and [18] give the stresses in the wall resulting from the moment and shear produced by the head.

On these results we must superpose the deflection and stresses produced by the internal pressure as well as those resulting from the temperature gradient as given by Equations [11], [13], and [14]. The totals are:

$$y = \frac{1-\mu^2}{EI}\frac{1}{2\beta^3}(180\psi - 3880\theta) + \frac{1+\mu}{2\beta^3}\frac{a\Delta T}{h}\psi + \frac{pc^2}{Eh}$$

$$\sigma_x = \frac{Ea\Delta T}{1-\mu}\frac{\eta}{h}(1-\phi) - \frac{12\eta}{h^3}(180\theta + 3880\psi) + \frac{pc}{2h}$$

$$\sigma_t = Ea\Delta T\frac{\eta}{h} + E\frac{y}{c} + \mu\left(\sigma_x - \frac{pc}{2h}\right)$$

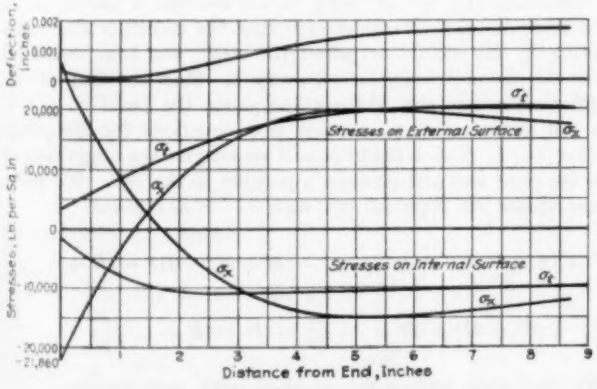

FIG. 11 CYLINDER WALL OF EXAMPLE 3

Fig. 11 shows the deflection of the cylinder wall and the stresses on the exterior and interior surfaces. For the plate, the effect of the internal pressure must be added to that of the moment and shear at the edges. The tensile stress along any radius of the outer surface is given by:

$$\sigma_r = {}^3/_4\frac{p}{h_1^2}(3+\mu)(2cx - x^2) - \frac{6M_0}{h_1^2} - \frac{q_0}{h_1}$$

Fig. 12 shows the deflection and tensile stress along a radius of the outer surface of the cylinder head.

VARIABLE TEMPERATURE GRADIENT IN RADIAL DIRECTION

Assume now that a hollow cylinder of the form we have been considering is heated in such a manner that its temperature gradient in the radial direction varies along its length. As the cylinder walls are assumed thin, this gradient still remains linear. In order to prevent deflection of the mid-plane of the cylinder its temperature must remain at a constant value which

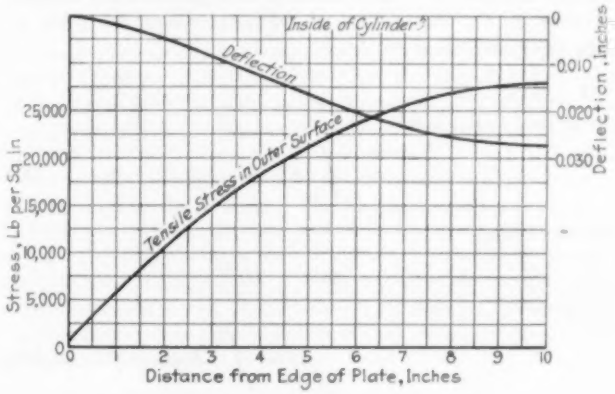

FIG. 12 CYLINDER HEAD, EXAMPLE 3

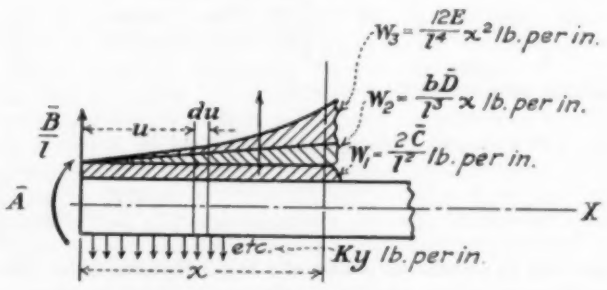

FIG. 13

we may take as zero. Let the temperature of the interior be given by the power series:

$$T_i = \frac{1}{2}\left[A + B\frac{x}{l} + C\frac{x^2}{l^2} + D\frac{x^3}{l^3} + E\frac{x^4}{l^4} + \ldots\right] \quad \ldots [19]$$

where A, B, etc., are constants.

Then the temperature of the exterior at any value of x is equal to $-T_i$. The temperature difference between the two surfaces is $2T_i$. This difference produces the curvature of the element shown in Fig. 1, and the radius of curvature is found, as in Equation [2], to be:

$$\frac{1}{r} = \frac{2aT_i}{h}$$

Obviously this curvature is not now a constant in the X-direction. If the unit strip of Fig. 3 were bent by moments and loads to the form described by this equation, its internal moment at any point x would be:

$$M_x = \frac{EI}{1-\mu}\frac{1}{r} = \frac{EI}{1-\mu}\frac{a}{h}\left[A + B\frac{x}{l} + C\frac{x^2}{l^2} + \ldots\right]$$

allowing no change in the angle θ, Fig. 3. To remove the curvature in the X-direction will require application of moments

and loads equal and opposite to those which produced the internal moment M_x. The moment at the ends is $M_{x(x=0)} = \overline{A}$, where $\overline{A}$ is written for $-\frac{EI}{1-\mu}\frac{a}{h}A$; the load at the end is $\frac{dM_x}{dx_{(x=0)}} = \frac{\overline{B}}{l}$; the distributed load is $\frac{d^3M_x}{dx^3} = 2\frac{\overline{C}}{l^2} + \frac{6\overline{D}}{l^3}x + \ldots$ pounds per unit length. The sum of these separate moments and loads represents the total forces acting on the strip. Fig. 13 shows these forces, remembering that all the loads have a minus sign, and that the number of distributed loads depends on the number of terms in T_i. Summation of moments about the point x, as in Equation [7], gives:

$$\frac{EI}{1-\mu^2}\frac{d^2y}{dx^2} - \frac{EI}{1-\mu}\frac{a}{h}\left(A + B\frac{x}{l} + C\frac{x^2}{l^2} + \ldots\right) + \int_0^x Ky\,(x-u)\,du = 0 \quad \ldots\ldots [20]$$

Differentiating,

$$\frac{EI}{1-\mu^2}\frac{d^3y}{dx^3} - \frac{EI}{1-\mu}\frac{a}{h}\left(\frac{B}{l} + \frac{2Cx}{l^2} + \frac{3Dx^2}{l^3} + \ldots\right) + \int_0^x Ky\,dx = 0 \quad \ldots\ldots [21]$$

Differentiating again and transposing,

$$\frac{EI}{1-\mu^2}\frac{d^4y}{dx^4} + Ky = \frac{EI}{1-\mu}\frac{a}{h}\left[\frac{2C}{l^2} + \frac{6D}{l^3}x + \frac{12E}{l^4}x^2 + \ldots\right]$$

Solving, after setting $C_1 = C_2 = 0$,

$$y = e^{-\beta x}(C_3\cos\beta x + C_4\sin\beta x) + \frac{ahc^2}{12(1-\mu)}\left[\frac{2C}{l^2} + \frac{6D}{l^3}x + \frac{12E}{l^4}x^2 + \ldots\right]$$

provided T_i contains no powers of x higher than the fifth. The modification of this solution to take care of higher powers of x is easily made. Let us assume that T_i is limited to the first four terms of Equation [19] and obtain expressions for the stresses produced. Then:

$$\frac{d^2y}{dx^2_{(x=0)}} = -2\beta^2C_4$$

From [20], when $x = 0$,

$$-\frac{EI}{1-\mu^2}2\beta^2C_4 - \frac{EI}{1-\mu}\frac{a}{h}A = 0$$

$$C_4 = -\frac{1+\mu}{2\beta^2}\frac{a}{h}A$$

$$\frac{d^3y}{dx^3_{(x=0)}} = 2\beta^3(C_3 + C_4)$$

and from [21]:

$$C_3 = \frac{1+\mu}{2\beta^2}\frac{a}{h}\left(A + \frac{B}{\beta l}\right)$$

Then

$$y = \frac{1+\mu}{2\beta^2}\frac{a}{h}\left[\left(A + \frac{B}{\beta l}\right)\theta - A\alpha\right] + \frac{ahc^2}{12(1-\mu)}\left[\frac{2C}{l^2} + \frac{6D}{l^3}\right] \quad \ldots\ldots [22]$$

$$\frac{d^2y}{dx^2} = (1+\mu)\frac{a}{h}\left[\left(A + \frac{B}{\beta l}\right)\alpha + A\theta\right]$$

$$\sigma_x' = -\frac{Ea}{1-\mu}\frac{\eta}{h}\left[\left(A + \frac{B}{\beta l}\right)\alpha + A\theta\right] \quad \ldots\ldots [23]$$

$$\sigma_t' = \frac{Ey}{C} + \mu\sigma_x \quad \ldots\ldots [24]$$

To these stresses produced by the deflection y must be added those due to the temperature difference which are given by substituting $2T_i$ for ΔT in Equation [4]:

$$\frac{Ea}{1-\mu}\frac{\eta}{h}\left(A + B\frac{x}{l} + C\frac{x^2}{l^2} + D\frac{x^3}{l^3}\right) \quad \ldots\ldots [25]$$

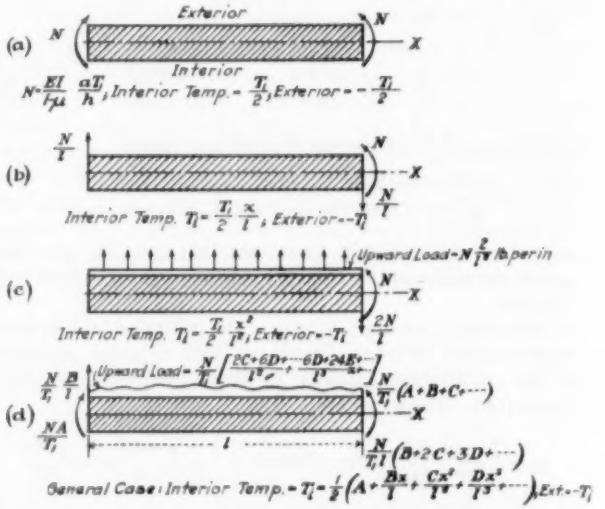

FIG. 14 MOMENTS AND LOADS ON SECTION OF CYLINDER WALL, 1 UNIT WIDE, PRODUCED BY THERMAL STRESSES. TEMPERATURE OF MID-PLANE = 0 DEG.

(In all cases the elastic foundation damps out deflection and stresses produced by moments and loads on ends before middle of cylinder is reached.)

Equations [19] to [24] apply to the left end of the cylinder. We have assumed l large enough that the moments and loads acting on one end do not affect the other, and have indicated that this distance should be at least $2\pi/\beta$. Since the temperature difference is not now symmetrical about the point $x = l/2$, it will be necessary to develop new equations for the range $l/2 < x < l$. This is easily done if we imagine the origin moved to the right end and measure x positive to the left. We must now replace x in Equation [19] with $(l - x)$ as follows:

$$T = [A + B + C + D + \ldots] - [B + 2C + 3D + 4E + \ldots]\frac{x}{l} + [C' + 3D + 6E + \ldots]\frac{x^2}{l^2} - [D + 4E + \ldots]\frac{x^3}{l^3} + \ldots$$

We may then replace the brackets with new constants, A', B', etc., as:

$$T = [A'] - [B']\frac{x}{l} + [C']\frac{x^2}{l^2} - [D']\frac{x^3}{l^3} + \ldots$$

Equations [20] to [24] might then be rewritten by placing a prime on each of the constants, A, B, etc., and thus apply to the right half of the same cylinder, remembering that x is measured positive toward the left.

A temperature distribution such as has been assumed in this

section would be rarely met with. Its usefulness lies in the fact that it produces no distortion of the mid-plane of the cylinder. We may then superpose on this case the stresses caused by a temperature gradient in the axial direction only, obtaining any desired temperature distribution on the two surfaces of the shell, assuming always that it has circular symmetry. Fig. 14 shows the moments and loads applied to secure the condition of free ends for different cases of temperature distribution. These moments and loads produce the deflection y in this section.

Temperature Gradient in Axial Direction Only

Assume again a thin cylindrical shell of elastic material, of mean radius c and of length l. Let the temperature rise be a constant over any cross-section, but vary with the axial coordinate in a manner that may be expressed by the power series:

$$T = \frac{1}{2}\left[A + B\frac{x}{l} + C\frac{x^2}{l^2} + D\frac{x^3}{l^3} + \dots\right] \dots\dots [26]$$

Consider a unit strip cut from this shell as in Fig. 3. Let s_t be the *average* tensile stress in the tangential direction acting on the sides of the strip and y its displacement in the direction of the radius. The unit strain in the circumferential direction is:

$$e_t = \frac{y}{c} = \frac{s_t}{E} + aT$$

Then

$$s_t = \frac{Ey}{c} - EaT$$

The force per unit length of each side of the strip is

$$s_t h = h\left(E\frac{y}{c} - EaT\right)$$

The component of this force in the radial direction per unit length of strip is

$$\frac{s_t h}{c} = \frac{Eh}{c}aT - \frac{Eh}{c^2}y$$

The change of sign indicates that for an outward deflection the force is inward. Referring to Fig. 5, there is now acting in addition to Ky the force $(Eh/c)aT$ per unit length of strip, which is equivalent to a distributed load of that intensity acting on a beam supported by an elastic foundation. The differential equation becomes:

$$\frac{EI}{1-\mu^2}\frac{d^4y}{dx^4} + Ky = \frac{Eh}{c}aT$$

The solution is, as before,

$$y = e^{-\beta x}(C_3\cos\beta x + C_4\sin\beta x) + \frac{ac}{2}\left[\left(A - \frac{6E}{\beta^4 l^4} - \dots\right) + \left(B - \frac{30F}{\beta^4 l^4} - \dots\right)\frac{x}{l} + \left(C - \frac{90G}{\beta^4 l^4} - \dots\right)\frac{x^2}{l^2} + \dots\right.$$

Assume T to be given by the first four terms of the series in Equation [26]. From the condition that the ends are free, we find:

$$\frac{d^2y}{dx^2}_{(x=0)} = 0 = -2\beta^2 C_4 + \frac{ac}{2}\frac{2C}{l^2}. \qquad C_4 = \frac{ac}{2}\frac{C}{\beta^2 l^2}$$

$$\frac{d^3y}{dx^3}_{(x=0)} = 0 = 2\beta^3(C_3 + C_4) + \frac{ac}{2}\frac{6D}{l^3}. \quad C_3 = -\frac{ac}{2\beta^3 l^3}(\beta lC - 3D)$$

$$y = \frac{ac}{2}\left[A + B\frac{x}{l} + C\frac{x^2}{l^2} + D\frac{x^3}{l^3} + \frac{3D - \beta lC}{\beta^2 l^2}\theta + \frac{C}{\beta^2 l^2}\alpha\right]. \quad [27]$$

$$\frac{d^2y}{dx^2} = ac\left[\frac{C}{l^2}(1-\phi) + \frac{3D}{\beta l^3}(\beta x + \alpha)\right]$$

$$\sigma_x = \frac{Eac}{1-\mu^2}\eta\left[\frac{C}{l^2}(\phi - 1) - \frac{3D}{\beta l^3}(\beta x + \alpha)\right] \dots\dots [28]$$

$$\sigma_t = \frac{Ea}{2}\left[\frac{3D - \beta lC}{\beta^2 l^2}\theta + \frac{C}{\beta^2 l^2}\alpha\right] + \mu\sigma_x \dots\dots [29]$$

No stresses result from temperature gradients in this direction unless Equation [26] includes at least the second power of x. If no terms above the third power of x are present, the deflection curve away from the ends is the normal expansion curve of the cylinder wall for the temperature rise assumed.

As in the preceding section, these equations apply only to the left end of the cylinder. For the right end we must again use the constants A', B', etc., and measure x positive to the left.

By combining this case with the preceding one we may arrive at the desired distribution. There may also be superposed on these the effect of end connections or of pressure. Stresses due to gradients in the axial direction will be small, except in cases of localized heating as in welding.

Interior Temperature a Linear Function of x

Let us now consider cases in which a variable temperature gradient exists in the radial direction accompanied by a gradient along the mid-plane of the cylinder in the X-direction. These will be solved by superposing the solutions already obtained in these two cases. Assume the external temperature of the cylindrical shell to be kept at zero and the interior to be held at a value: $T_i = T_1 x/l$. In Equation [19], $B = T_1$; all other constants are zero. In Equation [26], the temperature along the midplane is: $T = (T_1/2)x/l$, so that $B = T_1$ in this equation also, and other constants are zero. Substitute these values of the constants in Equations [22] and [27], which may then be added to give:

$$y = \frac{1+\mu}{2\beta^2}\frac{aT_1}{hl}\theta + \frac{acT_1}{2}\frac{x}{l}$$

In the same way, by adding Equations [23], [25], and [28],

$$\sigma_x = \frac{EaT_1}{1-\mu}\frac{\eta}{h\beta l}(\beta x - \alpha)$$

And by adding [24], [25], and [29],

$$\sigma_t = \frac{EaT_1}{1-\mu}\frac{\eta}{h\beta l}\left(\beta x - \mu\alpha + \frac{1-\mu^2}{2\beta^2 c\eta}\theta\right)$$

These equations apply to the left end of the cylinder. For the right end we must substitute A', B', etc., to obtain:

$$y = \frac{1+\mu}{2\beta^2}\frac{aT_1}{h}\left(\psi - \frac{\theta}{\beta l}\right) + \frac{aT_1}{2}\frac{c}{l}(l - x)$$

$$\sigma_x = \frac{EaT_1}{1-\mu}\frac{\eta}{h}\left(1 - \phi - \frac{\beta x - \alpha}{\beta l}\right)$$

$$\sigma_t = \frac{EaT_1}{1-\mu}\frac{\eta}{h}\left[1 - \frac{x}{l} - \mu\left(\phi - \frac{\alpha}{\beta l}\right) + \frac{1-\mu^2}{2\beta^2 c\eta}\left(\psi - \frac{\theta}{\beta l}\right)\right]$$

When $\eta = h/2$ and $x = l/2$,

$$\sigma_x = \sigma_t = \frac{EaT_1}{4(1-\mu)}$$

This value is necessarily the same as that obtained from the equations derived from the other end.

$$\text{When } x = 0,\ \sigma_x = 0, \text{ and } \sigma_t = \frac{EaT_1}{2}\left[1 + \frac{1+\mu}{\beta^3 hc}\left(1 - \frac{1}{\beta l}\right)\right]$$

We should expect the values of the deflection and tangential stress at the end where $T_i = 0$ to be quite low, as may be shown by an example.

Example 4. In order to compare the result with Example 1 we shall again assume a cylinder of the same material and dimensions, but the internal temperature is to be given by:

$$T_i = T_1 \frac{x}{l}$$

where $T_1 = 100$ deg. fahr., and the external temperature is zero.

The stresses at the middle are, of course, one-half those in

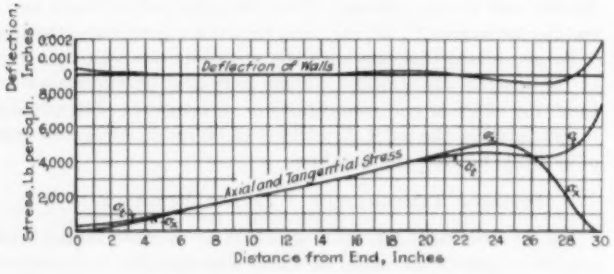

FIG. 15 CYLINDER OF EXAMPLE 4

the first example. The other results will differ at each end. At the end $T_i = 0$,

$$y = \frac{1+\mu}{2\beta^2}\frac{aT_1}{hl} = 0.182 \times 10^{-3} \text{ in.}$$

When $\eta = h/2$,

$$\sigma_t = \frac{EaT_1}{2}\frac{1+\mu}{\beta^3 hcl} = 272 \text{ lb. per sq. in.}$$

At the end $T_i = T_1$,

$$y = \frac{1+\mu}{2\beta^2}\frac{aT_1}{h}\left(1 - \frac{1}{\beta l}\right) = 2.05 \times 10^{-3} \text{ in.}$$

When $\eta = h/2$,

$$\sigma_t = \frac{EaT_1}{2}\left[1 + \frac{1+\mu}{3^3 hc}\left(1 - \frac{1}{\beta l}\right)\right] = 7575 \text{ lb. per sq. in.}$$

Fig. 15 shows graphically the stresses and deflection in this case.

INTERIOR TEMPERATURE A FUNCTION OF x^2

If in Equation [19] we place $C = T_1$ and all other constants equal to zero, we come to the case of parabolic distribution of the internal temperature in the direction of the axis. In Equation [26], if the temperature along the mid-plane is $T = T_1 x^2/l^2$, which makes $C = T_1$, and all other constants zero, we bring the exterior temperature to zero and the interior becomes $2T_i$.

After substituting these values for the constants we add Equations [22] and [27]:

$$y = \frac{aT_1}{1-\mu}\frac{hc^2}{6l^2} + \frac{aT_1 c}{2\beta^2 l^2}(\beta^2 x^2 - \psi)$$

Adding [23], [25], and [28],

$$\sigma_s = \frac{EaT_1}{1-\mu}\frac{\eta}{h}\frac{1}{l^2}\left(x^2 + \frac{hc}{1-\mu}(1-\phi)\right)$$

And from [24], [25], and [29],

$$\sigma_t = \frac{EaT_1}{1-\mu}\frac{\eta}{h}\frac{1}{l^2}\left[x^2 + \frac{h^2 c}{6\eta} - \frac{h\psi}{2\beta^2\eta}(1-\mu) + \mu hc(\phi - 1)\right]$$

By substitution of the values of the constants applying to the right end of the cylinder we obtain the equations for stress and deflection in this part. In general, the curves of deflection and stresses will be similar to those in Fig. 15, except that the stress curve connecting the two end portions now becomes a parabola instead of a straight line.

CASES INVOLVING VARIATIONS OF PREVIOUS METHODS

Cases of sudden changes in wall thickness may be investigated in the same way as this problem is handled in the ordinary beam. The strip is cut at the point of change of section and a moment and shear assumed at each of the cut ends. The magnitude of these is then determined by the conditions of continuity at the junction. For a slightly tapering wall thickness an average value may be assumed, since the wall thickness plays only a small part in determining the stress.

A sudden change in the form of the function describing the interior temperature T_i might be handled in the same way.[7] Usually such changes in the interior temperature will not occur suddenly, but merge into each other gradually, which requires no special treatment of the junction unless one portion be shorter than the half-wave-length, π/β.

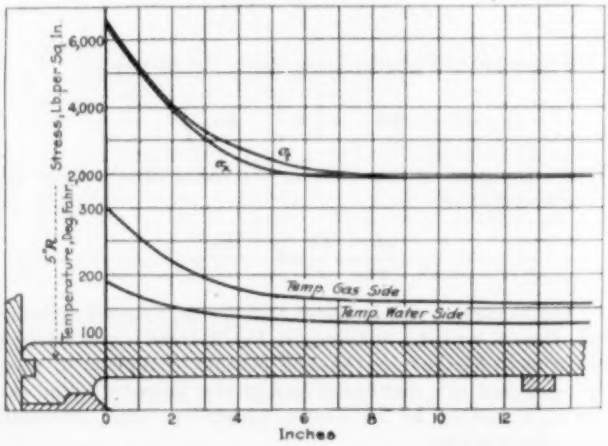

FIG. 16 TEMPERATURE AND STRESSES IN CYLINDER LINER—EXAMPLE 5

An example of this kind occurs in the cylinder liner of a Diesel engine. Near the combustion end the temperature of both the gas and water side are represented by equations of the second degree for distances of one-third to one-half the stroke. From this point on the curves become linear with a slight downward slope. Dr. Eichelberg (11) calculated these curves from a consideration of heat flow within the cylinder and later verified them by means of thermocouples embedded in the walls. Dr. Letson (12) also made experimental determinations of the temperature distribution in a liner, which agree with those of Dr. Eichelberg. Of course the maximum temperatures reached are far from being the same since these depend on the type of engine investigated, but the shape of the curves on both the gas and water sides were very similar.

Example 5. Fig. 16 shows a portion of a cylinder liner with temperature curves for the two surfaces as determined in the

[7] Timoshenko and Lessells, "Applied Elasticity," p. 146.

experiments referred to. At the upper end the liner is pressed into its casing which is assumed to exert a moment and shear sufficient to bring the slope and deflection of the liner to zero at this point. At other points the liner is simply supported, no moment being exerted. The material is cast iron and the dimensions are: mean diameter, 10 in.; thickness, 1 in.; complete length, possibly 25 to 30 in. The temperature of the liner on the gas side is given by

$$T_g = 300 - 50x + 5x^2$$

and on the water side by

$$T_w = 190 - 20x + 1.8x^2$$

The moment equation becomes, for the region between $0 < x < 7$:

$$\frac{EI}{1-\mu^2}\frac{d^2y}{dx^2} + \int_0^x Ky(x-\mu)d\mu + M_0 + q_0 x = \frac{EI}{1-\mu}\frac{a}{h}(T_g - T_w)$$

The solution of this equation yields the following results:

M_0 = 1004 lb. in. per in. of circumference.
q_0 = —294 lb. in. per in. of circumference.
y = $0.1066(1-\phi)10^{-3}$ in.

For $\eta = h/2$,

$$\sigma_x = 60(110 - 30x + 3.2x^2) - 191.2\psi$$
$$\sigma_t = 60(110 - 30x + 3.2x^2) + 319.8(1-\phi) - 47.8\psi$$

The temperature of the mid-plane in this case will be, $T = 55 - 15x + 1.6x^2$. Stresses resulting from the distortion of this plane will be

$$\sigma_x = 2\frac{Eac}{1-\mu^2}\eta\left[\frac{1.6}{l^2}(\phi - 1)\right]$$

$$\sigma_t = Ea\frac{1.6}{\beta^2 l^2}\alpha + \mu\sigma_x$$

The maximum value of σ_x in the above equations is —75 lb. per sq. in. in this example, and for σ_t is 36 lb. per sq. in. The effect of the distortion of the mid-plane on stresses in this case is therefore small.

Beyond the point $x = 7$ the temperature curve becomes a straight line, and its downward slope is so small that it may be neglected. The stress in this portion is then given by $Ea(T_g - T_w)/2(1-\mu)$, which corresponds with the value of σ_x taken from the equation above for the point $x = 6$. In the stress curves of Fig. 16 it is noted that σ_t is slightly higher for this value of x, which is owing to the effect of the constant deflection produced by the parabolic temperature distribution.

Because of the effect of the moment and shear at the end in limiting the deflection, the maximum stress in this case is only 150 lb. per sq. in. above that calculated by the usual formulas applying to long cylinders with temperature varying only in the radial direction. Example 2 indicated similar results. The general effect of such moments and shears is, of course, to approximate the conditions of a long cylinder, but whatever the value of external forces or moments applied, the method developed in this paper enables the resulting stresses to be easily calculated.

Appendix No. 1

FROM the curves of Figs. 17 and 18 may be taken the values of the expressions represented by ϕ, ψ, θ, and α, which are required for the calculation of stresses and deflection of the cylinder wall. The derivatives of these functions are required in many calculations and are given below.

$$\frac{d\theta}{dx} = -\beta\phi; \quad \frac{d\alpha}{dx} = \beta\psi; \quad \frac{d\phi}{dx} = -2\beta\alpha; \quad \frac{d\psi}{dx} = -2\beta\theta$$

$$\frac{d^2\theta}{dx^2} = 2\beta^2\alpha; \quad \frac{d^2\alpha}{dx^2} = -2\beta^2\theta; \quad \frac{d^2\phi}{dx^2} = -2\beta^2\psi; \quad \frac{d^2\psi}{dx^2} = 2\beta^2\phi$$

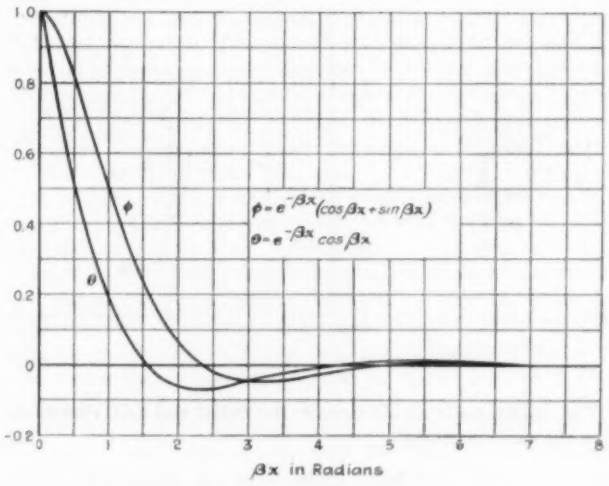

FIG. 17 VALUES OF THE FUNCTIONS ϕ AND θ

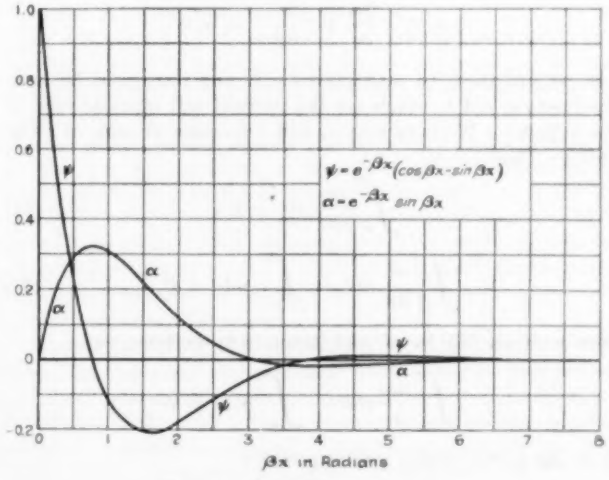

FIG. 18 VALUES OF ψ AND α

Appendix No. 2

ALTERNATE DERIVATION OF FORMULA [9]

Fig. 2(*a*) shows a portion of a thin cylinder which is assumed to be infinitely long. Its internal surface is held at the constant temperature T_1 while the outside is kept at zero. The resulting axial and tangential stresses are the same as those in a thin plate, similarly heated and not allowed to bend, that is, $\frac{EaT_1}{1-\mu}\frac{\eta}{h}$. We note that at the ends of the portion assumed, the axial stresses are such as to produce a moment whose value is $\frac{EI}{1-\mu}\frac{aT_1}{h}$. If we wish to investigate a cylinder of finite length we can produce a condition of free ends by imagining a moment of opposite direction applied to them as in Fig. 2(*b*). The stresses pro-

duced by this moment may then be added to those already existing.

To investigate the stresses produced by a moment acting on the ends of such a cylinder, we assume an infinitesimal parallelopiped cut from its wall as in Fig. 19. In this figure the expression $\sigma_r + \ldots$ is an abbreviation for $\sigma_r + \frac{\partial \sigma_r}{\partial r} dr$, and similarly for the stresses σ_x and τ.

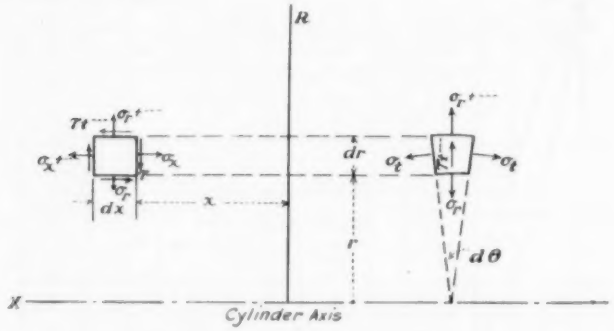

FIG. 19

The conditions of equilibrium in the radial and axial directions give the two equations:

$$r \frac{\partial \sigma_x}{\partial x} + r \frac{\partial \tau}{\partial r} + \tau = 0 \ldots\ldots\ldots\ldots [30]$$

$$\sigma_r + r \frac{\partial \sigma_r}{\partial r} + r \frac{\partial \tau}{\partial x} - \sigma_t = 0$$

Let each of these be multiplied by dr and integrated between the limits a and b, which are the internal and external radii of the cylinder. We note that σ_r and τ are zero at each of these limits. Then:

$$\int_a^b \frac{\partial \sigma_x}{\partial x} r dr = 0 \ldots\ldots\ldots\ldots [31]$$

$$\int_a^b \frac{\partial \tau}{\partial x} r dr - \int_a^b \sigma_t dr = 0 \ldots\ldots\ldots [32]$$

Now multiply [30] by rdr and integrate in the same way:

$$\int_a^b \frac{\partial \sigma_x}{\partial x} r^2 dr - \int_a^b \tau r dr = 0$$

Take the partial of this with respect to x:

$$\int_a^b \frac{\partial^2 \sigma_x}{\partial x^2} r^2 dr - \int_a^b \frac{\partial \tau}{\partial x} r dr = 0$$

and from [32] we have

$$\int_a^b \frac{\partial^2 \sigma_x}{\partial x^2} r^2 dr = \int_a^b \sigma_t dr \ldots\ldots\ldots [33]$$

Now consider a strip cut from this cylinder as in Fig. 3, whose width is $cd\theta$. The condition that the axial stress over any cross-section of the strip shall form a couple, is:

$$\int_a^b \sigma_x r d\theta dr = 0$$

The agreement of this equation with [31] indicates that this is a possible stress condition. The moment of this couple about any point is:

$$M = - \int_a^b \sigma_x r^2 d\theta dr$$

by choosing a point on the cylinder axis. Then from Equation [33]:

$$\frac{d^2M}{dx^2} = - d\theta \int_a^b \sigma_t dr \ldots\ldots\ldots\ldots [34]$$

Now by geometry $e_t = y/c$, and from the equations expressing Hooke's law for the two-dimensional stress condition,

$$e_t = \frac{\sigma_t}{E'} - \mu \frac{\sigma_x}{E}$$

where e_t is the unit tangential deformation. Then[8]

$$\sigma_t = E \frac{y}{c} + \mu \sigma_x$$

and since

$$\int_a^b \sigma_x dr = 0, \qquad d\theta \int_a^b \sigma_t dr = E \frac{y}{c} d\theta \int_a^b dr = E \frac{y}{c} h d\theta$$

Equation [34] becomes:

$$\frac{d^2M}{dx^2} = - E \frac{y}{c} h d\theta \ldots\ldots\ldots\ldots [35]$$

For the bending of a thin strip, we have[8]

$$M = \frac{EI}{1 - \mu^2} \frac{d^2y}{dx^2}$$

where $I = cd\theta h^3/12$. Then from [35]:

$$\frac{d^4y}{dx^4} + \frac{12(1 - \mu^2)}{h^2c^2} y = 0 \ldots\ldots\ldots\ldots [9]$$

and we have as before:

$$y = e^{-\beta x}(C_3 \cos \beta x + C_4 \sin \beta x)$$

At the ends the shear is zero and the moment is $M_0 = \frac{EI}{1 - \mu} \frac{aT_1}{h}$

By evaluating $\frac{d^2y}{dx^2_{(x=0)}}$ and $\frac{d^3y}{dx^3_{(x=0)}}$, we find $C_3 = - C_4 = \frac{aT_1}{h} \frac{1 + \mu}{2\beta^2}$.

The axial and tangential stresses produced by the application of the moment alone are then found to be

$$\sigma_x' = - \frac{EaT_1}{1 - \mu} \frac{\eta}{h}$$

$$\sigma_t' = \frac{EaT_1}{1 - \mu} \frac{\eta}{h} \left(\frac{1 - \mu^2}{2\beta^2 c \eta} - \mu \right)$$

The total stress in the cylinder walls will be found by adding to these the stress already existing owing to the temperature gradient. This, of course, reduces σ_x to zero at the ends and gives for σ_t, as before,[8]

$$\sigma_t = \frac{EaT_1}{h} \left(\frac{1 + \mu}{2\beta^2 c} + \eta \right)$$

Discussion

J. E. Boyd.[9] Determination of thermal stresses in hollow cylinders is of great importance for the design of modern high-pressure boilers and for internal-combustion engines. Some phases of the problem have been presented before the Society. At the Cleveland meeting, in May, 1924, O. G. C. Dahl gave a paper entitled, "Temperature and Stress Distribution in Hollow Cylinders," Trans., 1924, Vol. 46, pp. 161–208. This paper gives complete derivation of the equations for radial and tangential deformations for constant temperature differences and for temperature which undergoes a sinusoidal variation with time. The approximate theory is given on the assumption of a straight-line temperature gradient, together with the exact theory based on the logarithmic gradient.

[9] Professor of Mechanics, Ohio State University, Columbus, Ohio. Life Mem. A.S.M.E.

Dahl's Equations [71] and [72], on page 179, give the maximum tangential stresses at the inner and outer surfaces, calculated from the logarithmic temperature gradient. These stresses were computed on the assumption of zero axial stress. With axial deformation equal to the tangential deformation, as is found to be the case at some distance from the ends, these equations must be divided by $(1 - \mu)$ to get the true combined stress in either direction. (μ = Poisson's ratio.)

Dahl's paper and the appendix together develop the subject from the beginning. The reader with limited library facilities will find all that he needs for the study of the radial and tangential deformation caused by constant temperature difference between the inner and outer walls. The problem of sinusoidal temperature difference demands considerable training in advanced mathematics.

In addition to the tangential and radial deformations in a tube caused by a difference in temperature between the inner and outer surfaces, there is an axial deformation. If the ends are free to move, the entire tube elongates to a length which corresponds to the temperature approximately midway between the inner and outer surfaces. This temperature of a cylinder of filaments under zero axial stress may be represented by $\bar{t}$. Filaments of temperature $\bar{t}$ have their expansion reduced by shear transmitted from filaments of lower temperature. Unit deformation of a length Δx is calculated by subtracting the actual elongation from the elongation which corresponds with the temperature difference $t - \bar{t}$, and dividing the remainder by the original length Δx. The unit deformation is the change in unit length caused by forces from portions external to the element. Near the ends of an open tube the axial unit deformations are small, as the only external force is the shear over a small area. A plane section near the end, which is normal to the axis under constant temperature, becomes a conical surface when a temperature difference is established between the inner and outer surfaces of the tube. On the other hand, a length Δx at a considerable distance from the free end is subjected to a compressive or tensile force which is equal to the entire shear acting on the element from the end of Δx to the free end of the tube. At a relatively small distance from the end this direct force may produce a deformation in Δx nearly equal to the expansion caused by $t - \bar{t}$. A plane section then remains practically plane, and the unit deformation is given by $a(t - \bar{t})$, in which a is the coefficient of expansion.

For any part of the tube at sufficient distance from the ends to keep plane sections approximately plane when a temperature difference is established between the inner and outer surfaces, the calculation of the axial unit deformation at any position is easily made by elementary calculus. Using the logarithmic temperature gradient, the exact solution gives for the outer surface

$$\delta = at_1\left(\frac{1}{2\log k} - \frac{1}{k^2 - 1}\right) \quad [36]$$

and for the inner surface

$$\delta = at_1\left(\frac{1}{2\log k} - \frac{k^2}{k^2 - 1}\right) \quad [37]$$

in which t_1 is the difference of temperature between the inner and outer surfaces, a is the temperature coefficient, and k is the ratio of the outer radius to the inner radius. Since these expressions for axial unit deformation are exactly the same as the expressions for tangential unit deformation, the resultant unit stress in either direction is found by multiplying Equations [36] and [37] by $\frac{E}{1 - \mu}$ in which μ is Poisson's ratio.

At the outer surface

$$S_t = S_x = \frac{aEt_1}{1 - \mu}\left(\frac{1}{2 \log k} - \frac{1}{k^2 - 1}\right) \ldots\ldots [38]$$

At the inner surface

$$S_t = S_x = \frac{aEt_1}{1 - \mu}\left(\frac{1}{2 \log k} - \frac{k^2}{k^2 - 1}\right) \ldots\ldots [39]$$

in which S_t is the tangential unit stress and S_x is the axial unit stress.

The derivation of these formulas may be found in some advanced textbooks. For instance, the foregoing equations are written in slightly different form as Equations [159] and [160] on page 554 of Timoshenko's "Strength of Materials." These equations are given for the tangential stress, but it is shown below when b is substituted for r in Equation [161] for axial stress, the result is Equation [160], and when a is substituted for r, the result is Equation [159]. These equations then apply for both tangential and normal stress at the surfaces away from the ends.

Incidentally, the writer is not able to check the figures at the top of the second column on the fifth page. He gets 5810 lb. per sq. in. at the outer surface and —6190 lb. per sq. in. at the inner surface, instead of 5990 and —6100 lb. per sq. in. given by the author. In any case the deviation of the actual stress from the approximate value of 6000 lb. per sq. in. obtained from the straight line temperature gradient is little greater than 3 per cent.

Since the equations for the stresses under uniform conditions away from the ends have been well established, the author has attacked the more difficult problem of the stresses at or near the ends. To solve this problem he imagines a longitudinal strip to be separated from the tube by two planes which intersect on the axis and make an angle with each other. When this strip is heated at the inner surface, it bends upward at each end as it would be bent by a positive moment. The solution of the problem consists in finding the negative moment which will bend the strip considered as a beam back to its original straight form.

The author uses the straight-line temperature gradient which has been shown to cause relatively small error for ratio of external radius to internal radius commonly found in practice. The problem is sufficiently difficult with the straight-line gradient; it probably would be impossible if the logarithmic gradient were used. The author has shown ingenuity and skill in setting up the physical equations and in their mathematical solution. The writer was struck by the method for disposing of the constants C_1 and C_2.

As was to be expected from the fact that axial deformation is free at the end, the author finds the axial tension in the outer fibers to begin at zero at the end and gradually increase (Fig. 6). On the other hand, the maximum tangential stress is at the end and is 30 per cent greater than the stress near the middle. The curves of Fig. 6 alone represent a large and important addition to knowledge.

The author has also solved several problems of cylinder heads and other end connections and has investigated problems in which the temperature varies as the first and second powers of x.

Since the writer has lacked time to study these solutions, he must leave their discussion to others.

This paper forms a valuable contribution to the theory of an important practical problem.

Author's Closure

Professor Boyd has shown how it is possible to take the stress equations given by Mr. Dahl applying to a thin disk and adapt them to that portion of a long cylinder not near the ends. In either form the solutions are well known, but in making use of them one must know the limits of their applicability.

The numerical difference which Professor Boyd notes comes from the fact that the author used Equations [154] and [155] on page 553 of Timoshenko's "Strength of Materials," developed particularly for thin-walled cylinders. The results which Professor Boyd obtains take into account both the logarithmic temperature distribution and the radial stress. The error of the method used in the paper is seen to be larger than that given by Equations [154] and [155], but still small enough for practical purposes.

APM-53-14

Jets From Manifold Tubes

By JAKOB KUNZ,[1] URBANA, ILL.

After a brief reference to previous work on the subject, the author develops an expression for the discharge coefficient. He then determines the flow of a sheet of water through a slot of infinitesimal width in the wall of a pipe by means of a variable and a constant discharge coefficient. The slot is then conceived of as a row of separate holes and the flow problem is solved by means of difference equations for a variable and a constant discharge coefficient. A special case is also considered in which the pipe has a hole through its further (closed) end.

AN ANALYSIS of this problem was given by Prof. M. L. Enger and M. I. Levy in the Journal of the American Water Works Association, Vol. 21, No. 5, May, 1929. In what follows the author proposes to carry Professor Enger's investigation a little further, giving a higher approximation, considering special cases, and using difference equations as well as differential equations.

In a tube (Fig. 1) of cross-section A a stream of water enters with an initial velocity v_0 and escapes through a narrow slot of width b and length l. The tube is closed at the further end. It is found that the height of the jet h_0 at the beginning of the slot is much lower than at the end where it is h_n. This agrees qualitatively with Bernoulli's principle, where the velocity in the tube is high and the pressure low and vice versa; but we cannot simply apply Bernoulli's principle here because the volume of water which passes through any cross-section of the tube per unit time depends on the distance from the beginning of the slot to the cross-section. At a given point distant x from the beginning of the slot, let us assume the velocity in the tube to be v, the corresponding height of the jet, h, and the velocity of the issuing jet, w. Then conservation of energy gives Equation [1]:

$$-d(\tfrac{1}{2}mv^2) = d(mgh) \qquad [1]$$

or

$$dh = -\frac{1}{g}vdv$$

and

$$\int_h^{h_n} dh = h_n - h = -\frac{1}{g}\int_v^0 vdv = \frac{1}{g}\frac{v^2}{2}$$

whence

$$v = \sqrt{2g(h_n - h)} \qquad [2]$$

The volume of water which flows per unit time through the slot bdx is equal to

$$-Adv = wbdxc \qquad [3]$$

where c is the coefficient of discharge. By dimensional reasoning we see that this coefficient is a pure number, which depends at the same time on the height of the jet. The volume of water ΔV which flows with velocity w through an area a is equal to

$$\Delta V = wac$$

The dimensional equation is

$$\frac{L^3}{T} = \frac{L}{T}L^2c$$

hence c is a pure number. Consider now a volume dV which passes through a slot of length dx per unit time, so that

$$dV = wdxc$$

Then the dimensional equation gives for c a length, say, h, whence

$$c = kh, \quad c_n = kh_n, \quad \text{and} \quad \frac{c}{c_n} = \frac{h}{h_n}$$

or

$$c = c_n\frac{h}{h_n} \qquad [4]$$

or, from Equation [2],

$$c = c_n\frac{h_n - \frac{1}{2g}v^2}{h_n}$$

This formula has been verified by Enger; the deduction here given involves at the same time the principle of similitude, as two slits of length dx and dx_1 and of the same width are compared.

A more rigorous deduction would be expected from the theory of streamlines. In this case the height of the jet in the position x is given by

$$\tfrac{1}{2}mw^2 = mgh$$

or by

$$w = \sqrt{2gh} \qquad [5]$$

From [2], [3], [4], and [5] we obtain

$$dv = -c_n\frac{h}{h_n}b\frac{dx}{A}\sqrt{2gh} = -g\frac{dh}{\sqrt{2g(h_n - h)}}$$

$$\frac{2bc_n}{h_nA}\int_0^x dx = \int_{h_0}^{h}\frac{dh}{\sqrt{(h_n - h)h}} = \frac{-2\sqrt{h_nh - h^2}}{h_nh}\Bigg|_{h_0}^{h}$$

or

$$x = \frac{A}{bc_n}\left[\frac{\sqrt{h_nh_0 - h_0^2}}{h_0} - \frac{\sqrt{h_nh - h^2}}{h}\right] \qquad [6]$$

This formula gives x as a function of h; but as we wish the inverse function, we write

$$x = C - C_1\frac{\sqrt{h_nh - h^2}}{h} \qquad [6a]$$

where

$$C_1 = \frac{A}{bc_n} \quad \text{and} \quad C = \frac{A}{bc_n}\frac{\sqrt{h_nh_0 - h_0^2}}{h_0} \qquad [7]$$

From [6a],

$$\frac{(C - x)^2 + C_1^2}{C_1^2} = \frac{h_n}{h}$$

or

$$h = \frac{h_nC_1^2}{(C - x)^2 + C_1^2} \qquad [8]$$

[1] Professor of Physics, University of Illinois.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

which gives the curve of Fig. 1. Introducing the boundary conditions, for $x = 0$, $h = h_0$, hence

$$h_0 = \frac{h_n C_1^2}{C^2 + C_1^2} \quad [9]$$

and for $x = l$, $h = h_n$, hence

$$h_n = \frac{h_n C_1^2}{(C - l)^2 + C_1^2} \quad [10]$$

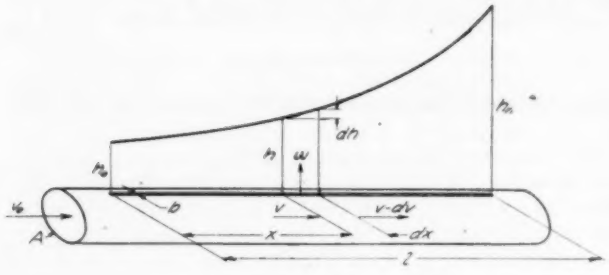

FIG. 1

From this it follows that

$$C = l = C_1 \frac{\sqrt{h_n h_0 - h_0^2}}{h_0} \quad [11]$$

or

$$C^2 = C_1^2 \left(\frac{h_n}{h_0}\right) - C_1^2$$

or

$$\frac{C^2 + C_1^2}{C_1^2} = \frac{h_n}{h_0}$$

If the tube and slot dimensions and the initial velocity of the flow of water are given, then h_n and h_0 are determined as follows. From [2] we obtain

$$V_0^2 = 2g(h_n - h_0)$$

or

$$h_n = \frac{V_0^2 + 2gh_0}{2g} \quad [12]$$

and from [11]

$$l = \frac{A}{bc_n} \frac{\sqrt{h_n h_0 - h_0^2}}{h_0}$$

or

$$\left(\frac{lbc_n}{A}\right)^2 = \frac{h_n}{h_0} - 1$$

or by [12],

$$\left(\frac{lbc_n}{A}\right)^2 + 1 = \frac{V_0^2 + 2gh_0}{2gh_0} = \frac{V_0^2}{2gh_0} + 1$$

whence

$$h_0 = \frac{V_0^2 A^2}{2g(lbc_n)^2} \quad [13]$$

From [12],

$$h_n = \frac{V_0^2}{2g}\left[1 + \frac{A^2}{(lbc_n)^2}\right] \quad [13a]$$

h_n and h_0 are now determined. Let us next assume that the pipe has at the end $x = l$ a hole of cross-section A_1 through which the water flows with the velocity v_0 so that $A_1 v_0 = A v_1$; then we obtain from

$$dh = -\frac{1}{g} v dv$$

$$\int_h^{h'_n} dh = -\frac{1}{g}\int_{v_1}^{v_0} v dv = \frac{1}{2g}(v_0^2 - v_1^2) = h_n' - h$$

h_n' is the height of the new jet at $x = l$, and h_0' the initial height at $x = 0$, or

$$v_0^2 = 2g(h_n' - h) + v_1^2$$

hence

$$v_0^2 = 2g(h_n' - h_0') + v_1^2$$

or

$$\frac{v_0^2 - v_1^2}{2g} = h_n' - h_0'$$

But from [2],

$$\frac{v_0^2}{2g} = h_n - h_0$$

hence

$$\frac{h_n' - h_0'}{h_n - h_0} = 1 - \frac{v_1^2}{v_0^2} \quad [14]$$

We can now obtain the curve by the equation:

$$x = \frac{A}{bc_n}\left[\frac{\sqrt{h_n' h_0' - h_0'^2}}{h_0'} - \frac{\sqrt{h_n' h - h^2}}{h}\right]$$

or

$$-x = -C' + \frac{C_1\sqrt{h_n' h - h^2}}{h}$$

where

$$C_1 = \frac{A}{bc_n} \quad \text{as before}$$

and

$$C' = \frac{A}{bc_n}\frac{\sqrt{h_n' h_0' - h_0^2}}{h_0'}$$

hence

$$h = \frac{h_n' C_1^2}{(C' - x)^2 + C_1^2}$$

and the whole curve of the liquid sheet appears lowered with respect to the original sheet. It is easy to calculate the limiting heights of the sheet as before, the result being given by the equations

$$h_0' = \frac{(v_0^2 - v_1^2)A^2}{2g(lbc_n)^2}$$

$$h_n' = \frac{v_0^2 - v_1^2}{2g}\left[1 + \frac{A^2}{(lbc_n)^2}\right]$$

If we replace the slot by a row of holes each of area a, so that

$$lb = Na \quad \text{and} \quad xb = N_x a$$

where $N = n + 1$ is the total number of holes and N_x is the number of holes over the distance x, then the sheet will be broken up into isolated jets of variable heights h, so that we obtain from

$$h = \frac{h_n C_1^2}{(l - x)^2 + C_1^2}$$

the equation

$$h = \frac{h_n C_1^2}{\left(\frac{a}{b}\right)^2 (N - N_1)^2 + C_1^2}$$

where now

$$C_1 = \frac{A}{bc_n} = \frac{Al}{N_a c_n}$$

hence

$$h = \frac{h_n}{1 + \frac{a^2 c_n^2}{A^2}(N - N_1)^2}$$

If h_f is the loss of height per unit distance through friction, then

$$h = \frac{h_n}{1 + \frac{a^2 c_n^2}{A^2}(N - N_1)^2} - \sum h_f \quad \ldots\ldots\ldots [15]$$

Next put $c = c_n$ = constant. Then, from [3],

$$dv = -\frac{wbdxc_n}{A}$$

or

$$dv = -\sqrt{2gh}\,\frac{b}{A}\,c_n dx$$

From [2]

$$dv = -\frac{gdh}{\sqrt{2g(h_n - h)}}$$

hence

$$\frac{2bc_n}{A}\int_0^x dx = \int_{h_0}^{h} \frac{dh}{\sqrt{h(h_n - h)}} = -\arcsin\left(1 - \frac{2h}{h_n}\right)_{h_0}^{h}$$

whence

$$x = \frac{A}{2bc_n}\left[\arcsin\frac{h_n - 2h_0}{h_n} - \arcsin\frac{h_n - 2h}{h_n}\right] \quad [16]$$

or

$$x = C - \frac{A}{2bc_n}\arcsin\frac{h_n - 2h}{h_n}$$

or

$$\sin(C - x)\frac{2bc_n}{A} = 1 - \frac{2h}{h_n}$$

or

$$h = \frac{h_n}{2}\left[1 - \sin\left\{(C - x)\frac{2bc_n}{A}\right\}\right] \quad \ldots\ldots\ldots [17]$$

This equation is given by Enger. Let us now proceed to apply the method of difference equations to the given problem, assuming that the tube contains at equal distances Δl holes of cross-section a, and that the water escapes in jets of heights h_0, h_1, h_2, h_k, h_{k+1} . . . . h_{n-1}, h_n. Then $h_{k+1} = h_k + \Delta h$, and the velocity of the water through the hole k is w_k and through the following hole $k + 1$ is w_{k+1}. The principle of conservation of energy leads to the equation

$$-\Delta(\tfrac{1}{2}mv^2) = \Delta(mgh)$$

$$\Delta(v^2) = -2g\,\Delta h$$

or

$$(v - \Delta v)^2 - v^2 = -2g\,\Delta h$$

or

$$\Delta h = \frac{1}{2g}[2v\,\Delta v - (\Delta v)^2] \quad \ldots\ldots\ldots [18]$$

Moreover

$$\tfrac{1}{2}mw_k^2 = mgh_k$$

or

$$w_k = \sqrt{2gh_k}$$

The velocity of the water in the pipe arriving at the hole k is v (or v_k), and leaving the hole it is v_{k+1} or $v - \Delta v$; the principle of conservation of mass gives the equation

$$-A\,\Delta v = ac_k w_k$$

$$= a\sqrt{2gh_k}\,C_n\frac{h_k}{h_n}$$

Instead of a we may write $a = b\,\Delta l$; hence

$$\Delta v = -\frac{b\,\Delta l}{A}\sqrt{2gh_k}\,\frac{h_k}{h_n}c_n$$

and

$$\tfrac{1}{2}mv^2 = mg(h_n - h_k)$$

or

$$v = \sqrt{2g(h_n - h_k)}$$

and

$$\Delta v = \sqrt{2g}\,[\sqrt{h_n - (h_k + \Delta h)} - \sqrt{h_n - h_k}] \quad \ldots [19]$$

From the last two equations we obtain

$$\frac{b\,\Delta l c_n}{A h_n} = \frac{\sqrt{h_n - h_k} - \sqrt{h_n - (h_k + \Delta h)}}{h_k^{3/2}} \quad \ldots\ldots [20]$$

The left-hand member of Equation [20] is a constant C, and if instead of h_n we write a, the equation then assumes the form

$$\frac{\sqrt{a - h_k} - \sqrt{a - h_{k+1}}}{h_k^{3/2}} = C \quad \ldots\ldots\ldots [21]$$

In order to put this expression into a more standard form of difference equation, let us write

$$g_k^2 = a - h_k, \quad g_{k+1}^2 = a - h_{k+1}$$

whence

$$g_k - g_{k+1} = C(a - g_k^2)^{3/2} \quad \ldots\ldots\ldots [22]$$

or

$$g_{k+1} = g_k - C(a - g_k^2)^{3/2} \quad \ldots\ldots\ldots [23]$$

If h_0 and $g_0^2 = a - h_0$ are given, then we can calculate from [23] the values g_1 and h_1 from $h_1 = a - g_1^2$. Having determined g_1, we can use [23] again to calculate g_2, and so on. In this way the problem is essentially solved. Equation [22] is a difference equation of the first order, but non-linear. For such a difference equation we have no general theory and no theorems as yet. If we consider g_{k+1} as given, then it is more difficult to calculate g_k or h_k. In order to take the first step let us assume h_n as given and calculate h_{n-1} by means of [20]; $k = n - 1$, and $h_k + \Delta h = h_n$, hence

$$\frac{b^2\,\Delta l^2 c_n^2}{A^2 h_n^2} = \frac{\Delta h}{h_{n-1}^3} = \frac{h_n - h_{n-1}}{h_{n-1}^3} = \frac{h_n}{h_{n-1}^3} - \frac{1}{h_{n-1}^2}$$

Let $\alpha = h_n$, $\beta = \dfrac{b^2\,\Delta l^2 C_n^2}{A^2 h_n^2}$, and $x = \dfrac{1}{h_{n-1}}$; then we obtain the cubic equation

$$\alpha x^3 - x^2 - \beta = 0 \quad \ldots\ldots\ldots [24]$$

We can obtain approximate values of x and h_{n-1} by the following method, assuming $C = C_n$ = constant. Instead of [18] we obtain:

$$\Delta v = -\frac{b\,\Delta l c_n}{A}\sqrt{2gh_k}$$

and by means of [19]

$$\frac{b\,\Delta l c_n}{A} = \sqrt{\frac{h_n - h_k}{h_k}} - \sqrt{\frac{h_n - (h_k + \Delta h)}{h_k}}$$

or using the same abbreviations as before,

$$\sqrt{a - h_k} - \sqrt{a - h_{k+1}} = C\sqrt{h_k} \quad \ldots\ldots [25]$$

Let

$$g_k^2 = a - h_k \quad \text{and} \quad g_{k+1}^2 = a - h_{k+1}$$

then

$$g_k - g_{k+1} = C\sqrt{a - g_k^2} \quad \ldots\ldots [26]$$

or

$$g_k^2 - 2g_k g_{k+1} + g_{k+1}^2 - C^2(a - g_k^2) = 0$$

or

$$g_k^2 - \frac{2g_k g_{k+1}}{1 + C^2} + \frac{g_{k+1}^2 - C^2 a}{1 + C^2} = 0$$

or

$$g_k = \frac{g_{k+1}}{1 + C^2} \pm \sqrt{\left(\frac{g_{k+1}}{1 + C^2}\right)^2 - \frac{(g_{k+1}^2 - C^2 a)}{1 + C^2}} \quad \ldots [27]$$

For every value g_{k+1} we can calculate g_k and $h_k = a - g_k^2$. This value we can use as a first approximation and calculate a second approximation by means of Equation [20].

Discussion

W. E. Howland.[2] The writer has been interested in this problem in its relation to the design of filter laterals through which water is forced into the bottom of a filter for the purpose of washing the sand. It is important to maintain an approximately equal distribution of water in the base of the filter as expressed in rate of water applied per unit area of horizontal cross-section of sand. This means that for ordinary arrangements of piping the rate of water emitted per unit distance along the pipe should be approximately a constant. If the pressure distribution along the pipe were known, as well as the hydraulic characteristics of the orifice in the pipe under the conditions of the problem, then one could effect the desired uniformity of distribution either by varying the diameter of the holes or their spacing.

The importance of a correct prediction of the pressure distribution curve is of fundamental importance to this practical problem.

Such studies as this of Professor Kunz and the earlier one of Professor Enger throw considerable light upon the problem. The effect of the velocity in the main pipe upon the coefficient of the orifice shown by Professor Enger's studies is especially valuable. Fortunately the practical problem which the writer has named is much simpler than the one considered by Professor Kunz. It involves a differential equation of an ordinary type, and the very interesting method so ably presented by Professor Kunz does not appear to be required.

The fundamental hydraulics of the two problems are, however, the same. The assumptions made at the beginning of the analysis required further study, it is believed.

[2] Assistant Professor of Civil Engineering, School of Civil Engineering, Purdue University, Lafayette, Ind.

Effect of Velocity Upon Coefficient of Discharge

Professor Enger's formula for coefficient of discharge fits the values determined from his experiment very well, but obviously it could not be correct for all cases even though dimensionally consistent as implied by Professor Kunz. Consider the case where the pressure in the pipe was equal to the velocity head. Then the numerator in the equation $c = \dfrac{y - \dfrac{v^2}{zy}}{y} c_e$ is zero. The formula would indicate that no water would flow from the pipe, and yet so long as there is static pressure at the hole, water obviously would flow from the pipe. This is not a criticism of the formula, but rather of the method used for rationalizing it given by the author.

It is to be noted that the author interprets the formula in a slightly different way from that given by Professor Enger. According to Professor Kunz, the formula should be $c = \dfrac{h_n - \dfrac{v^2}{zg}}{h_n}$, where h_n is the pressure at the closed end of the pipe. Considering the case where there is very considerable friction in the pipe—i.e., where the holes are widely spaced—then it is possible that at some orifice the pressure will be the same at the closed end of the pipe. If at this point the pressure were equal to the velocity head, as before, the formula would indicate no discharge, and yet surely there would be discharge from the orifice.

Energy Distribution at the Orifices

Both Professors Enger and Kunz have assumed that the velocity energy of the water in the pipe is largely dissipated. Consider the energy of that portion of the stream within the pipe which is about to leave an orifice. It is equal to $qw\left(h + \dfrac{v^2}{zy}\right)$, where q is the rate of flow from the orifice, w the weight of a cubic foot, h the pressure, and v the velocity. The author assumes that the water leaves the pipe at a rate proportional to $h^{1/2}$, as if the energy of the water leaving were pressure energy only. This would imply that the remaining part of this energy $qw\dfrac{v^2}{zy}$ is lost or is given to the stream of water in the pipe and remaining within the pipe. The author assumes that it is lost, for he says that the differential change in pressure along the pipe is merely $\left(\dfrac{vdv}{g}\right)$. Here he is considering an orifice of differential area. This effect is entirely the result of the change in kinetic energy of that portion of the water which remains within the pipe, as may be shown in the following way:

Let Q_1 be rate of flow of that portion of the water which remains within the pipe. The amount of energy possessed by this water will be considered a constant; i.e., the differential change in the energy of this water is zero. The energy of this water is $Q_1 w\left(hp + \dfrac{v^2}{zy}\right)$

$$Q_1 w\left(dhp + \frac{2vdv}{zy}\right) = 0$$

$$dhp = -\left(\frac{vdv}{g}\right)$$

The writer believes that this assumption may sometimes be wrong; that in many cases there is a significant transfer of energy from the side stream to the main stream which predominates over the loss of energy in the main stream in the vicinity

of the orifice, thus producing a significant increase in pressure in the main stream which the simple Bernoulli equation used by Professors Kunz and Enger cannot explain. The writer is aware that this statement may not seem plausible, and so it is repeated for emphasis. The simple Bernoulli equation in the form of head is wrong as applied to manifold pipes. Actually there is a greater increase in pressure along the line of flow than can be accounted for by means of this equation. The total energy equation must be used to explain the phenomenon.

In support of this assertion the writer quotes the following experiments, with references appended:

(1) The Malishewsky experiments can be explained by assuming a recovery of approximately $^3/_4$ of the initial velocity energy of the water of each side stream. The Enger-Kunz theory does not explain the results of the experiment.

(2) The experiments of Professor Goodenough on the model of ventilation ducts of the Holland tunnel and subsequently upon the tunnel itself indicate that about 40 per cent of the initial velocity energy of the side streams is recovered.

(3) The Enger experiments are well explained by the theory to which the writer is objecting, but when he applies the assumption that 30 per cent of the initial velocity energy of the side stream is recovered he obtains results which are in close agreement with the results of the experiment, and the disagreement is less than the experimental error. In other words, the effect which the writer is mentioning in this case is too small to be significant.

(4) The experiments conducted at the laboratory at Munich under the direction of Thoma in divided flow on a single tee fitting show a noticeable gain in total head in the main stream, which the authors explain in the following way: "One can assume that through the side pipe a greater part of the slow-moving edge layers is scooped off."

This is a slightly different way of looking at the phenomenon from that of the writer and is believed to be of considerable merit, but in effect it is the same, for it assumes that the water leaving the orifice takes with it less than its proportion of the mean velocity energy and also that the water remaining possesses more than its proportional amount of energy. Thus it helps to explain the mechanism of transfer of energy from the side stream to the main stream.

This viewpoint may also help to compose the differences between the Enger and the Malishewsky experiments. In the Malishewsky experiments only about $^1/_{40}$th of the total flow was taken through a single orifice, for there were 40 orifices; in the Enger experiments $^1/_{19}$th. Thus in the Malishewsky experiments a larger portion of the "scooped off" water was obtained from the edge layer.

It is true, as shown by the experiments of Professor Enger, that cases do arise in which the effect which the writer is mentioning is of no practical consequence. But in other cases, particularly that of unequally spaced orifices designed to accommodate the large flows now demanded in water works practice, this effect of an additional velocity-head recovery will probably be very significant.

Further experimental studies of the problem are urgently needed.

M. L. Enger.[3] The discharge of jets from manifold tubes must be determined in many cases in engineering practice. When high velocities are used in manifold pipes, unexpected results will sometimes occur. The wash-water system of water filters should supply water uniformly over the entire filter area if the filter is to be washed effectively; and as it is often economical to use high velocities in the manifold pipes, the problem has

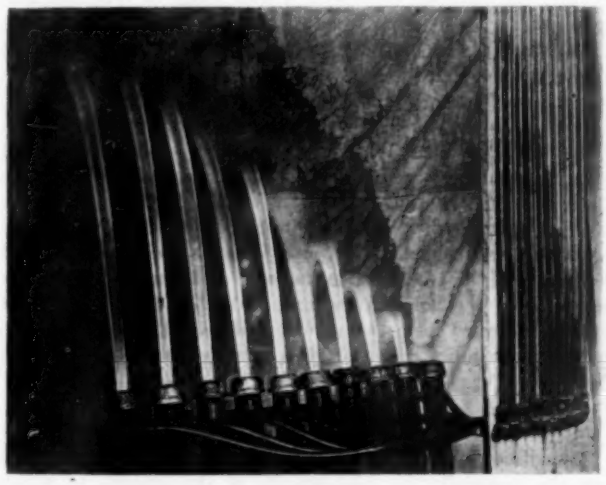

Fig. 2

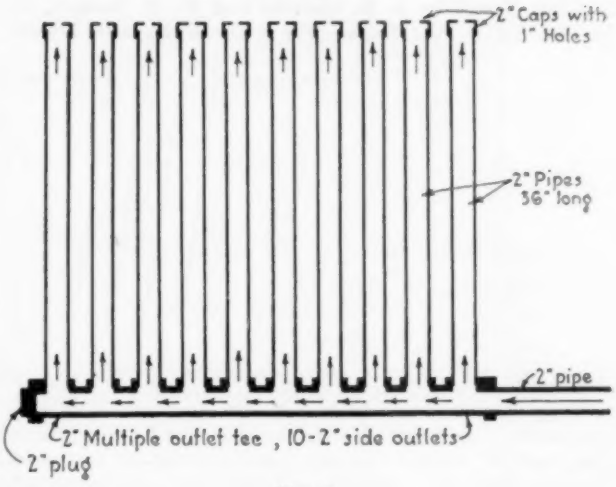

Fig. 3

been given much study in this connection. The problem of delivering the water uniformly beneath the filter bed has been solved in three different ways: (*a*) By the use of large manifold pipes, thus making the velocities small; (*b*) by the use of manifold pipes of a variable diameter, thus keeping the velocities in the manifold nearly constant; and (*c*) by the use of variable spacing of the discharge openings from the manifold pipes. The first two methods are too expensive except in the case of large, costly filter plants.

Another application occurs in hot-water heating when a num-

[3] Professor of Mechanics and Hydraulics, University of Illinois, Urbana, Ill.

ber of radiators are connected to one header. In this case the loss of head at the entrance is also a function of the velocity in the manifold as well as of the velocity of the diverted water.

The converse problem occurs in the case of the wash-water collecting pipe for pressure filters. The method used by the author can be applied to this case.

The writer is particularly interested in the derivation of the equation for the coefficient of discharge from openings in the manifold pipe in terms of the pressure and the velocity in the pipe. The equation is the same as the one derived by the writer from experiments and which was assumed to be purely empirical. Further experiments will soon be undertaken to determine whether the equation holds over a wide range of velocities and pressures.

An extreme case of the variation of pressure and discharge from a manifold pipe is shown in Fig. 2, which is from a photograph taken in the Hydraulics Laboratory of the University of Illinois. A diagrammatic sketch of the arrangement used is shown in Fig. 3. Ten 2-in. pipes, each 36 in. long, are connected to a manifold pipe, which was lined with cement to make its inside diameter exactly 2 in. On the ends of the 2-in. laterals are caps in which 1-in. holes have been drilled. The end of the manifold was plugged. The water entered from the right and flowed out of the 1-in. holes in the caps. The heights of the jets issuing from the holes in the caps indicated the quantities of water discharged from the various orifices. The heads on the orifices were indicated in 10 glass tubes which can be seen in Fig. 2.

Author's Closure

The discussion by W. E. Howland contains some valuable remarks, especially the bibliography of the subject, to which there should be added: "Friction Heads in One-Inch Standard Cast-Iron Tees," by F. E. Giesecke and W. H. Badgett, *Jl. Am. Soc. Hig. & Vent. Engrs.* The results of this latter investigation have been recalculated and show that the loss of head due to water flowing out of the side of a tee can be expressed over a large interval by $h = 0.91\ v^2/2g$ in accordance with our theory. In the paper the author has neglected the friction of the flowing liquid except in formula [15]. The analysis is therefore only a first approximation. Against the criticism of Mr. Howland, the author has to raise only few objections.

(1) The discharge coefficient c is equal to:

$$c = \frac{h_n - \frac{v^2}{2g}}{h_n} c_n = c_n \frac{h}{h_n};$$

c would only vanish if h were equal to zero. This cannot happen in the phenomenon studied; but if it did happen, then no liquid would flow through the given hole.

(2) Bernoulli's equation applies only to a given streamline, and not to dividing streamlines; it can therefore not be used in the present problem and Enger and the author have not used it.

(3) The author cannot understand the statement by Mr. Howland that in many cases there is a significant transfer of energy from the side stream to the main stream, which predominates over the loss of energy in the main stream in the vicinity of the orifice. How is this compatible with the principle of conservation of energy?

(4) In the theory of N. Malishewski there are found the formulas

$$dh = \frac{K(Q + qx)dx}{d^5}, \qquad h = \frac{K}{d^5}(Q_1 + 0.55Q_2)^2$$

which the author does not understand. But the phenomenon, which he observed, agrees qualitatively at least with the author's theory.

A comprehensive critical review of the present literature will be presented in a later paper, the author hopes.

The Yield Point of Mild Steel

By C. W. MacGREGOR,[1] EAST PITTSBURGH, PA.

This paper is a review of some of the more important investigations made concerning the yield point, together with the effect of certain conditions on the yielding of mild steel. Recent investigations concerning the yield point are also described. The pronounced effect on the yield stress of grooves inclined at 45 deg. to the axis of the test piece is discussed. In addition, tests are included to show the effect of notches in the test piece on the yield stress.

IT IS customary to base the design of structures and machine parts made from ductile metals and subjected to static loading on the limit of plasticity. The limit of plasticity is, as its name implies, that stress at which plastic flow of the material begins. At this stress the deformations begin to become permanent, and increase at practically constant stress. It has been customary to call this limit the yield stress of the material. It is then obvious that one of the reasons for choosing the yield stress as a criterion in design is that such permanent deformations as those which occur at this stress are prohibitive in engineering practice. For structural-steel shapes submitted to a compressive stress such as columns and beams, buckling is likely to occur if they are stressed above the yield point. This is true since on the exceeding of the yield stress the modulus of elasticity E can no longer be used in Euler's simple column formula and the critical load under which buckling occurs is greatly reduced. It is therefore apparent that a more exact knowledge of what is taking place at the yield point and of the various factors affecting its value may be of considerable aid to the designer.

The limit of plasticity, or yield point, has been a subject of much controversy, both in this country and in Europe. At different times many definitions have been proposed, and then subsequently revised. Moser[2] and Körber[3] have indicated the difference in significance of the definitions of a yield point based on an arbitrary amount of deformation and that based on the drop of the beam of the testing machine. They have pointed out that the yield stress of mild steel in tension based on the drop of beam is a natural limit or property of the material, while the other is only arbitrarily based on a conventional rule. In the following discussion, when the yield point is mentioned, reference is made only to the limit of plasticity and not to that corresponding to an arbitrary amount of deformation.

However, it is not the purpose of this paper to analyze the conventional methods of defining the yield point or to present new definitions in this connection. It is more the intention to review a few of the important investigations made by other experimenters concerning the physical aspect of the yield point and to contribute to this the results of a few tests that were made on the same question. These tests will show the effects of certain mechanical conditions, such as grooves and notches, on the yield stress.

Previous Work on the Physical Side of the Yield Stress by Other Investigators

Since the beginning of the twentieth century, much attention has been paid to the yield point. Among the first to investigate this question in Germany were Bach and Martens. Later such

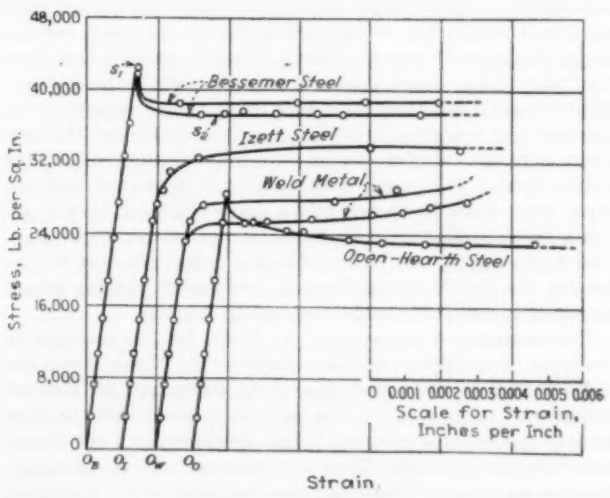

Fig. 1 Portions of Stress-Strain Curves for Different Materials Tested in Tension

men as Moser, Nádai, Körber, Ludwik, and Sachs, with many others, took up this question. Recently Kühnel, Kuntze, and Schwinning have been added to the list. The field of work covered by these many investigators is too broad to go into in much detail, and so only a few of the important results will be described.

(*a*) *Mechanism of Yielding.* C. von Bach[4] seems to have been the first to notice the remarkable phenomenon of the upper and lower yield stresses present in mild steel. He defined the upper yield limit as the stress which, if exceeded, would start the flow process, and the lower yield limit, the lowest value of stress at which the extension proceeds still further. Thus, as represented in Fig. 1, the stress s_1 is the upper yield stress and s_2 the lower yield stress.

In order to explain more clearly what is meant by the flow proc-

ess mentioned by Bach, the formation of Lueders lines, or slip layers, in mild steel will be briefly discussed. Many investigators have studied these slip layers which begin to form at the upper yield stress s_1 and continue to form through the lower yield point s_2. Among the early investigators of this question are included Hartmann,[5] Lueders,[6] and Martens and Heyn,[7] and others.

It has been found that these Lueders lines consist of wedge-shaped slip layers which extend through the material and are not just a surface phenomena. They initially form at a point along the test bar where there is a slight concentration of stress, and gradually proceed along the bar until the entire length has become work-hardened. When this has been effected, the load can start to increase to its maximum value, since no more single layers are forming. These layers nearly coincide with the planes of maximum shear stress which are theoretically at 45 deg. to the bar axis, but which have been found by various investigators to form at 47 deg. for tension and 43 deg. for compression.

There is considerable variation in the type of yielding even among mild steels. Some of these metals exhibit a sharply defined yield point with considerable drop in load, while others have a more gradual transition from the elastic to the plastic stage. The reasons for the difference in shapes of the various types of stress-strain curves near the yield point have not been definitely settled. An explanation for the difference in many cases has been suggested by A. Nádai[8] on the basis of the difference in strength of the grain-boundary substance. It has been observed that materials which exhibit a sharply defined yield point in a tensile test with considerable drop in load usually have a fine grain structure, while those with a gradual transition from the elastic to the plastic states are often coarse-grained. Since the grain-boundary substance forms a rigid cement about the grains in a fine-grained mild steel, the ability for the flow layers to form is thus prevented until the skeleton-like structure breaks down. This means that yielding is prevented until the upper yield point is reached and a sharply defined limit is obtained. In coarse-grained materials, or metals having less grain-boundary cement, this latter substance is less effective in preventing the flow layers in forming, and earlier yielding occurs without a sudden break in the stress-strain diagram.

This suggested explanation of A. Nádai for the variation in the types of transition from the elastic to the plastic states has found further corroboration through G. Sachs and W. Kuntze[9] and others. Kuntze and Sachs have emphasized that the yield point in mild steel is governed by the breaking down of a brittle constituent in the steel. They have observed that in the majority of cases yielding first begins near the head of the test piece, where more or less stress concentration[10] may be present, depending on the actual shape of the head of the bar. One would expect that when the yield point is reached in a ductile material, the stresses would become more evened out and not affect so much the yielding of the entire bar. However, they have pointed out that this phenomenon of first yielding at a point of stress concentration is analogous to that which happens in the failure of a brittle material, in that brittle materials are much more subject to the effects of stress concentration than ordinary ductile metals. Where in a brittle material cracks form due to stress concentration, slip layers form due to the same cause in a ductile metal.

At the same time that these slip layers are forming, the cross-section of the test bar is decreasing. Kuntze and Sachs[11] have shown by very illustrative profile diagrams how the area of cross-section gradually decreases along the test bar with progressive yielding.

(b) Effect of Certain Mechanical Conditions on the Yield Point. It has been shown that mild steel exhibits the phenomenon of an upper and a lower yield point. The question of whether to use the upper or lower value of stress as a limit is, in many countries, not definitely settled. In Germany, Kühnel and others advocate using the upper value, while Moser, Körber, and others believe that the upper yield stress is unstable and can be affected by testing conditions. The latter therefore advocate using the lower yield stress.

Many investigations have shown the effects of various conditions on the yield point. Some of the more important factors which have been found by other investigators to affect the value of the yield stress will be mentioned here.

Velocity. This is a large question, and only a few phases of it will be discussed. Among a large number of tests may be mentioned those of E. H. Schulz and H. Buchholtz,[12] together with those of F. Körber.[13] It was found that both the lower and the upper yield stresses increased with greater testing speed. However, the upper yield point showed itself much more unstable and affected by increasing velocity than the lower stress.

In this connection the tests of Kühnel[14] may also be quoted. He arrives at different results from those of the former tests mentioned. His test results seemed to indicate that the lower and upper yield stresses increased in a parallel manner with increasing speed. From this fact he concludes that the upper yield stress could hardly be called unstable and the lower stable. However, by consulting his diagrams for St-48 steel tested under various mechanical conditions, it appears that the lower yield stress is much less affected by variations in testing conditions than the upper, indicating that the lower yield stress is the more stable of the two.

Type of Head on Test Bar. It has been shown by F. Körber[15] and M. Moser[16] that the sharper the transition from the head of the test piece to the cylindrical portion, the lower will be the upper yield stress. The change of section from the head of the test piece to the cylindrical length does not affect the lower yield stress to any great extent. The effect of no head on the test piece is similar to that with a sharp transition. This follows since there is a sharp discontinuity at the point of the bar where it joins the grip of the testing machine, and consequently high stress concentrations similar to a sharp fillet exist.

Notches in Test Bars. Among a large number of tests made on the effects of notches in test pieces the more recent tests of A. Nádai,[17] P. Ludwik and R. Scheu,[18] and W. Schwinning[19] may

be mentioned. The effect of the raising of the ultimate strength by short notches in bars of mild steel is quite widely known. As this discussion is confined to the yield point, only those tests will be described which show an effect on it. Both A. Nádai and W. Schwinning have shown that the lower and upper yield stresses are increased by short notches, while the difference between the two is constantly decreasing. For very short notches they practically coincide. This fact may be noticed by reference to Fig. 16, which shows the load-deformation diagrams for bars containing grooves of different lengths.

Cross-Section of Test Bars. In some of his early tests Bach[20] investigated the effect of the cross-section of the bar on the upper yield stress. His tests have shown that the highest upper yield stress was obtained with round bars, the next with rectangular bars, and the lowest with a double T-shaped cross-section. This is easily explained since the round bar has the most uniform distribution of stresses over the cross-section, and hence a higher value of yield stress may be reached due to a prevention of local yielding. In all cases the lower yield stress was not appreciably affected by a change of cross-section.

Aging of Test Pieces.[21] Another factor influencing the yield point is the aging of the steel. Much work has been done on this question in the last few years by various men. Among them may be mentioned P. Ludwik and R. Scheu,[22] who have illustrated how the yield point of various metals may be greatly increased due to aging. Steel bars were stretched to a few per cent elongation, unloaded, heated to various low temperatures for a short time, and then reloaded. On reloading, the yield point was considerably raised. Many other important investigations have been carried on in this field which will not be mentioned here.

Recent Tests on the Yield Point

In the following, tests will be described showing the changes which take place on polished surfaces of various steels at the yield point, and in addition the effect of surface conditions and notches in the test piece on the yield stress.

(*a*) *Sharpness of Transition From Elastic to Plastic States in the Stress-Strain Diagram in Relation to the Formation of Lueders Lines.* The fact that the upper yield stress is associated with the formation of Lueders lines has been mentioned before. It has been noticed, however, that certain mild steels do not show these strain lines as well as others. In order to show that the most pronounced Lueders lines appear in steels which have a sharp transition from elastic to plastic states, tensile tests were made on four materials—namely, a bessemer steel, an open-hearth steel, an Izett steel,[23] and an arc-deposited weld metal.[24] All of these metals were of low-carbon content. The stress-strain curves for each material are shown in Fig. 1. From these curves it is to be noticed that the bessemer steel shows the most sharply defined yield point. The materials may be listed in the order of sharpness of transition from the elastic to the plastic states in the following manner, those with the sharpest transition being placed first: bessemer, open-hearth, weld metal, and Izett steel.

In order to correlate these results with the ability of each steel to show Lueders lines, or slip layers, tests were made on cylinders of each material stressed in two different manners. In the first case, cylinders of Izett and bessemer steel with highly polished faces were compressed laterally between hard plates. The cylinders after they were stressed are shown in Figs. 2 and 3. A comparison of these photographs with the stress-strain curves of Fig. 1 indicates that the steel with the most sharply defined yield point shows many more Lueders lines than the other material. The Izett steel indicates a boundary of the elastic and plastic regions, but no individual slip layers. The other manner of stressing the test pieces was to press a small, hard cylinder axially on the polished surface of each. Fig. 5 shows the slip lines produced by this type of loading in the four different materials in the form of logarithmical spirals. The test pieces in each of these photographs originally came from the same material from which were taken the tensile test pieces whose curves are shown in Fig. 1. By comparing these last results with the curves of Fig. 1, it follows immediately that the material with the sharpest transition from the elastic to plastic states exhibits the most pronounced Lueders lines. It is more difficult to distinguish between the weld metal and the Izett steel, but for this material it appears that the weld metal has a sharper transition in the stress-strain curve and consequently shows more slip lines than the Izett steel. Somewhat better flow layers were exhibited by a test piece from a different bar of Izett material than that shown in Figs. 2 and 5. This example is shown in Fig. 4.

Along this line of investigation tests are now in progress concerning the effect of nitrogen on the ability to etch these flow figures. This work is being done with the cooperation of Dr. Hensel, of the Metallurgical Division of the Research Laboratories, and will be reported at a later time.

(*b*) *Effect of Surface Conditions of Test Bar on the Upper Yield Stress.* It has been generally known for some time that small scratches will greatly reduce the strength of a brittle material. As mentioned in the discussion of the mechanism of yielding, the yield point of mild steel seems to be governed by the breaking down of a brittle constituent in the steel. It is naturally not to be expected that for such a ductile metal as mild steel, small scratches would have much effect. However, it is still conceivable that if it is true that the yield point is governed by a brittle constituent, small scratches might still affect the upper yield point.

It has been shown in many tests by A. Nádai that a slight stress concentration even in a ductile metal such as mild steel produces flow layers and local yielding. Fig. 6 shows a flat bar with grooves along the sides which has been tested in tension and from which it can be readily seen how the flow layers have originated at the corners of the grooves. This early local yielding means that the upper yield stress may be thus reduced by such stress concentrations.

In order to try to determine the effect of small scratches and grooves on the upper yield stress, tests were made on several bars of the types shown in Fig. 7. The round bars *a* and *b* were highly polished and designed so as to have a very small amount of stress concentration. This was done by providing a very gradual change of cross-section at the heads. Test piece *b* is identical with *a* except that it contains four small grooves around the circumference of the bar in two places. These grooves are perpendicular to the axis of the bar. The flat bar *d* is provided with a large number of sharp grooves inclined to the axis of the bar on the two faces at an angle of 45 deg. and perpendicular to the bar axis on the two sides. The results of the tests on these bars are recorded in Table 2.

The highly polished bar of type *a* showed a large difference between lower and upper yield stresses. The bar containing small grooves perpendicular to the axis *b* showed about the same yield-

[20] C. v. Bach, *Z.V.D.I.*, 49 (1905), I, 615; Mitt. Forshungsergebnisse Heft, 29 (1905), I, 61.

[21] There are several other factors which have been found to affect the yield point which will only be referred to here. Such items as the type of machine used, the length of test piece, etc., are known to have some influence.

stress difference as type *a*. Hence, single small grooves perpendicular to the bar axis do not seem to decrease the upper yield stress appreciably. However, on close examination of bar *b* after unloading, some local yielding could be distinguished near the grooves. This means that although the grooves had some effect in causing local yielding, it was not great enough to cause a lowering of the upper yield stress. It may be remembered in this connection that small holes through a test piece perpendicular to the axis of the bar have been shown in tests by A. Nádai to produce definite flow layers. The action of these grooves is similar to the case of the holes in producing yielding.

A further test concerning the effect of small scratches on the upper yield point was made with bars of type *c*. These tests were included to show the effect, if any, of scratches due to the knife edges of the Martens extensometer equipment. Some of the bars were tested with the extensometer knife edges inside the part of the bar with reduced section, and others had the knife edges resting on the parts of the bar of larger diameter, the comparison strips spanning

the reduced section. The results were similar to those found for the bar with small perpendicular grooves, in that no appreciable effect on the upper yield point could be noticed.

The results of tests on the flat bars of type *d*, however, were quite different from those obtained in the previous cases. In all of the flat, grooved bars tested, the upper yield stress showed a very marked decrease from that obtained for bars of type *a*. The lower yield stress for both types *a* and *d*, however, was practically the same. Fig. 8 gives a comparison of the stress-deformation diagrams, obtained for these two types *a* and *d*, and shows

how the upper yield stress for the flat, grooved bar has approached the lower in value. Fig. 9 shows the type of stress-strain curve obtained for an unannealed round bar of type *a* indicating for comparison the position of the upper yield point of an unannealed flat bar of type *d*. It is thus seen that in every case the upper yield stress for a flat, grooved bar is much less than that obtained for a round bar.

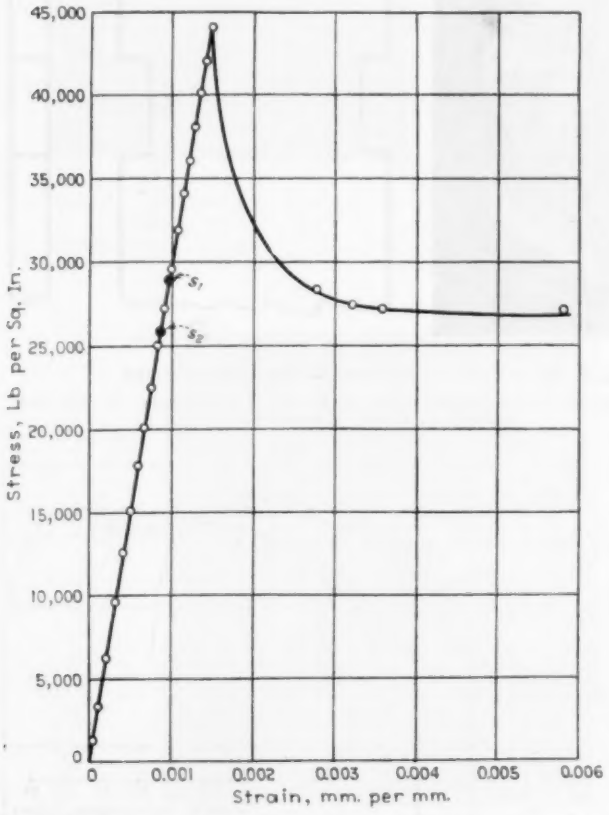

FIG. 9 PORTION OF STRESS-STRAIN CURVE FOR ROUND TENSILE-TEST BAR NO. 9

(s_1, upper yield stress for flat, grooved bar No. 10, s_2, lower yield stress for same.)

The grooves in the flat bars have contributed to a marked degree in reducing the upper yield stress. Bach[25] has shown that the upper yield stress was reduced in changing from a round bar to one with a rectangular cross-section. This reduction, however, was not nearly so marked a decrease as has been obtained with the grooved rectangular bars. A comparison of the differences between the upper and lower yield stresses for a change from round to rectangular cross-section obtained by Bach with those given here shows this clearly. Using data obtained from his tests, the ratio of the difference between the upper and lower yield stresses for rectangular bars to that of round bars is 0.59, while the same ratio for tests shown here is about 0.20. By referring to Fig. 10, the traces of the slip layers in the central non-grooved portion of the bar

NOTE: Material 1, not annealed; material 2, annealed; material 3, annealed.

can be seen. These slip layers have followed the course prescribed for them by the grooves, which illustrates how the grooves have influenced the yielding of the bar with the reduction of the upper yield point. With close examination of the slip layers it can be noticed that they bend away slightly from the direction of the grooves. This fact coincides with experience, since in most cases for tension the angle of inclination of the slip layers to the bar axis seems to be slightly greater than 45 deg., or about 47 deg.

The flat test bars containing grooves were loaded until failure, and Figs. 11 and 12 are included to illustrate the sliding of the material between the grooves during the necking of the test piece. The relative sliding of the layers can be seen in Fig. 11, and Fig. 12 shows how the layers have slipped until finally cracks formed between them. This should not, however, be confused with the slip layers occurring at the yield point.

In order to further illustrate the effect of grooves along a direction of the bar coinciding with the direction of maximum shear stress, compression tests on the cylinders shown in Fig. 13 were made. The cylinders with helical grooves allow the load to be applied on one-half of the cylinder only. Each test piece consists of two separate cylinders one above the other. In each

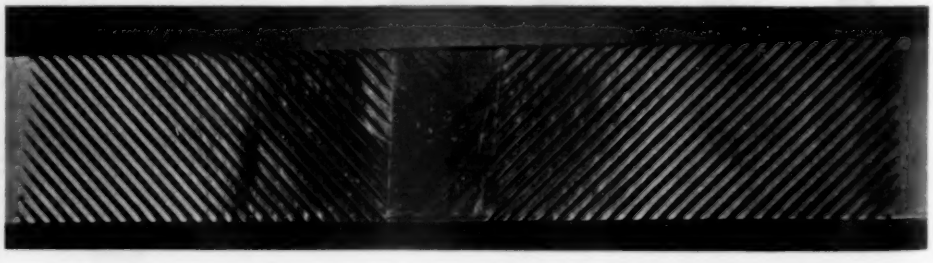

FIG. 10 GROOVED TEST BAR SHOWING HOW THE SLIP LAYERS FOLLOW THE INCLINATION OF THE GROOVES

(The slip layers may be seen in the central rectangular non-grooved part of the bar.)

case the upper and lower test pieces were grooved in opposite directions at 45 deg. to the axis of the bar. When the load was applied, the material between the grooves displaced itself in the same direction in both cylinders, thus minimizing the effect of friction at the common surface of each. Both test pieces have an axial hole bored along the entire length in order to separate the flow layers on opposite sides of the cylinder. Lines were drawn axially along the cylinder. Indentations were provided on the compression faces of each cylinder in order to allow the material between the grooves to slide.

When the load was applied, the material between one pair of grooves displaced itself with respect to that between the adjacent pair. Fig. 14 shows how the test pieces deformed. The amounts of lateral displacement of the vertical lines are given in Table 1. This shows that the material displaced itself along the directions prescribed by the grooves. By so designing the test piece, it is possible to thus produce a rotation of the material about the axis of the cylinder by the application of a pure compressive force. The screw action of the material on opposite sides of the grooves is similar to that between a bolt and nut.

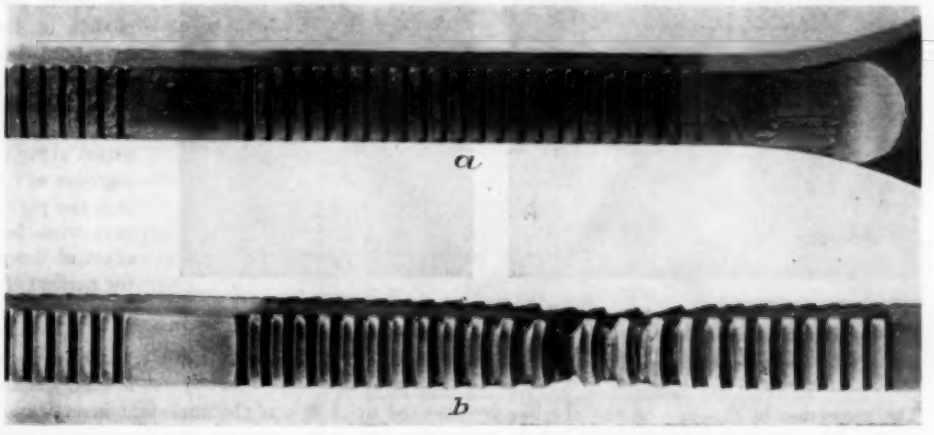

FIG. 12 SIDE VIEW OF GROOVED BAR SHOWING HOW THE LAYERS SLIPPED AT FRACTURE
(*a*, before deformation; *b*, after deformation.)

FIG. 13 COMPRESSION-TEST CYLINDERS WITH HELICAL GROOVES

The helical groove on each test piece is a curve whose osculating plane at every point coincides with a slip layer. In other words, the helical groove prescribes a course for the formation of an infinite number of slip layers. The surface of slip then in this case is a helicoid. On the basis of what has gone before, one would then naturally expect that these grooves should have a marked effect on the upper yield point.

In order to show this, tests were also made on plain cylinders for comparison. Curves shown in Fig. 15 illustrate the difference in the type of yielding in the two cases. Although a well-defined yield point with considerable drop in load was obtained for the plain cylinder, the helically grooved cylinders showed a rather gradual transition from elastic to plastic stages. Local yielding in the formation of slip layers has caused the upper yield point to entirely disappear.

From the tests on surface conditions so far completed it can then be concluded that small scratches do not appreciably reduce the upper yield stress of mild steel. The same is true of small grooves perpendicular to the axis of the bar. However, when grooves of sufficient depth are placed at 45 deg. to the axis of the bar, the upper yield point practically disappears.

(*c*) *The Effect of Notches in Test Piece.* In the first part of the

paper, the effect of notches on the magnitude of the lower and upper yield stresses was discussed. From the autographic curves shown in Fig. 16, it can be readily seen that the notches do not only affect the magnitude of the stresses, but also the magnitude of the deformation. It is therefore the intention for the remainder of the paper to describe in more detail how the notches have affected the deformations.

In order to facilitate the discussion of this question, it will be worth while to define in a short manner a certain quantity which will be repeatedly referred to. To show the effect of notches on the deformations at the yield point, it will be necessary to measure the projection of a certain line on the abscissa of the stress-strain diagram. This line consists in that portion of the stress-strain curve extending from the upper yield point to that point on the curve at which the load starts to rise to its maximum value.

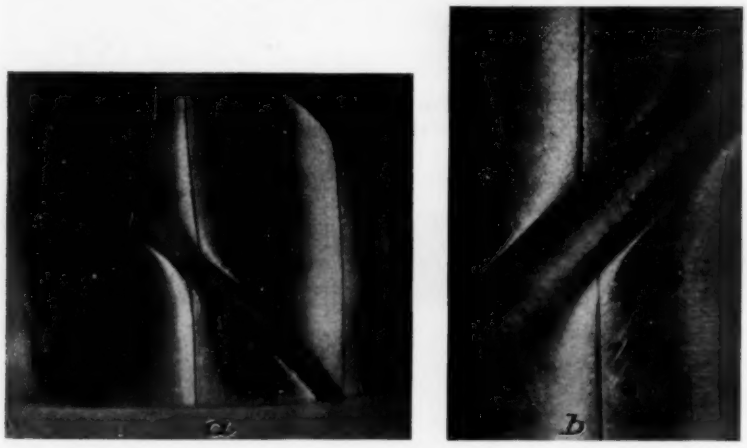

FIG. 14 CYLINDERS WITH HELICAL GROOVES AFTER DEFORMATION SHOWING RELATIVE SLIPPING OF MATERIAL ON EACH SIDE OF GROOVE

(*a*, view of entire test piece; *b*, close-up view of material near the groove.)

The projection of this line on the abscissa is indicated by *A-B* in Fig. 16. Hereafter, this length will be referred to as *A-B*.

For the investigation of the per cent elongation of the length *A-B* with various widths of notches, tensile tests were made on seven bars. Five of these bars contained notches as shown in Fig. 18; the other two were of a uniform cross-section such as type *a*, Fig. 7. The load-deformation diagrams for these bars have already been shown in Fig. 16. The elongation of *A-B* was measured with the Martens extensometer, the knife edges resting on the section of the bar of larger diameter than that in the notch, with the comparison strips spanning the notch. The value of the elongation of *A-B* contributed by the cylindrical portion of the notch in each bar was then estimated. It was possible to obtain this value of elongation for *A-B* without knowing how much of the total value measured between the knife edges was taken up in the fillets, etc. This becomes apparent from consideration of Fig. 18, bar No. 15. The total elongation between *X* and *Y* on bar No. 15 to the upper yield point *A* of Fig. 16 consists approximately of an elastic elongation in each of the regions *L*, *M*, and *N*. After the upper yield point has been passed and the bar has stretched to point *B*, the regions *L* and *N* are still sensibly elastic, and their elongations have not changed appreciably, since the load is still about the same. Region *M*, however, has both an elastic elongation, and in addition the plastic portion consisting of *A-B*, Fig. 16. If now the total elongation measured between *X* and *Y* to the upper yield point *A* and after the upper yield point is passed to point *B* are subtracted from each other, the result is the average plastic elongation in the notch, or *A-B*. This elongation so found for each test piece was then divided by the cylindrical length of its respective notch, and the average per cent elongation plotted as a function of the length of notch in Fig. 17.

In referring to this latter figure, it is noticed that the per cent elongation of *A-B* decreases as the length of notch increases until a certain length of notch has been reached. For short notches the lateral contraction of the cross-section is prevented. Thus, as the length of notch is increased, the gage length is increased at a faster rate than the amount of elongation, causing a decrease in per cent elongation. This effect continues until such a length of notch is reached that the prevention of lateral contraction of the test piece in the notch is no longer very effective over a larger portion of it. From this point on, as the length of notch is further increased, material is being added which is doing the same amount of extending in per cent as for the bar of uniform cross-section. Hence for bars with long notches, the per cent elongation of the quantity *A-B* approaches the case of the bar with a uniform cross-section, as shown in Fig. 17.

In order to get a clearer picture of how the per cent elongation changes in the neighborhood of the notch, tests were made on some flat rubber models of the bars shown in Fig. 18. After stretching these rubber models a certain amount, the per cent elongations were measured, both along the outside edges and along the middle. Fig. 19 shows the variation of the per cent elongation along the notch for a rubber test piece with a groove of 1 in. length, and it can be readily seen that the per cent elongations in the notched portion were far from uniform. This shows the effect of the prevention of lateral contraction in the portion of the bar of smaller diameter.

SUMMARY

A brief discussion has been given of the yielding of mild steel, together with a brief review of a few of the important investigations which have been carried on relative to the upper and lower yield points.

The effects on the yield point of velocity, type of head on the test piece, different kinds of cross-sections, etc. were briefly described.

To this discussion were added tests both in tension and compression, to show the effect of scratches and grooves on the upper yield point. It was found that small grooves and scratches perpendicular to the bar axis did not appreciably affect the upper yield stress.

However, if grooves were placed at 45 deg. to the axis of the bar, there resulted a marked change in the shape of the stress-strain curve in the neighborhood of the yield point. The upper yield stress was also greatly reduced.

Tests were also included to illustrate how the sharpness of transition from the elastic to the plastic state affected the resulting Lueders lines. It was found that materials having a sharply defined yield point showed the best slip layers.

Finally, tests on notched bars were described showing the effect of notches on the per cent elongation of a portion of the stress-strain diagram after the upper yield point has been passed.

ACKNOWLEDGMENT

The author wishes to acknowledge the valuable aid given him by Dr. A. Nádai, who has supervised the investigation. Acknowledgment is also due Mr. J. M. Lessells for encouragement of the work and to Mr. P. G. McVetty and Mr. K. R. Waugh for assistance in the various tests.

Discussion

GEORGE C. PRIESTER.[26] It is pleasing to note that the author has demonstrated the fact that there exists an upper and a lower yield point. Most American engineers assume that the stress-strain diagram is always a horizontal line representing the unit stress at the upper yield point. This is not the case for our ordinary low-carbon bessemer or open-hearth steel. The writer has tested many specimens of hot-rolled steel bars, round, square, and rectangular, in cross-section, and has obtained autographic stress-strain diagrams similar to type *a* in Fig. 8. The specimens were not polished or machined, but still retained the mill scale over their entire length. From this it is evident that the polishing of the specimen is not a factor in producing this type of a stress-strain diagram.

The writer has also carried out tests on bars of rectangular cross-section in which holes had been drilled perpendicular to the axis of the bar. The stress-strain diagram for these specimens were similar to type *d*, Fig. 8, of the author's paper. In test pieces in which there was placed a series of holes along the axis of the bar, the stress-strain diagrams were similar to the author's diagrams shown in Fig. 16. The shape of the diagrams varied when different-sized holes were drilled in the specimen.

The author should be commended for his valuable contribution to the study of plastic flow in mild steel. It is hoped that he may find it possible to continue his studies along this line.

J. A. VAN DEN BROEK.[27] The paper raises a number of queries. The first one is on terminology. In the title there occurs the term "yield point." In the fourth line of the first page the author introduces the term "plasticity." Furthermore, by implication, he seems to suggest substituting the term "limit of plasticity" for the well-tried term "yield point" and the word "plasticity" for the good old English word "ductility." The writer cannot help but wonder whether a certain German influence is not responsible for this change in our terminology. It may be that the German language has but one word, "plastizität," by which it describes the property of modeling clay as well as the property of mild steel when stressed past the yield point. The writer's objection is twofold. In the first place, the author thus blurs a useful distinction, and in the second place, he impoverishes our language by rejecting the term "ductility" and by making the word "plasticity" less explicit.

Further, when the author speaks of the limit of plasticity, why not mention a third limit? It would appear that what is meant in the paper by plasticity is what is graphically represented by the horizontal part of the stress-strain curve. How about the right extremity of this horizontal portion of the stress-strain curve? And further, how about the point S_1 on Fig. 1? The writer understands that there are two terms to describe the stress condition represented by S_1, Fig. 1—namely, elastic limit and proportional limit. He fails to see any gain in offering some more terms, such as upper yield stress. On the first page, first column, line 16, the author states that in "columns and beams, buckling is likely to occur if they are stressed above the yield point." The writer had the idea that the essential characteristic of buckling of columns is that it occurs within elastic-limit stresses.

In 1918 the writer published the results of some 250 tests on mild steel in the Carnegie Scholarship Memoirs of the British Iron and Steel Institute, Vol. 9. This paper was also published in *Engineering*, July 26, 1918.

[26] Professor of Materials of Engineering, University of Minnesota, Minneapolis, Minn.

[27] Professor of Engineering Mechanics, University of Michigan, Ann Arbor, Mich.

The writer was very much interested in the amorphous-cement theory as an explanation of the effects of cold-working on the elastic properties of steel. In 1918 he found Bauschinger's classic experiments of 1886 uniformly misinterpreted in American and English literature. Some of this misinterpretation persists till this day. See Rosenhain, in his "Physical Metallurgy," 1914, page 247. See also page 15 of the writer's paper referred to and also page 18, from which is quoted, "If the contentions set forth in this paper are correct, it would appear that the strongest evidence Rosenhain mentions against the validity of his favorite amorphous-cement theory is invalid." Pertinent matter may be found on page 27, "Tests on Steel Balls."

The paper mentions the fact that the specimens used were very highly polished. On the third page, second column, is discussed the effect of surface conditions, yet the author neglects to attribute any weight to the highly polished surface. It would seem that, after the thousands of stress-strain curves of mild steel recorded during the last 60 years, little need exists for recording still more unless new features are brought out and attempts are made to explain such new features. The writer regards Fig. 9, which shows an upper yield stress 66 per cent higher than the lower yield stress, as uncommon to say the least. He does not deny that they may be obtained. On the second page, second column, the author says, "The question of whether to use the upper or lower values of stress as a limit is in many countries not definitely settled." So far as the bridge-engineering and building-engineering professions in America are concerned, the writer offers without much fear of contradiction by any one in responsible charge of designing of either bridges or skyscrapers the statement that the question is quite definitely settled. It is recognized that by special test a condition may arise similar to one in a supercooled liquid, or possibly similar to the difference manifested by static as against dynamic friction. The writer does not believe that the American bridge engineer, one of the greatest users of mild steel, will accept the curve in Fig. 9 as representative of the behavior of material in his structure as a train thunders over it. The writer further feels that, in his efforts to eliminate concentration of stresses, the author has coated his specimens with a layer of exceedingly tough, amorphous steel which materially affects the behavior of the specimen. Witness the results the writer obtained with his tests on steel balls previously quoted. The tests recorded then are not so much representative of mild steel as the title of the paper leads one to suppose, but are tests of steel bars consisting of mild steel in the core, which core is effectively supported by polished steel, or amorphous steel, or intercrystalline steel, whichever term one prefers, on the surface.

R. E. PETERSON.[28] A series of tests of grooved specimens is described in which the width of the groove is varied. It is not quite clear what happens when the notch width becomes zero—in other words, a circumferential crack. From Fig. 17 it is not apparent what the percentage elongation of *A-B* becomes at zero width of groove. If total elongation of *A-B* is plotted, the origin may be used as a point on the curve.

A series of fatigue tests was made by the writer some time ago in which circumferential cracks were produced in the test specimens by a method suggested by P. G. McVetty. A very narrow and deep groove was turned in a bar, which was then heated and compressed axially to close the groove and thus form an artificial circumferential crack. A few tensile tests were also made. These tests indicate that failure is of a triple-tension type, producing a fracture of crystalline appearance. No apparent yielding occurs, and it is suggested that the stress at breaking is

[28] Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

the cohesion strength[29,30] of the material and further that all ordinary strength properties (elastic limit, upper and lower yield points, true ultimate strength) approach the cohesion strength as a limiting value as the width of groove approaches zero. These are, of course, suggestions, and it is hoped that further tests will be made along this line.

A. NÁDAI.[31] The various interesting phenomena accompanying the yield point of mild steel as observed or determined in the standard tensile testing methods and the various factors which seem to have an influence on the magnitude of the stress under which the first permanent deformations of considerable magnitude in steel are produced, deserve perhaps more attention than they have found until now. To the Verein deutscher Eisenhüttenleute in Düsseldorf is due the credit of having stimulated a number of investigations several years ago among the engineers with the aim to determine the various mechanical and thermal factors which have an influence on the magnitude of the yield stress of mild steel. The main results of these investigations are contained in a number of valuable reports mentioned in the paper. Among these, particular attention may be called to the valuable contributions contained in the investigations of P. Ludwik,[32] M. Moser,[2] and F. Körber.[3] In these recent investigations and in tests made by other experimenters not quoted here, many points have been brought out concerning the conditions that have an influence on such an important mechanical material constant as the stress under which the permanent deformations start to develop in mild steel. It has been shown that besides the carbon content, which has its primary influence on the shape of the stress-strain curve at normal temperatures, a number of other factors must be taken into account for a more exact determination of the yield stress of steel.

The influence of notches and of local stress concentrations in a tensile-test specimen on the upper yield point has been particularly studied by the author. It is a noteworthy result of his tests that he has carefully tried to correlate the occurrence of the drop of the load so characteristic for mild steel at the yield point to the appearance of the flow or strain figures.

The yield point or yield stress as a mechanical characteristic and as an expression of one of the important qualities of steel will mean more for the designer and the engineer, who must base their calculations on certain standard quantities, if they will keep in mind, together with the limiting stress values, the more important mechanical behavior of the steel chosen for a given purpose. The engineer should perhaps not be satisfied to know that his working stresses are well below one or the other of the material constants on which, according to our present knowledge, he must base the dimensions in his constructions. He should consider rather the whole behavior of the material, as read from the stress-strain diagram, and should take into account all those factors described in the paper and in the references mentioned above. These various factors have a definite influence on the magnitude of the yield stress and on the shape of the transition curve from the purely elastic state to the plastic state of steel. A more complete study of the various modes of yielding will help finally to establish a more satisfactory knowledge of the factors limiting dimensions of machine parts in design than a more or less rigid adherence to a limiting stress or a similar material constant.

Apart from the points reported in the paper, there are a number of other questions which may still be investigated in connection with the yield stress. One or two of these points may briefly be touched here.

It has been shown by P. Ludwik that age hardening has a great influence on the upper yield stress. He has shown that a comparatively small change of the temperature after a first tensile test may raise considerably the upper yield stress in a subsequent test. In this connection some further results obtained by W. Koester,[33] which point to the nitrogen content in steel as a determining factor of the magnetic age hardening, should be mentioned here. Small quantities of nitrogen (0.005 to 0.01 per cent) which can be dissolved in steel or precipitated from it under various conditions seem not only to produce these variations (for example, magnetic aging) but also to affect the developing of the dark lines by Fry's etching solution. On this point further work is in progress at the Research Laboratories of the Westinghouse Company.

As a last point, which might perhaps also need further investigation, should be mentioned the study of the conditions of stability in various testing methods. As was observed long ago by Considère and a number of other investigators, the static equilibrium in a test bar subjected to pure tensile stresses becomes unstable. Under certain conditions when the load-extension curve reaches an analytical maximum (a test bar at the upper yield point is in such a condition), an unstable state of equilibrium results. It would be interesting to discuss the mechanical conditions of the equilibrium, or rather the dynamic conditions while the equilibrium is disturbed, after the upper yield point has been reached and during the period in which the stress decreases from the upper to the lower yield stress.

From the metallurgical side some points deserve further investigation. For example, the strength of the boundary substance lying between the grains in the structure of mild steel influences the yield point. There are indications that to the excessive strength of the boundary substance enclosing the soft ferrite grains in mild steel may be attributed the cause for the sharp break in the stress-strain diagram at the yield point of mild steel.

AUTHOR'S CLOSURE

The author wishes to thank Professor Priester for further emphasizing several important points brought out in the paper. It is interesting to hear that he has made tests which corroborate and check the results reported in the paper. The tests which he made show very plainly that the polish on the specimen has nothing to do with producing the peak in the stress-strain curve. In regard to the tests mentioned on flat bars with holes drilled perpendicular to the axis, local yielding in the formation of slip layers prevented the attainment of a high peak, and in this respect should produce diagrams similar to the notched-bar tests results plotted in Fig. 16. It is interesting to note that Professor Priester's tests check this observation.

With regard to Professor Van den Broek's remarks concerning the terminology used in the paper, the author wishes to say that the term "yield point" was employed throughout in the majority of cases, and was not discarded for another term. The expression "limit of plasticity" was used in certain cases in order to differentiate between the actual physical phenomenon taking place and that arbitrarily defined quantity corresponding to an arbitrary percentage of elongation. As was mentioned in the paper, the subject treated here deals only with that yield point which expresses a natural limit or a physical property of the material, and not with that stress which is based on an arbitrary

rule. The term "limit of plasticity" expresses clearly and exactly what type of yield point we are then dealing with, and excludes the possibility of confusion with such conventional definitions as are used in the testing of materials. The upper yield point is in truth the limit of plasticity of the material. The term "limit of plasticity" expresses the fact that in such

metals as mild steel the permanent deformations begin to become of a large magnitude at this stress. This term is not a new one in the English language or in other languages, and the author does not claim in any respect to be responsible for originating it. At the present he has on his desk a few of the Engineering Index Service cards, and on looking through them he found the word "plasticity" mentioned several times. The term "limit of plasticity" may be found, for instance, on card number 25,458, serial No. 31, of recent publication, and also in a large number of recent publications which cannot be listed here. However, to further clear up this point the author would like to call to Professor Van den Broek's attention the statement on the first page of the paper: "It is not the purpose of this paper to analyze the conventional methods of defining the yield point or to present new definitions in this connection." It was more the intention to contribute to the physical knowledge of the various conditions which have been found to have an influence on the magnitude of the yield stress in mild steel.

Concerning the word "ductility," the author preferred not to apply this word in this connection on account of the various meanings which are generally attributed to it in the testing of materials.

Professor Van den Broek also states that "there are two terms to describe the stress condition represented by S_1, Fig. 1, namely, elastic limit and proportional limit. He (the writer) fails to see any gain in offering some more terms such as upper yield stress." Here the author wishes to remark that the terms "elastic limit" and "proportional limit" were not used for a similar reason as was stated above for the word ductility. Again, the author does not claim to introduce a new term in using the expression "upper yield point." This term appears to have been introduced by C. von Bach, as was mentioned earlier in the paper, and has been used very frequently since that time.

Concerning Professor Van den Broek's remark regarding the buckling of beams, the author wishes to point out that the statement referred to in the paper in the first column of the first page refers to the well-known theory of buckling after the yield point has been passed. The phenomenon of the buckling of columns and beams is not confined to purely elastic deformation, as several cases have been treated in the technical literature in which buckling occurs after the yield stress has been passed.[34]

In the oral discussion Professor Van den Broek brought up the fact that the stress-strain curves included in the paper seemed to be of an unusual shape. With regard to this, the author believes that this may perhaps best be answered by reference to a large amount of work already done in this same field. This previous work is described in the various papers published by M. Moser, F. Körber, W. Kuntze, G. Sachs, P. Ludwik, R. Scheu, C. von Bach and others which were referred to in the paper itself. These various publications contain many stress-strain curves for mild steel having the same shape and form as those included in this paper, which indicates that they are not of an unusual shape but are the same as those usually received for mild steel.

The author would like to also point out in this connection that the type of testing machine used plays an important part in the determination of the lower yield point. The hydraulic testing machine with a continuous equilibrium of the force-measuring device provides a much quicker determination of this lower yield point than does the beam-type machine. If the beam-type machine has been used by Professor Van den Broek, this may perhaps account to a certain extent for his difficulty in observing this drop in load at the yield point.

The question of the effect of the polish on the test bar on the behavior of the specimen is next discussed by Professor Van den Broek. It is believed by him that in polishing the test bars so highly, the bars were thus coated with a layer of tough, amorphous steel which seriously affected the behavior of the specimen. In other words, he believes that the steel bars were mild at the core, but that the core was supported by the amorphous steel which changed the behavior of the material under stress. Professor Priester mentioned several tests which he had made on hot rolled bars having a heavy mill scale on them. He obtained

[34] For a discussion of some of these cases see A. Nádai, "Der Bildsame Zustand der Werkstoffe," J. Springer, Berlin, 1927, p. 128, and also H. M. Westergaard and W. R. Osgood, "Strength of Steel Columns," Trans. of A.S.M.E., vol. 49–50, p. 65.

stress-strain curves similar to that shown for the highly polished bar, type *a* in Fig. 8. This shows clearly, then, that the polish had no appreciable effect on the behavior of the material.

In order to further check this since the paper was presented, several different tests have been made, as this question is rather important.

First a round bar of mild steel of type *a* was machined, and then annealed in the customary manner at 900 deg. cent. The annealing produced a heavy oxide scale over the test piece as shown in Fig. 20. This scale was left on the bar, and it was tested in this condition. The autographic diagram is shown in Fig. 21. This shows that even with an unpolished bar that has only a heavy oxide scale over the surface, the same type of stress-deformation curve is obtained as with the highly polished bar in Fig. 8 and having a high peak of similar magnitude. Second, five round tensile-test bars were made similar to the one shown in Fig. 22. Three of these were highly polished, one was well machined but not polished, and one was only roughly machined and not polished. Two of the three well-polished test pieces were placed in concentrated hydrochloric acid for 1 hour and $1^1/_2$ hours, respectively. In both cases the polish was completely removed by the acid. When these bars were tested, stress-deformation diagrams were obtained as shown in Fig. 23. The results of the tests are tabulated in Table 3. It was found that there was no difference in the values of upper yield point obtained for the highly polished bar and the unpolished but well-machined bar. The rough-machined bar showed a small decrease in the upper yield point due to the presence of a large number of stress concentrations produced by the lathe tool. This effect in reducing the upper yield point is somewhat similar to that produced in the grooved flat bars, type *d*, mentioned in the paper, but of smaller magnitude. Slip layers form at the grooves in both cases, and local yielding reduces the upper yield point. The effect of the etching on the polished bars was of a similar nature. Minute stress concentrations here also tended to slightly reduce the upper yield point. In all of the cases, however, Fig. 23 shows essentially the same type of high peak with sudden drop in load, indicating that the polish had no effect whatsoever in producing the peak. An additional test was made to further emphasize this. A cylinder of hard-drawn copper was annealed at 500 deg. cent. for two hours and then tested in compression. The copper was quite soft after this annealing treatment. The deformation was measured by means of two dial gages. When a load of 20,000 lb. was reached, the cylinder was unloaded, and the deformation was also measured during unloading. The cylinder was then polished highly on the lathe and reloaded. The stress-strain curve obtained is shown in Fig. 24. According to what was said, if polishing had any effect on increasing the load, there would be a sudden discontinuity in the curve at the point *A* in the figure. None was obtained on reloading in this case, however, since the curve continued along the same path it was traveling before being interrupted by unloading.

From these various tests it seems apparent, therefore, that polishing had no effect in producing the peak in the stress-strain curves as thought by Professor Van den Broek.

Further, in regard to Professor Van den Broek's compression tests to determine the crushing strength of steel balls, it might be said that the results of these tests could hardly be applied here to the yield point, since the crushing strength in such cases is governed by a very complicated three-dimensional stress distribution, and depends besides more on the ultimate or breaking strength than on the yield point determined in simple tension.

It was mentioned in the oral discussion by Professor Timoshenko that through certain precautions the yield point could be raised even to the ultimate strength of the material. This no doubt refers to Ludwik's age-hardening tests. The author would also like to add in this connection that such precautions as the careful design of the test piece in order to prevent

[(1) Highly polished bar. (2) Well-machined bar, not polished. (3) Rough-machined bar, not polished. (4) Same as (1) but etched in HCl for 1 hr. (5) Same as (1) but etched in HCl for $1^1/_2$ hr.]

TABLE 3 RESULTS OF TESTS ON FIVE DIFFERENT TENSILE TEST BARS WITH A VARIETY OF SURFACE CONDITIONS

(All bars included here were round of the type shown in Fig. 22.)

Type of test bar	Upper yield stress, lb. per sq. in.	Lower yield stress, lb. per sq. in.	Diff. between upper and lower yield points, lb. per sq. in.
Highly polished bar	37,900	28,400	9,500
Well-machined bar (no polish)	37,900	28,200	9,700
Roughly machined bar (no polish)	35,700	28,900	6,800
Well-polished bar etched for 1 hr. in conc. HCl	35,400	28,600	6,800
Well-polished bar etched for $1^1/_2$ hr. in conc. HCl	36,000	28,600	7,400

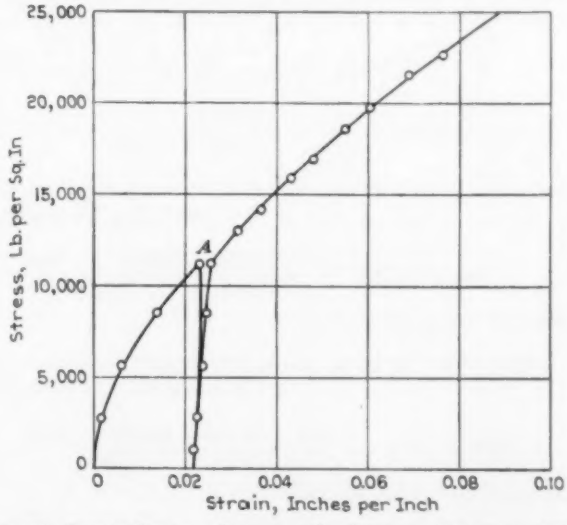

FIG. 24 STRESS-STRAIN CURVE FOR COPPER CYLINDER WITH REPEATED LOADING

stress concentrations is very important to attain this high peak. If a test bar has sharp fillets between the head and the cylindrical length, both M. Moser and F. Körber have shown that the peak will be greatly reduced, as was mentioned earlier in the paper.

A very important additional point was brought out in the discussion by Dr. Nádai, in that the designing engineer should keep in mind not only the value of the yield stress, but also the various factors affecting it. In doing this the engineer will arrive nearer to the true condition present in his structure. It is also to be noted that Dr. Nádai has indicated a number of other interesting questions in this connection which may still be investigated, and it is hoped that more research will thus be stimulated in this field.

It was pointed out by Mr. Peterson that it is not apparent from Fig. 17 what the percentage of elongation of $A - B$ becomes at zero width of groove. This fact is indeed true. The author, however, was more interested in the percentage of elongation as used in the ordinary stress-strain curve than in total elongation in an effort to compare the actual lengths of the portion $A - B$, as would be shown in the diagram. The total elongation, if plotted, would pass through the origin, as was suggested by Mr. Peterson.

APM-53-16

Stresses in Curved Bars

By H. C. PERKINS,[1] ITHACA, N. Y.

Because of the difficulty of computing accurately the stresses in curved bars by the ordinary method, the author has derived simple formulas which give sufficiently reliable results with the use of a slide rule. The paper sets forth these derivations and gives several examples of the application of the formulas.

CURRENT methods of computing stresses in curved bars are complicated and, unless carried out with extreme care, likely to give inaccurate results. It is the object of this paper to describe simpler methods and to propose formulas which will give reliable results with the use of a slide rule. Statement of the formulas will be followed by illustrative applications, after which the methods of derivation will be described.

Fig. 1 shows part of a curved bar above the cross-section GH in equilibrium under the action of a load P and the stress on the cross-section GH. The plane of the cross-section GH passes through the axis of curvature O of the centroidal axis of the bar. The load P is applied in a plane of symmetry of the bar and perpendicular to the cross-section GH. In this figure and in Figs. 2 and 3, let

R = radius of curvature of the centroidal axis of the bar
A = area of the cross-section GH
dA = area of an elementary strip
S = unit normal stress on the element dA
r = radius from O to the element dA
v = distance from centroidal axis of A to element dA
x = distance from neutral axis ($S = 0$) to element dA
(both v and x are positive when measured toward O)
x_1 = distance to centroidal axis from neutral axis
M = moment of P about the centroidal axis of A
M_0 = moment of P about the axis of curvature O
h = radial depth of the cross-section, and
n = the ratio R/h of centroidal radius to depth of section.

The proposed formula for unit stress at any point in the cross-section is

$$S = \frac{P - \frac{M}{R}}{A} + \frac{M}{RF}\frac{v}{r} \qquad [1]$$

in which

$$F = \int \frac{v}{r}\,dA$$

The limits of integration are such as to include the entire area A. Since F appears in the denominator of the expression for bending stress and its units are those of area, F may be called the effective area of the cross-section for bending about the centroidal axis, or simply "the effective area."

Convenient Approximate Formulas

Integration yields such awkward forms for F that the following formulas are to be preferred both for convenience and probable accuracy of result, provided that the least value of r for the given section is greater than one-tenth of the depth of section h. This limit is seldom likely to be exceeded.

For the effective area of a rectangle use

$$F = \frac{An^2}{12(n^2 + 0.04)(n^2 - 0.188)} \qquad [2]$$

The value of n should not be less than 0.6.

For the effective area of a circular or elliptical section use

$$F = \frac{An^2}{16(n^2 + 0.035)(n^2 - 0.161)} \qquad [3]$$

The value of n should be not less than 0.6.

For the effective area of a triangular section, base parallel to the axis of curvature, vertex directed toward the axis of curvature, use

$$F = \frac{A}{18(n^2 - 0.145)} + \frac{A}{135\,n(n^2 - 0.342)} \qquad [4]$$

The value of n should not be less than 0.77.

Examples

Example 1. To illustrate the use of these formulas, consider the curved bar in Fig. 4. Compute the maximum unit normal stress on the cross-section GH, which is circular. $P = 5000$ lb., $A = 12.57$ sq. in., $R = 4$ in., $h = 4$ in., $n = 1$, $M = 40{,}000$ lb-in., and $M/R = 10{,}000$ lb.

To evaluate F, use Equation [2], or

$$F = \frac{12.57(1)}{16(1 + 0.035)(1 - 0.161)} = 0.904 \text{ sq. in.}$$

The maximum tensile stress is at H. Substituting this value in Equation [1] and taking $v = 2$, $r = 2$

$$S = \frac{5000 - 10{,}000}{12.57} + \frac{10{,}000\,(2)}{0.904\,(2)} = -398 + 11{,}050$$
$$= 10{,}652 \text{ lb. per sq. in. tension}$$

The maximum compressive stress is at G. Substituting in [1], with $v = -2$ and $r = 6$,

$$S = \frac{5000 - 10{,}000}{12.57} + \frac{10{,}000\,(-2)}{0.904\,(6)} = -398 - 3685$$
$$= -4083 \text{ lb. per sq. in. compression}$$

In case the section is a composite of several standard parts, such as a T-section composed of two rectangular parts, it is necessary to obtain the effective area of each part for bending about the centroidal axis of the complete section. The effective

---

[1] Assistant Professor of Mechanics of Engineering, Sibley School, Cornell University. Mr. Perkins received the M.E. degree from Cornell University in June, 1915. After a year as machinist in the toolroom of the Morse Chain Works at Ithaca, N. Y., he was appointed instructor in mechanics in Sibley College. He was for one year instructor in the Department of Heat Power in Sibley College and one year as instructor in the Department of Mechanics of the University of Wisconsin.

Contributed by the Applied Mechanics Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

area of the composite section is then equal to the sum of the effective areas of the parts when referred to this axis.

$$F = F' + F'' + \ldots \quad [5]$$

To find the value of the effective area F' for bending about an axis at radius R', from the area A_1 whose centroid is at radius R_1 and whose effective area is equal to F_1, use the formula

$$F' = \frac{F_1}{R_1} R' + \frac{A_1}{R_1}\left(R' - R_1\right) \quad [6]$$

Example 2. To illustrate the use of formulas [5] and [6], find the maximum unit normal stress on the T cross-section

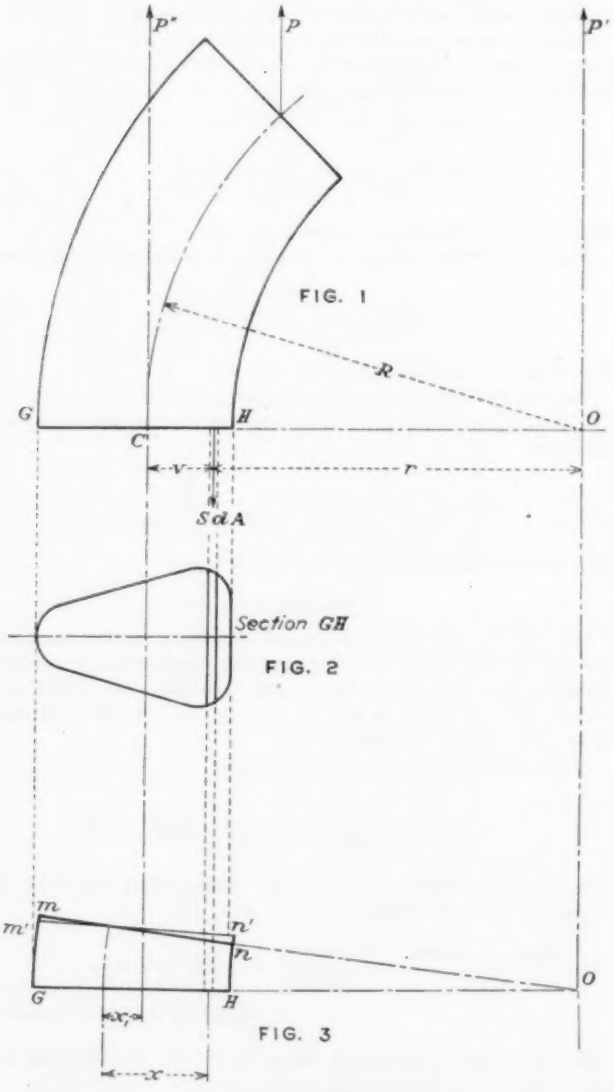

FIG. 1

FIG. 2

FIG. 3

FIGS. 1–3

of Fig. 5 when $P = 4000$ lb. For the rectangle at the left, $A_1 = 6$ sq. in., $R_1 = 6$ in., $h_1 = 6$ in., and $n_1 = 1$. From [2]

$$F_1 = \frac{6\ (1)}{12(1 + 0.04)(1 - 0.188)} = 0.592 \text{ sq. in.}$$

Transferring to the combined axis, $R' = 4.6$ in., and using Equation [6],

$$F' = \frac{0.592}{6}\left(4.6\right) + \frac{6}{6}\left(4.6 - 6\right) = -0.946 \text{ sq. in.}$$

For the rectangle on the right, $A_2 = 4$ sq. in., $R_2 = 2.5$ in., $h_2 = 1$ in., and $n_2 = 2.5$, whence

$$F_2 = \frac{4\ (6.25)}{12(6.25 + 0.04)(6.25 - 0.188)} = 0.0547 \text{ sq. in.}$$

Transferring to the combined axis, $R'' = 4.6$ in.,

$$F'' = \frac{0.0547}{2.5}\left(4.6\right) + \frac{4}{2.5}\left(4.6 - 2.5\right) = 3.467 \text{ sq. in.}$$

The effective area of the T-section is therefore

$$F = F'' + F' = 3.467 - 0.946 = 2.52 \text{ sq. in.}$$

and the maximum tensile stress, for which $v = 2.6$ in., and $r = 2$ in., is, from Equation [1],

$$S = \frac{4000 - 7480}{10} + \frac{7480\ (2.6)}{2.52\ (2)} = -348 + 3860$$
$$= 3512 \text{ lb. per sq. in.}$$

For the maximum compressive stress, $v = -4.4$ in., and $r = 9$ in., so

$$S = \frac{4000 - 7480}{10} + \frac{7480\ (-4.4)}{2.52\ (9)}$$
$$= -348 - 1452 = -1800 \text{ lb. per sq. in.}$$

Example 3. As a further illustration, consider the hook described in article 133 of Morley's "Strength of Materials." The section is trapezoidal as shown in Fig. 6. $P = 1.25$ tons applied through the axis of curvature O, $A = 3.375$ sq. in., and $R = 3$ in. Regard the trapezoid as composed of two parts, a positive rectangle 2 in. $\times$ 2.25 in., and two negative triangles (treated as one part) each of 0.5 in. base $\times$ 2.25 in. altitude. For the rectangle, $A_1 = 4.5$ sq. in., $R_1 = 3.125$ in., $n_1 = 3.125/2.25 = 1.389$, and $n_1^2 = 1.929$. Substituting in Equation [2],

$$F_1 = \frac{4.5\ (1.929)}{12(1.929 + 0.04)(1.929 - 0.188)} = 0.2109 \text{ sq. in.}$$

Transferring to the axis of the trapezoid, using Equation [6],

$$F' = 0.2109\ \frac{3}{3.125} + \frac{4.5}{3.125}\left(3 - 3.125\right) = 0.2027 - 0.18$$
$$= 0.0227 \text{ sq. in.}$$

For the triangles together, $A_2 = -1.125$ sq. in., $R_2 = 3.5$ in., $n_2 = 3.5/2.25 = 1.556$, and $n_2^2 = 2.42$. Substituting now in [4]

$$F_2 = \frac{-1.125}{18(2.42 - 0.145)} + \frac{-1.125}{135(1.556)(2.42 - 0.342)}$$
$$= -0.0275 - 0.00258 = -0.0301 \text{ sq. in.}$$

Transferring to the axis of the trapezoid, using Equation [6],

$$F'' = (-0.0301)\ \frac{3}{3.5} + \left(-1.125\right)\frac{(3 - 3.5)}{3.5} = -0.0258$$
$$+ 0.1607 = 0.1349 \text{ sq. in.}$$

The effective area of the trapezoid is then

$$F = 0.0227 + 0.1349 = 0.1576 \text{ sq. in.}$$

The maximum tensile stress occurs where $v = 1$ and $r = 2$. Substituting in Equation [1] $P = 1.25$ tons, $M = 1.25 \times 3$ ton-in., and $M/R = P = 1.25$ tons,

$$S = \frac{1.25 - 1.25}{3.375} + \frac{1.25\ (1)}{0.1576\ (2)} = 0 + 3.97 \text{ tons per sq. in.}$$

The maximum compressive stress occurs where $v = -1.25$ and $r = 4.25$ in., or

$$S = \frac{1.25 - 1.25}{3.375} + \frac{1.25(-1.25)}{0.1576(4.25)} = -2.33 \text{ tons per sq. in.}$$

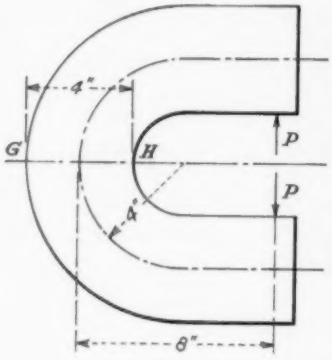

FIG. 4

These stresses differ from Morley's by about three per cent. It is an unexpected demonstration of the comparative reliability of the new formulas to discover that the error is in Morley's numerical work. Computing the value of A' from his figures, $A' = 3.5328$, so that his value for the effective area should be $A' - A = 0.1578$ sq. in., which makes the unit stresses, respectively, 3.96 and 2.33 tons per sq. in. The magnitude of the error is of course too small to affect the practical value of the result, but it does demonstrate that the older formulas are very sensitive to small errors of computation and likely to yield inaccurate results.

DERIVATION OF EQUATION [1]

Fig. 3 represents a short portion of the bar included between two successive cross-sections GH and (before loading) mn. After loading, the section mn has rotated about its neutral axis into a new position $m'n'$, thus extending each longitudinal fiber of the bar in proportion to its distance x from the neutral axis. The original length of each fiber is proportional to its distance r from the axis of curvature O, so the unit deformation of each fiber is proportional to the ratio x/r. Within the elastic limit, unit stress is proportional to unit deformation, so, in terms of a constant of proportionality K,

$$S = K\frac{x}{r} \qquad [7]$$

For equilibrium, the moments of all forces in Fig. 1 taken about the axis O must be equal to zero, or

$$M_0 = \int rS\,dA = K\int x\,dA = Kx_1A$$

One conclusion to be drawn from this equation is that the action line of a load P', which bends the bar in such a way that the neutral axis passes through the centroid of A, must pass through O for $x_1' = 0$, consequently $M_0' = 0$. Since $x' = v$ for this case, Equation [7] may be written

$$S' = K'\frac{v}{r} \qquad [8]$$

Summing vertical components of the forces applied to the bar

$$P' = K'\int \frac{v}{r}\,dA = K'F$$

in which the value of the integral F depends only upon the form of a given curved bar. Solving for K' and substituting in [8],

$$S' = \frac{P'}{F}\frac{v}{r} \qquad [9]$$

To make use of this result, resolve P in Fig. 1 into two parallel components, P' acting through the center of curvature, and P'' acting through the centroid of the cross-section. Writing moments about C, $P'R = M$, so

$$P' = \frac{M}{R}$$

and, from a force summation,

$$P'' = P - \frac{M}{R}$$

Since P'' acts through the centroid of A, it produces a uniform stress at all points of the cross-section, or

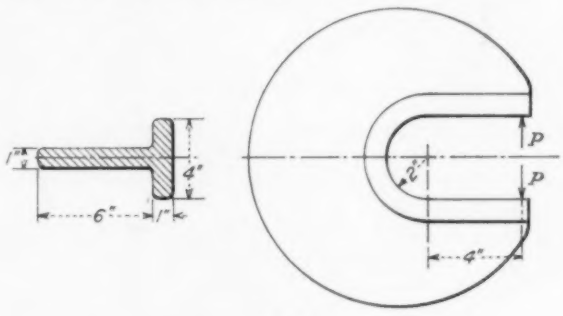

FIG. 5

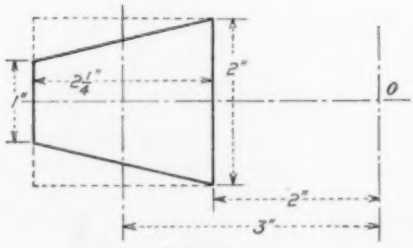

FIG. 6

$$S'' = \frac{P - \dfrac{M}{R}}{A}$$

Substituting the value of $P' = \dfrac{M}{R}$ in [9],

$$S' = \frac{Mv}{RFr} \qquad [10]$$

The stress at any point in the cross-section may now be written in the desired form.

$$S = S'' + S' = \frac{P - \dfrac{M}{R}}{A} + \frac{Mv}{RFr} \qquad [1]$$

DERIVATION OF EQUATIONS [2], [3], AND [4]

For a rectangular cross-section, area $= A$, depth $= h$, and radius from center of curvature to centroid $= R$, a value of F may be found by integration:

$$F = \frac{A}{Rh}\log\left(\frac{R + \frac{h}{2}}{R - \frac{h}{2}}\right) - A \qquad [11]$$

This expression requires careful calculation with the aid of tables and is quite unsuited to use with a slide rule. The more convenient form [2] may be obtained as follows. Expand [11] in the form of a series, or

$$F = \frac{Ah^2}{12R^2} + \frac{Ah^4}{80R^4} + \frac{Ah^6}{448R^6} + \ldots\ldots\ldots [11a]$$

Place the series in the denominator by division, giving

$$F = \frac{A}{12\dfrac{R^2}{h^2} - 1.8 - 0.0516\dfrac{h^2}{R^2} + \ldots\ldots\ldots} \quad [11b]$$

Neglect further terms, adjust the constants empirically for best agreement with [11], factor for convenience in computation, and put $R/h = n$, giving

$$F = \frac{An^2}{12(n^2 + 0.04)(n^2 - 0.188)} \quad [2]$$

When $R/h = n$ is greater than 1, this expression gives results which differ from results of [11] by less than 0.2 per cent. The greatest errors, when n is less than 1 but greater than 0.6, are less than 0.6 per cent.

Equation [3] for an elliptical or circular section may be derived as follows, integration shows that

$$F = 8A\frac{R}{h}\left(\frac{R}{h} - \sqrt{\frac{R^2}{h^2} - 0.25}\right) - A \quad [12]$$

Expansion, division, adjustment, and factoring as for the rectangle result in the form

$$F = \frac{An^2}{16(n^2 + 0.035)(n^2 - 0.161)} \quad [3]$$

When $n = 0.6$ this expression differs from [12] by about 0.7 per cent in value, the error decreasing to 0.2 per cent and less when n is greater than 1.

Equation [4] for a triangular section with vertex toward O may be obtained as follows. By integration,

$$F = 2A\frac{R}{h}\left(1 - \frac{3R - 2h}{3h}\log\frac{3R + h}{3R - 2h}\right) - A \quad [13]$$

Expanding in series,

$$F = \frac{An^2}{18} + \frac{An^3}{135} + \frac{An^4}{135} + \frac{4An^5}{1701} + \ldots\ldots [13a]$$

Summing the even-powered terms and odd-powered terms separately and dividing,

$$F = \frac{A}{18n^2 - 2.4 + \ldots\ldots} + \frac{A}{135n^3 - \dfrac{300}{7}n + \ldots\ldots} \quad [13b]$$

Neglecting further terms and adjusting the constants,

$$F = \frac{A}{18(n^2 - 0.145)} + \frac{A}{135\,n(n^2 - 0.342)} \quad [4]$$

Values obtained from this expression will differ less than 0.5 per cent from the corresponding value of [13], if n is less than 0.77.

Formulas for other forms of cross-section could be derived but would be less useful than Equations [2], [3], and [4]. In particular, an expression for the effective area of a triangle with the vertex directed away from O would be similar to [4] with the negative sign between terms but inferior to [4] in range and accuracy.

Derivation of Equations [5] and [6]

For a composite section, the integral F may be extended over the parts separately and the results added, for integration is a form of addition.

$$F = F' + F'' + \ldots\ldots\ldots\ldots [5]$$

Given the value of the effective area $F_1 = \int \frac{v}{r}dA$ for bending about a centroidal axis at radius $r = R_1$, to find the value of the effective area $F' = \int \frac{x}{r}dA$ for a parallel axis at radius $r = R'$. Put for x its value $R' - r$, then

$$F' = \int \frac{x}{r}dA = \int \frac{R' - r}{r}dA = R'\int \frac{dA}{r} - A$$

$$\int \frac{dA}{r} = \frac{F' + A}{R'}, \text{ and for the special case where } x = v$$

$$= \frac{F_1 + A}{R_1}$$

Solving for F', there results the desired expression,

$$F' = \frac{F_1}{R_1}R' + \frac{A}{R_1}(R' - R_1) \quad [6]$$

The effective area may be evaluated graphically or by approximate integration, using Simpson's Rule. Morley expresses the effective area as the difference of two areas $A' - A$, and in article 131 of his "Strength of Materials" describes a graphical construction. In using Simpson's Rule it will be seen that v changes sign at the centroidal axis, so some terms in the rule will be negative. This may be avoided if desired by using the expression,

$$F = \frac{1}{R}\int \frac{v^2}{r}dA \quad [14]$$

which may be derived as follows: $\int vdA = v_1A = 0$, so that

$$F = \int \frac{v}{r}dA - \int \frac{v}{R}dA = \int\left(\frac{v}{R - v} - \frac{v}{R}\right)dA = \frac{1}{R}\int \frac{v^2}{r}dA$$

Discussion

E. O. Waters.[2] The author's formula [1] is very interesting, by way of showing how a given mathematical process may be simplified for purposes of computation. Theoretically, the standard formulas, such as those on p. 483, Marks' Handbook, 3d ed., which are derived from Morley, should give identical results. Actually, however, it is necessary to compute three differences in these formulas, as against one difference in the author's formula. The difficulty of obtaining accurate results from formulas involving the differences of two or more terms is well known, when the slide rule is used for computation. Even with five-place tables and computing machines, the percentage error of the result is appreciable, if the differences are small in comparison with the magnitude of the separate terms.

Apparently, this desirable transformation has been secured by replacing the integral $R\int \frac{dA}{r}$ (Morley's "modified" area) with the integral $\int \frac{v}{r}dA$ (the author's "effective" area), the two being related by the equation:

[2] Associate Professor of Mechanical Engineering, Yale University, New Haven, Conn. Assoc-Mem. A.S.M.E.

$$R \int \frac{dA}{r} - A = \int \frac{v}{r} dA$$

Another form in which the equation for stress in a curved bar is sometimes written is (using the author's notation)

$$S = \frac{P}{A} + \frac{Mx}{Ax_1(R + x_1 - x)}$$

This looks simple, but before it can be used it is necessary to calculate not only the location of the centroidal axis, but also that of the neutral axis in pure bending.

In contrast with the foregoing, it would seem that the author's method for evaluating the "effective" area of irregular shapes, while theoretically sound, would introduce as great a chance of error as is obviated by using formula [1]. It also seems pertinent to ask on what basis the constants in Equations [2], [3], and [4] have been empirically adjusted. In making such adjustments, it is likely to be the case that high accuracy over a certain range of the variable in question is obtained only at the expense of considerable inaccuracy beyond this range.

C. H. KENT.[3] No exact solution of the problem of stresses in curved bars applicable to all sections has so far been discovered. For the special case of a thin rectangular section, an exact solution based on the theory of elasticity was obtained by Golovin in 1880. The approximate solutions in general use which neglect radial stresses are based on the work of Winkler published in 1858. These solutions also make the assumption that a cross-section of the curved bar remains plane as the bar is bent, which the exact solution for the section referred to shows to be actually the case.

The author has presented an approximate solution in a form which is at once easy to demonstrate and reliable to use. He is no doubt familiar with the following equation presented by the writer[4] in a different form from his own, but similarly derived:

$$S = \frac{P}{A}\left(1 - \frac{R}{r}\right)\frac{A - eX}{A - r_g X} \quad \ldots\ldots\ldots\ldots [15]$$

where

$R = A\,\dfrac{r_g - e}{A - eX}$ = radius of curvature of neutral axis

r_g = radius of curvature of gravity axis

e = distance from center of curvature of bar to line of action load

$$X = \int \frac{dA}{r}$$

and other terms have the same meaning as in this paper.

In this form the equation has the advantage that the value of $\int \dfrac{dA}{r}$ is readily obtained for regular sections, making unnecessary the use of the approximation for F as in this paper. It has, however, the disadvantage of additional complexity and sensitivity to numerical errors. The equation for R shows at once that the neutral axis coincides with the centroidal axis when e is zero, as the author has pointed out.

When applied to Example 1 of this paper, Equation [15] gives stresses of 10,350 and —4010 lb. per sq. in. at the points H and G, respectively. In applying this formula it should be remembered that e in Example 1 is negative. Comparison with the author's results indicates the accuracy of the expressions he has given for F.

One may compare the results of these formulas with the exact solution for the case of a thin rectangular section. Let $n = 1.5$, and assume that the line of action of the load passes through the center of curvature. The exact solution in this case gives $S = 12.88P/A$. Equation [15] gives $S = 12.63P/A$. The author's Equation [1], using his approximation for F and $V/F = {}^1/_2$, gives $S = 12.60P/A$.

We may conclude that formula [1] and the approximations for F which have been given are sufficiently accurate for practical purposes and possess the distinct advantage of yielding reliable results with the use of the slide rule.

AUTHOR'S CLOSURE

After the interesting and pertinent comments of Mr. Waters and Mr. Kent, further discussion would seem to be unnecessary, but for the question of the method of adjusting the constants in Equations [2], [3], and [4]. As to the effect of this adjustment, it should perhaps have been stated that the adjustment is small and does not appreciably affect the results in most practical cases. In Equation [11*b*], for instance, the third term in the denominator is usually small enough to neglect, but in the unusual case where n is less than 1, this term becomes important. It is therefore possible to select a suitable value for this term, which with an extremely small change in the second term will permit the use of the final formula for all values of n greater than 0.6, and without introducing appreciable error into the range where n is greater than 1. It is true that the result is very much in error for values of n less than 0.6, but no engineer is likely to meet such an extreme case (inside radius of curvature less than one-tenth of the depth of section).

Mr. Waters also suggests that computations for the effective area of an irregular section are subject to chances of error when computed by the method used in Examples 2 and 3. The main advantage of that method is its similarity to that used in computing the moment of inertia of a composite section. An engineer who can compute the moment of inertia of a composite section should be able to obtain equally reliable results when he uses this method of computing effective area. It is also well to keep in mind the advantages of Simpson's Rule, especially when used in connection with Equation [14].

Strength of Thin Cylindrical Shells Under External Pressure

By HAROLD E. SAUNDERS[1] and DWIGHT F. WINDENBURG,[2] WASHINGTON, D. C.

The scope of existing formulas for the design of cylindrical tubes and vessels under external pressure, especially with regard to the determination of empirical constants and coefficients by systematic and comprehensive experimental data, is rather limited. The introduction and expansion of industrial processes, involving the treatment of materials under a vacuum, or within double-walled chambers whose jackets are filled with steam under high pressure, has, in conjunction with reduction in operating costs by the use of large units, resulted in the building of cylindrical vessels of great size, in the design of which engineers have had to be guided largely by what little past experience they could muster. The dimensions and proportions of these units fall far beyond the scope of any previous experiments. With fabrication costs so high and with satisfactory performance in service so important an item, the use of inadequate formulas can hardly be justified. Engineers called upon to execute these designs very rightly feel that they must have at their command workable scientific formulas, based upon logical application of accepted theories and capable of establishing proportions which will result in proper distribution and economy of material. It was because of the lack of adequate design formulas of this kind that the A.S.M.E. Special Research Committee on the Strength of Vessels Under External Pressure was organized. This paper represents the first attempt of the committee to meet the needs of designer and engineer. It is being published in advance of completion of research work on this project, to fill urgent needs in the profession and to bring forth suggestions, comment, and criticism from those interested in this work.

THE lack of scientifically proved and generally accepted formulas for the design of cylindrical vessels that must withstand external pressure is the result not so much of lack of ingenuity or enterprise in the theoretical treatment of the design problem, but of the rather limited field of application and the dearth of comprehensive experimental data which would permit the establishment of satisfactory constants and coefficients in existing formulas.

H. E. Saunders

To be sure, certain portions of the field have been carefully explored and are well covered. For example, the scantlings of tubes and cylindrical furnaces for fire-tube boilers are being selected by reference to simple formulas which have been proved by many years of practical experience. In these cases, however, the design is so involved with allowances for fabrication, for corrosion, for unequal heating, and for varying degrees of auxiliary support, that the fundamental strength formulas can scarcely be recognized.

D. F. Windenburg

The classic experiments of Fairbairn, Stewart, Carman, Cook, and others provide simple and useful design formulas for pipes subjected to external pressure, but for the most part they apply only to commercially manufactured tubular members of moderate diameter and long length, which are in many cases assumed free from end or axial loading and from other restraints. Specifically, the diameters covered by these tests are 12 in. or less, and the tubes generally have a length-diameter ratio of 4 or more. The thickness-diameter ratios, however, are in every case so small that the pipes may be expected to collapse by instability.

The present-day problem involves diameters of the order of 20 to 50 ft., length-diameter ratios of from 4 down to 1 or less, and working conditions which in almost every case involve end loading. The problem then becomes one of the strength of thin shells of pressure vessels rather than the resistance of long pipes and tubes to external pressure. The simple conventional formulas are found no longer applicable when the length-diameter ratio falls below about 6, since the collapsing pressure rises very rapidly with a decrease in this ratio. For the majority of modern designs, the thickness-diameter ratio may be assumed to lie below 0.020, and the ultimate collapsing pressure, for a tube of infinite length, below 500 lb. per sq. in. These limits will be adhered to in the present paper.

General Theory

The two-dimensional collapse of an infinitely long, thin tube has been carefully investigated. The formula

$$p_e = 2\,\frac{m^2 E}{m^2 - 1}\left(\frac{t}{d}\right)^3 \qquad [1]$$

[1] Senior Assistant to Officer in Charge, U. S. Experimental Model Basin, Navy Yard, Washington, D. C. Commander Saunders is a graduate of the United States Naval Academy and of the Massachusetts Institute of Technology, Department of Naval Architecture. For three years he was head of the submarine-design section in the Bureau of Construction and Repair, Navy Department, and for five years in charge of the construction of large V-class submarines at the Navy Yard, Portsmouth, N. H. Since October, 1929, he has been in his present position.

[2] Assistant Physicist, U. S. Experimental Model Basin, Navy Yard, Washington, D. C. Mr. Windenburg was graduated from Cornell College, Iowa, with the M.A. degree, followed by two years of graduate work in physics and mathematics at the University of California. For three years he was head of the mathematics department of the Polytechnic College of Engineering, Oakland, Calif., and for two years head of the mathematics department of the Long Beach Junior College, Long Beach, Calif. Since January, 1929, he has been in his present position.

Contributed by the A.S.M.E. Special Research Committee on the Strength of Vessels Under External Pressure and presented at a joint session with the Applied Mechanics Division during the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

given by Bryan (1)[1] is generally accepted. Here,

p_c = collapsing pressure
E = Young's modulus
$1/m$ = Poisson's ratio
t = the thickness of the tube
d = the diameter of the tube to the neutral axis (middle of the shell or wall).

All units are given in inches and pounds per square inch.

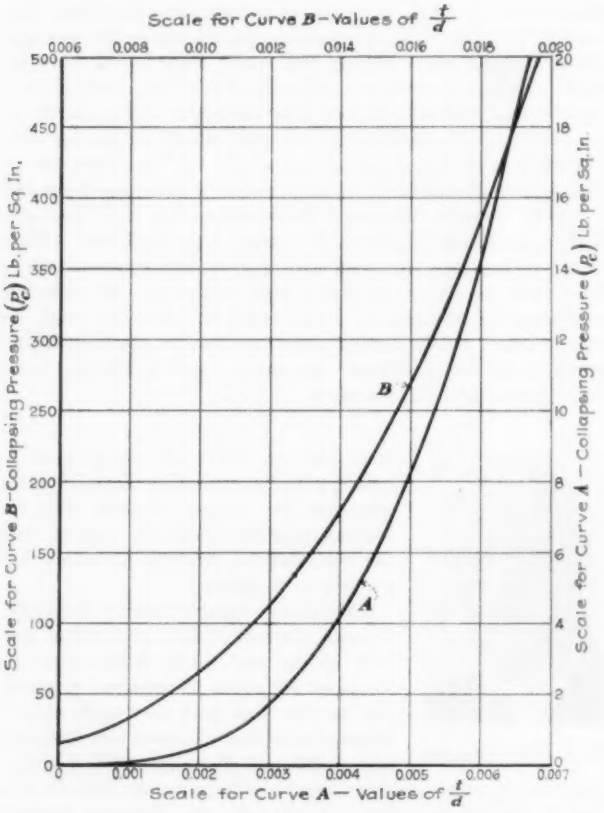

FIG. 1 RELATION BETWEEN COLLAPSING PRESSURE AND t/d RATIO IN THE FORMULA $p_c = 66 \times 10^6 \left(\frac{t}{d}\right)^3$

This is essentially the same as the well-known Föppl formula for the buckling of a circular ring under external pressure:

$$p = \frac{3EI}{r^3L} \quad \ldots\ldots [2]$$

where

p = collapsing pressure
I = moment of inertia of the cross-section of the ring
r = radius of the ring to the neutral axis
L = length of the ring.

When the ring is of rectangular cross-section and unit length, Equation [2] reduces to

$$p = 2E\left(\frac{t}{d}\right)^3 \quad \ldots\ldots [3]$$

This latter differs from Equation [1] only by the factor $\frac{m^2}{m^2-1}$, which is approximately 1.1 when $1/m$ (Poisson's ratio) = 0.3.

[1] Numbers in parentheses are those of references given at the end of the paper.

The pressures represented by these formulas are attainable only with geometrically perfect tubes, when the basic assumptions are fulfilled. For thin steel tubes, where $1/m = 0.3$ and $E = 30 \times 10^6$ lb. per sq. in., Equation [1] becomes

$$p_c = 66 \times 10^6 \left(\frac{t}{d}\right)^3 \quad \ldots\ldots [1a]$$

Stewart's corresponding empirical formula for commercial lap-welded steel tubes (2) and Carman's formula for thin seamless steel tubes (3) is

$$p_c = 50.2 \times 10^6 \left(\frac{t}{D}\right)^3 \quad \ldots\ldots [4]$$

where D is the outside diameter instead of the diameter to the neutral axis as given in all theoretical formulas. This value is some 25 per cent lower than that given by Equation [1a], but it must be remembered that Equation [4] represents the *average* of a great many commercial tubes taken at random from stock. In several individual tests the values predicted by Equation [1a] were obtained. For example, as pointed out by Slocum (4), Stewart's tests Nos. 92 and 94 (2) give the following:

Test No.	t/d ratio	Collapsing pressure: By experiment	Collapsing pressure: By [1a]
92	0.0312	2030	2004
94	0.0323	2200	2224

A graphic representation of Equation [1a] for general use is given in Fig. 1.

Theoretical solutions to the problem of collapse of short tubes have been obtained by Lorenz (5), Southwell (6), and von Mises (7). Southwell developed a formula for the collapsing pressure of a short tube, taking into account the effect of limited length on the elastic behavior of the cylinder. He obtained an expression involving not only all the usual factors, but the number of lobes n and a constant Z, which latter was dependent upon the type of end constraints. This equation is as follows:

$$p = 2E\frac{t}{d}\left[\frac{Z}{n^4(n^2-1)}\left(\frac{d}{L}\right)^4 + \frac{1}{3}\frac{m^2}{m^2-1}\left(n^2-1\right)\frac{t^2}{d^2}\right] \quad \ldots\ldots [5]$$

where n is the number of lobes in a complete circumferential belt at collapse, and Z is a factor depending upon the type of end constraints.

The preceding formula gives distinctly separate curves for successive integral values of n when p is plotted against L/d with a constant ratio t/d. Theoretically, the number of lobes will be that value of n which will produce the minimum collapsing pressure by Equation [5] for any given length. Southwell (8), however, showed that the single hyperbola

$$p = \frac{32}{9}E\frac{t^2}{Ld}\sqrt[4]{\frac{Z}{36}\left(\frac{m^2}{m^2-1}\right)^3\frac{t^2}{d^2}} \quad \ldots\ldots [6]$$

represented very closely the envelope of the family of curves given by various values of n in Equation [5], and that this hyperbola could be used with safety to determine the collapsing pressure of short tubes.

Later, Cook (9) evaluated the constant Z for an ideal type of end constraints. He obtained the value $Z = \pi^4/16$, and showed a very remarkable experimental verification of Equation [5] when this value of Z was used.

If we assume this value of Z and substitute the values $E = 30 \times 10^6$ lb. per sq. in. and $1/m = 0.3$ in Equation [6], we obtain

$$p = 73.4 \times 10^6 \frac{t}{L} \frac{t}{d} \left(\frac{t}{d}\right)^{1/3} \quad \ldots\ldots\ldots\ldots [6a]$$

Curve C of Fig. 2 represents the hyperbola of this equation for $t/d = 0.003$.

The vertical scale represents the collapsing pressure of a tube of given L/d ratio in multiples of the collapsing pressure of a similar tube of infinite length. Denoting this multiplying factor by M, we may then write

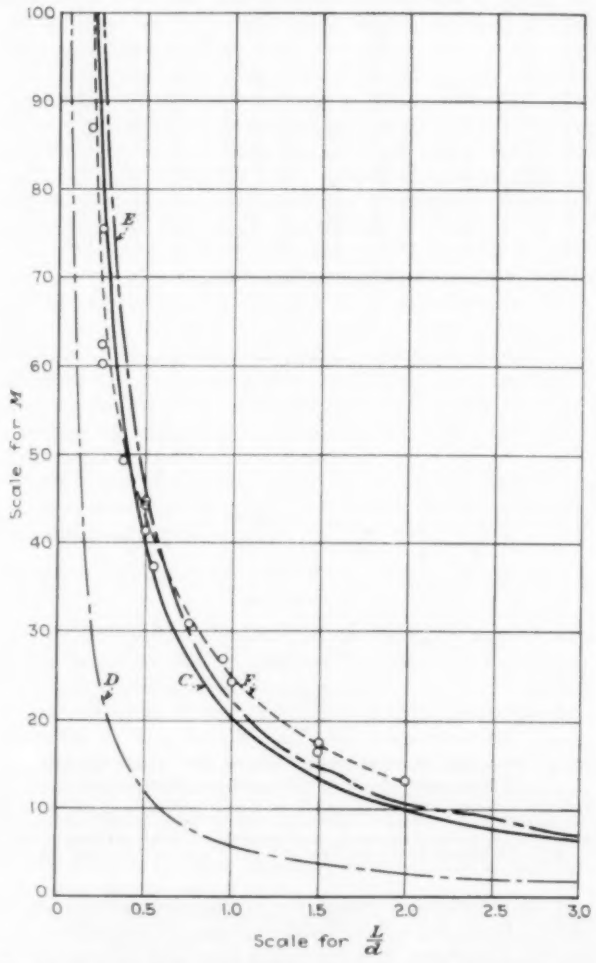

FIG. 2 CURVES ILLUSTRATING COMPARATIVE THEORETICAL AND EXPERIMENTAL DATA

(Curve C, Southwell's single hyperbola, Equation [6]; D, Equation [9] for critical length = $6D$; E, von Mises' Equation [10]; F, experimental curve for best models. These curves are for t/d ratios of approximately 0.003.)

$$M = \frac{p}{p_e} \quad \ldots\ldots\ldots\ldots [7]$$

where p is the collapsing pressure of any tube and p_e is the collapsing pressure of a tube having the same t/d ratio but of infinite length. However, if we divide Equation [6a] by Equation [1a], we obtain

$$M = \frac{p}{p_e} = \frac{1.11}{L} d \sqrt{\frac{d}{t}} \quad \ldots\ldots\ldots\ldots [8]$$

It is evident that Equation [8] will give a different curve for M against L/d for each value of t/d. This is actually seen to be the case from the experimental data obtained by Cook (10).

It will also be noted that Equation [8] can be written as

$$p = \frac{p_e}{L} \; kd \sqrt{\frac{d}{t}} \quad \ldots\ldots\ldots\ldots [8a]$$

where the factor $kd\sqrt{d/t}$ is the expression for the "critical length" given by Southwell (6). Equation [8a] then becomes

$$p = \frac{p_e L_c}{L} \quad \ldots\ldots\ldots\ldots [9]$$

where L_c is the critical length, defined as the minimum length beyond which the resistance of the tube to collapse is independent of the length, and p_c is the pressure at which a tube of critical length will collapse as calculated by Equation [1].

This is identical with the expression given by Carman (11). Carman, however, says that the critical length is equal to about $6D$, and hence is independent of the t/d ratio. Curve D, in Fig. 2, shows the hyperbola represented by Equation [9] when the critical length is placed equal to $6D$. If this hyperbola were used for the ratio $t/d = 0.003$, the experimental values would exceed the theoretical by as much as 400 per cent.

Cook's experimental work (10) seems to confirm Southwell's theoretical expression for the critical length, but he obtains the numerical value 1.73 for the constant k, instead of 1.11 as indicated by Equation [8]. Cook's values of t/d ranged from 0.0097 to 0.0146. The values used in the tests conducted thus far at the Experimental Model Basin are from 0.003 to 0.004.

The first to develop a theoretical expression for the pressure at which short tubes *under end load as well as circumferential load* would collapse by instability was von Mises (12), who gave the following:

$$p = \left\{ \frac{\frac{E}{n^2}\frac{t}{r}}{\left[1 + \left(\frac{n}{\pi}\frac{L}{r}\right)^2\right]^2} + \frac{n^2}{12}\left[1 + \left(\frac{\pi}{n}\frac{r}{L}\right)^2\right]^2 \frac{m^2 E}{m^2 - 1}\frac{t^3}{r^3} \right\} \times \frac{1}{1 + \frac{1}{2}\left(\frac{\pi}{n}\frac{r}{L}\right)^2} \quad \ldots\ldots [10]$$

The evaluation of this formula is rather complicated, for its use involves finding the value of n which gives the lowest collapsing pressure.

Curve E, Fig. 2, represents values calculated from von Mises' Equation [10].

Curves C, D, and E, Fig. 2, cannot be extended indefinitely to low values of the ratio L/d because, under these conditions, collapse by pure instability will no longer occur. Von Sanden and Günther (12), who have made a theoretical investigation of this phase, find that collapse of very short tubes (L/d less than about 0.20) is brought about by development of high stresses adjacent to the stiffening or supports, which stresses exceed the proportional limit and reach the yield point of the material.

Actual measurements on many models, similar to those listed in Table 1, having low L/d ratios (of about 0.15), indicate that collapse is brought about by overstressing the material before there is any indication of the lobe formation which precedes collapse by instability.

Since all the preceding formulas contain E, they cannot be expected to hold strictly under such conditions. Von Kármán (13) has brought out to excellent advantage the variation in modulus of elasticity in the vicinity of the yield point. These matters, however, pertain to a fundamentally different type of collapse, and it is proposed to defer discussion of them to a subsequent paper.

$E = 30 \times 10^6$ lb. per sq. in. $1/m$ (Poisson's ratio) = 0.3 All models subject to full axial as well as circumferential loading.

Elastic Behavior of a Cylindrical Vessel Under External Pressure

When a long, thin tube is subjected to external pressure, it first contracts uniformly around the circumference; that is, the circumferential elements of the shell, loaded similarly to long slender columns, will suffer uniform contraction or shortening before bending.

Fig. 3 Model of Thin Cylindrical Vessel With Closely Spaced Internal Stiffening Rings, Showing Symmetrical Lobe Formation at Collapse

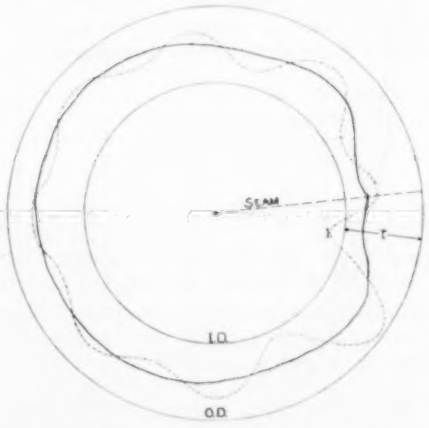

Fig. 4 Diagram Representing Shape of Thin Cylindrical Vessel and Mode of Collapse by Instability

(Full line, original contour of middle of shell; broken line, contour just prior to collapse. Position of lobe formation of entire model is influenced by position of lobe at the point 1, where the original local variation in radius was great. Collapse finally occurred at point 1 and at the two adjacent lobes.)

As the pressure is increased, the circular elements will assume elliptical forms and will eventually collapse by instability. The tube will flatten out, with two bulges extending outward beyond the original circular form and two extending inward, forming what is known as two-lobe collapse.

If circumferential supports are provided in the tube, at a distance apart less than the critical length, the presence of these supports causes a reduction in the length of the equivalent circumferential columns. This is analogous to the well-known subdivision of a simple slender strut into bays, with the actual neutral axis crossing the original axis at intermediate points.

The circumferential elements of the tube between supports take the form of long, thin plates, loaded longitudinally and stiffened along their edges. These plates will buckle into numerous bays or lobes, depending generally upon the proportion of width to length of the plates.

The subdivision of the original circumferential columns in a cylindrical vessel evidences itself in an increase in the number of lobes above two, and a considerable increase, as in the simple column divided into numerous bays or bulges, of the collapsing or buckling load. It is this phenomenon which gives rise to the increased strength of a tube with decrease in length.

Von Sanden and Günther (12) state that Equation [10]

"has always given the number of bulges on the circumference, and, for isolated bulges, the calculated length of the bulge has always checked with the observed length, even in cases where the experimental bodies were far from being ideal in form and scantlings." On the other hand, Cook (9), in referring to Equation [5] declares that "the number of lobes in the collapsed tube does not correspond with that indicated by theory. . . . . It is to be expected that the observed number of lobes will usually be *less* than that predicted by theory, and this is actually seen to be the case."

The tests thus far conducted at the Experimental Model Basin, as shown in Table 1, have in nearly every case given the correct number of lobes as predicted by both Equations [10] and [5]. The one notable exception is the model No. 1000D1 shown in Fig. 4, where the actual number of lobes is seen to be 8, while Equations [10] and [5] both predict 7. Thus, the number of lobes is *greater* than predicted by theory.

It is possible that Cook, who states that "in most cases the collapse was fairly symmetrical," may have been misled by the fact that all the lobes in any one circumferential belt did not appear upon collapse, for it is by no means certain that a complete circle of bulges will be found. The photograph, Fig. 3, represents a typical case, where only a few bulges appear. If, however, the center-to-center distance for each pair of bulges is stepped off around the circumference the correct number of lobes (in this case 16) will be found.

The number of lobes will in service be found to vary from 2 for a long tube to as high as 17 for tubes with closely spaced circumferential stiffeners (14).

Effective Unsupported Length of a Tube and Method of Stiffening

It is fairly well established that the length L may be taken as the length of the unsupported cylinder between adjacent transverse or circumferential supports, whether those supports are the solid ends of the vessel, whether they are bulkheads or partitions, or whether they are only circumferential rings or stiffeners, provided they possess rigidity in their own plane relatively greater than the shell of the vessel, and provided they extend continuously around the circumference. Hemispherical ends may be reckoned effective in preserving the circular section at their point of junction with the cylindrical shell, in the same manner as flat or dished ends.

As a measure of the necessary rigidity for a circumferential stiffener, recourse may be had to Equation [2] by inserting for the factor L the length of the unsupported wall or shell *between* stiffeners. This will give the required moment of inertia for a continuous stiffening ring of uniform section which will collapse by instability simultaneously with the shell. It has been customary, however, to make the stiffener 10 per cent stronger than the shell (14), in which case the formula becomes $1.1p = 3EI/r^3L$, or

$$I = \frac{0.37\, r^3 L}{E}\, p \qquad [11]$$

The stiffening rings may take on manifold forms as shown in Fig. 5. Circumferential supports for trays, platforms, and other accessories may be made to serve as stiffeners, but for this purpose they should be continuous and attached to the shell.

Frames, stiffening rings, and supports may be either internal or external, and may be attached by riveting, welding, or other convenient means. In special cases where the shell must remain intact, it may be possible to design the internal stiffening rings so that they simply rest against the shell. Shell connections to external rings must be substantial enough to cause the rings to contract under load with the shell.

Effect of Variation From True Cylindrical Form

One would not expect columns with varying amounts of eccentricity to support equal loads before collapse, nor to support the maximum load of which a straight column is capable. It should not therefore be expected that cylindrical tubes or vessels having variations from circular sections will withstand external pressure alike nor to the maximum degree of which the material is capable.

This is borne out by the experience of many experimenters,

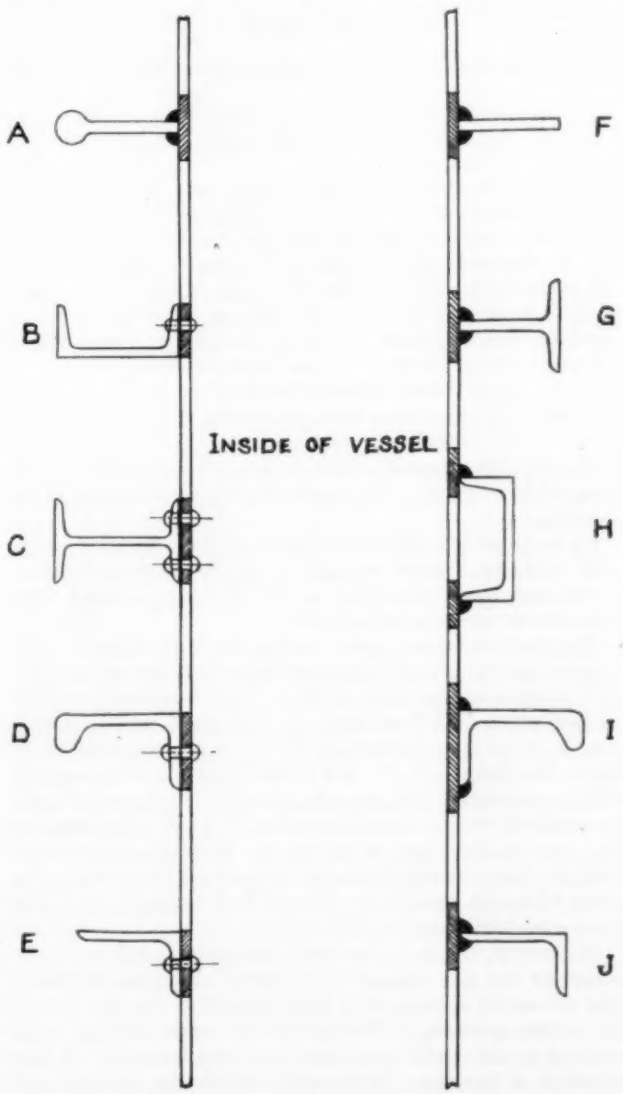

Fig. 5 Forms for Stiffening Rings

(The hatched portions of the shell represent approximately the amounts which may be reckoned effective in calculating the moment of inertia of the frame. Note that for riveted construction, reckon only that portion of shell effective which lies under the faying flange. Compare types *I* and *D*. Types shown as riveted may also be welded. Welding need not be continuous; should preferably be intermittent in many cases. *A*, bulb plate, welded. Probably the lightest, simplest, and most effective design. At present this section is only rolled abroad, but should be introduced into this country. *B*, channel, riveted (or welded). Simple design but unbalanced section, which will tip under heavy load. *C*, I-beam, riveted (or welded). Symmetrical, but probably unnecessarily heavy and difficult to fabricate. *D*, bulb angle, riveted. Good section except for unsymmetrical position of web and bulb. *E*, angle, riveted. Simple but unbalanced, in that the neutral axis lies too close to the faying flange. *F*, flat-plate ring, welded. Light, simple, and effective. *G*, T-bar, welded on stem. Good section, but somewhat difficult to fabricate. *H*, channel, welded on toes. Attractive design, but probably needlessly heavy and involving dead space for corrosion. *I*, bulb angle, welded. Good section except for unsymmetrical position of web and bulb. *J*, angle, welded on toe. Simple but lacking in symmetry. Will tip under extreme load.)

notably Stewart and Carman, who found it necessary to reduce the coefficient 66×10^6 in the rational Equation [1] to about 50×10^6 for *average* commercial tubes. Numerous tubes in Stewart's tests (2) collapsed at much lower pressures, which led Slocum (4) to state that "instead of substituting the actual radius of the tube in Equation [1], there should be substituted its radius of curvature at the *flattest portion*. Considering the tube to be elliptical in section, this will be the radius of curvature of the ellipse at the extremity of its minor axis, which is $R = a^2/b$, where a and b are the semi-axes. Since $a = \frac{D_{max.}}{2}$ and $b = \frac{D_{min.}}{2}$, this becomes $2R = \frac{D^2_{max.}}{D_{min.}}$, and substituting this corrected value of the diameter in Equation [1] it becomes

$$p_c = 2\frac{m^2}{m^2 - 1} E \left(t \frac{D_{min.}}{D^2_{max.}} \right)^3 \quad \ldots\ldots\ldots\ldots [1b]$$

This correction is of course only approximate, but should give good results for the range of eccentricities in question."

This was a step in the right direction, but it probably applies only to two-lobed collapse, although this feature was not brought out at the time. For the case of collapse of tubes into higher-lobed formations, it is readily seen that an initial dent or bulge approximating the shape and size of one part of a lobe will be the equivalent of eccentric column loading at that point.

In the model whose cross-section is given in Fig. 4, there were noticeable departures from the circular form in the vicinity of the seam. There was, however, no appreciable reduction in the collapsing pressure, because the variations from circular form were not excessive as compared with the thickness of the material.

On early models, having variations of the order of twice the shell thickness, collapse occurred irregularly at pressures much lower than those calculated, so that the tests had no value whatever for comparative purposes.

This leads to the conclusion that for short tubes, simple variation in diameter is a less important factor than is local variation in the region of one bulge or lobe. This is strikingly evident in tests which have been made on both small- and large-scale models, up to 8 ft. diameter, at the U. S. Experimental Model Basin, Washington, D. C., and at the Navy Yard, Portsmouth, N. H.; so much so that the point of initial failure can generally be predicted from a careful inspection of the diagram depicting the exact initial form, as in Fig. 4. However, experimental work at these two establishments has not yet progressed to the point where the quantitative effect of local or general variations from cylindrical form can be predicted.

In practice, the departure from circular form is found to increase as the size (diameter) decreases. Working allowances and tolerances decrease at a lesser rate than the size or scale of the tube or vessel; stiffening rings and supports are generally omitted in the smaller sizes, and dents and bulges are of more common occurrence. Fortunately, allowances for hot and cold working, corrosion, and the like are greater on small than on large tubes, so that some compensation is thereby obtained.

It is perhaps somewhat premature to set up any definite tolerances for the fabrication of tubes and vessels subjected to external pressure, especially of the built-up variety, but it may be safe to state that for thin tubes the *total variation in radius* at all points shall not exceed the shell thickness; that the middle of the shell plating in any circular section shall lie between two circles representing the outside and the inside diameter, drawn from the geometrical center of the shell. Furthermore, as brought out previously, extreme variations in radius within the region of any one bulge are to be avoided.

For comparative and systematic tests on models and structures, the fabrication tolerance should be reduced to one-half—or better, to one-third—of this amount. The model from which the data in Fig. 4 were taken complies with the latter requirement.

Manifestly, the establishment of such a requirement involves the use of some method whereby compliance with the given specifications or whereby variation in circular form of existing structures may be indicated. A simple device of this kind, as shown in Fig. 6, has been developed and used at the Navy Yard, Portsmouth, N. H. It consists of a temporary central bar or spindle upon which is mounted a swinging arm of pipe or tubing, carrying at its outer end a tracing wheel with pointer and multiplying mechanism, and a chart. The chart is graduated in radial lines representing degrees or divisions of a whole circle, and in concentric circles representing given absolute radial displacements of the tracing wheel.

A belt (or chain) mounted on two pulleys, one clamped on the central spindle and one on the chart holder, maintains the chart in a given direction in space as the arm is rotated. The simple operation of rolling the tracing wheel around the inside of the tank causes an automatic record, to a magnified scale,

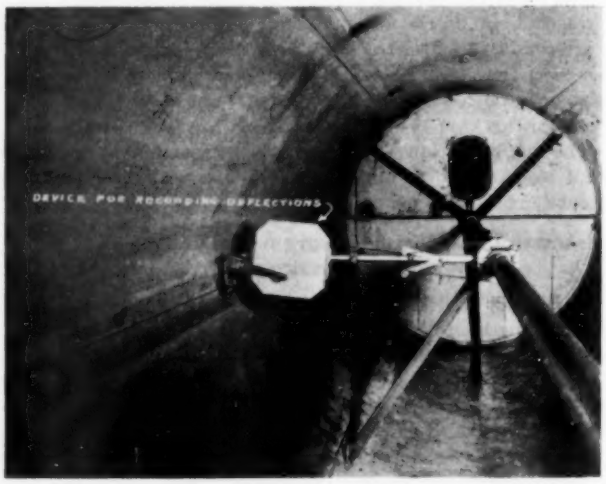

FIG. 6 DEVICE FOR TRACING CONTOURS OF SECTIONS

to be made of the exact shape of the section corresponding to the heavy full line on Fig. 4. By moving the arm along the spindle, similar records may be made at other sections.

EFFECT OF LOCAL STIFFENING, CONCENTRATED LOADS, ETC.

Much more extensive study and research than have already been undertaken will be necessary before definite answers can be given on this phase of the subject.

For guidance, however, it may be stated that since the shell or wall of a cylindrical vessel contracts nearly uniformly under external pressure to about the elastic limit of the material, anything which *prevents* the shell from contracting in this manner may cause unnatural deformation and may result in the equivalent of eccentric loading, thus weakening the structure. Hence the paradox that very stiff frames or rings, numerous solid bulkheads, and heavy longitudinal seams *may* result in a *reduction* of the collapsing pressure. The best and most economical design is that in which the various members are each just strong and rigid enough to carry the designed collapsing load.

SCALE EFFECTS IN TESTS OF MODELS AND IN EXTRAPOLATION OF DATA

Since t, L, and d in the various formulas are all functions of a

linear dimension, the constant k, as found by a relation such as $50.2 \times 10^6 = k \frac{m^2}{m^2 - 1} E$, as well as the factor Z for types of end constraints, are both non-dimensional. Collapsing pressure p is therefore independent of scale *so long as geometrical similarity is maintained* and so long as the physical properties E and $1/m$ of the material remain constant. To comply with the requirements for geometrical similarity, variations in form should be of the order of the scale. For example, the diagram, Fig. 4, would apply equally to any tube or vessel, whether 1 in. or 100 ft. in diameter, simply by expanding the scale. Available data on reliable tests with models and cylinders of various sizes verify the conclusion that scale effect is practically non-existent.

Experimental Data

The experiments of Fairbairn (15) were made with riveted steel pipes, which do not represent geometrically similar models of the pressure vessels being constructed at the present time.

The tests of Stewart (2) were conducted on commercial lap-welded steel tubes, which were probably inferior in respect to adherence to cylindrical form to those being turned out today.

The tests of Carman (3 and 11) were all with quite small tubes of various metals, and those of Cook (9 and 10) were on small tubes of brass and steel.

The tests made in Germany during the World War (14), although on a scale more nearly commensurate with the large cylindrical vessels under discussion in this paper, were made on admittedly inferior models, and the results show it. The German experimenters (16) stated that owing to unavoidable departure from circular form the collapsing pressures as found by Equation [10] should be reduced by the use of coefficients as low as 0.4, 0.5, and 0.6. It is to be noted, however, that they were applying this formula to very low values of L/d where, as stated above, instability formulas such as Equation [10] are not directly applicable.

The great majority of the published data are for pipes or tubes having an L/d ratio of 4 or more; hence they are of little assistance in this problem. Physical characteristics of the materials used are in general not given, although they may be assumed with reasonable accuracy.

The great stumbling block to careful analysis of previous experimental data is the almost total lack, especially for large diameters, of information as to "out of roundness." For example, the German experimenters (14) report that their vessels were not strictly circular in cross-section, but they do not describe in detail such irregularities as were found to cause 2-to-1 variation in collapsing pressure for nearly identical models.

Table 1 gives the results of tests made on structural models of simple cylindrical forms by the U. S. Experimental Model Basin, Washington, D. C., under the cognizance of the Bureau of Construction and Repair, Navy Department. The models are built of high-grade sheet steel as used for metal-furniture manufacture, to obtain uniform thickness and curvature throughout.

They are made with heavy jigs which serve to hold the shell in correct shape during assembly. Difficulties are experienced in obtaining the proper curvature adjacent to the longitudinal seam, but the irregularities are probably no greater than those obtaining in the best commercial practice. Charts similar to Fig. 4 are constructed for several stations in each model, and curves showing variation in circular form are drawn for successive pressures.

Curve F of Fig. 2 represents values of the multiplier M for these models, based upon the experimental collapsing pressure and Equation [1a]. The t/d ratio for the present series has been limited to about 0.003; it is hoped to give similar data for other ratios in subsequent papers.

It will be noted that for values of the L/d ratio greater than 0.5, the experimental collapsing pressure is considerably above the theoretical pressure for ideal tubes, while for values of the L/d ratio below 0.5, the experimental pressures fall below the theoretical.

In all computations, the values $E = 30 \times 10^6$ lb. per sq. in. and $1/m = 0.3$ were assumed. The shell plating of the models so far tested is rather thin to permit accurate determination of these physical properties.

It will also be noted (by reference to Table 1) that those models which collapsed at pressures below the theoretical values were inferior in adherence to circular form.

It must be emphasized that in experiments and analyses of this kind, the matter of geometrical and physical similarity amounts to very much more than fine talk on the subject. Nonconformity to cylindrical form and non-similarity between specimens is unquestionably responsible for 90 per cent or more of the discrepancies found by experimenters in the past. For this reason, experimenters in the future should always determine and give the exact shape of the cylinders they are testing and the physical properties of the material they use.

Factors of Safety

It will be noted that, throughout this discussion, the *working* pressure of the tube or vessel has not yet been mentioned. It is considered preferable to execute the design upon the basis of *collapsing* pressure, as having a much more direct bearing, for example, upon the physical properties of the material and as offering an opportunity for confirmation by model tests.

The designed collapsing pressure may be arrived at by a combination of the working or test pressure and the factor of safety.

The latter is to be selected by judgment or by experience, embodying allowance for reduction in actual overcalculated collapsing pressure due to unavoidable out-of-roundness, unknown effects of local or non-uniform stiffening, and indeterminate stresses due to loads or forces foreign to the static pressure load.

In this case, $p = FP$, where F is the factor of safety and P is the working pressure.

For the selection of the factor of safety F in his empirical formula, Stewart (2) gives some excellent general rules. It must be remembered, however, that the numerical values of the factors which he gives must be modified for use in the rational formulas recommended in this paper. For example, for steel tubes, the coefficient of Stewart's Equation [4] would be 50.2×10^6, whereas that of the rational formula for ideal tubes would be 66×10^6. Definite rules for the selection of this factor can hardly be given, since the complex circumstances surrounding each design will have to be considered and properly evaluated.

It may be pointed out here that careful study of the influence of variation of circular section on factor of safety shows that a decrease in that factor with an increase in diameter is entirely reasonable. As previously brought out in somewhat different form, it will be found that tolerances of several per cent of the diameter are customary and perhaps necessary on small diameters of the order of 1 ft., whereas it will be economically possible to limit variations on large vessels, of a diameter of 10 ft. or more, to fractions of 1 per cent. Likewise, any deviation from circular form due to damage or excessive pressure is much more easily detected on the larger than on the smaller sizes.

Practical Application of Design Formulas

For the present it appears advisable to use the combination of Bryan's rational formula, Equation [1], for tubes of length greater than the critical length, and Southwell's approximate hyperbola, Equation [6], for shorter tubes. This was the suggestion of Southwell in 1915 (8), but at that time he had not determined a value for Z and had no experimental verification of his formula, Equation [6]. A comparison of the curves C and E with the experimental curve F (Fig. 2) shows that either Equation [6] or Equation [10] can be used with safety for values of L/d between 0.50 and 2.0 and for a t/d ratio of 0.003.

It must be emphasized that these curves represent only one

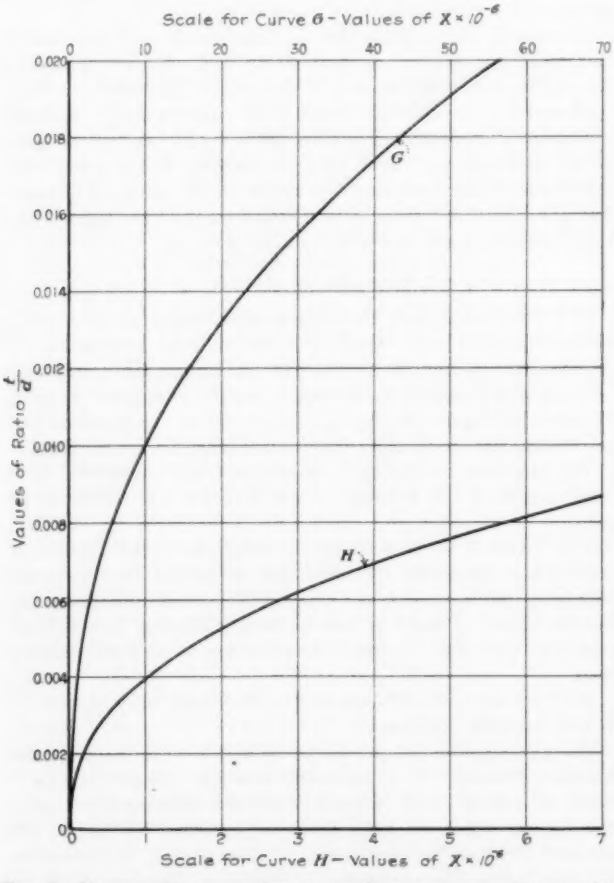

Fig. 7 Curves Showing Relation Between the Ratio t/d, p, and L/d in the Equation: $t/d = \left(\frac{p\ L/d}{\text{constant}}\right)^{2/5} = X^{2/5}$

value of t/d. However, this value was chosen at random, and there is no reason why any other value should not fit the theoretical formulas as well. Nor is there any reason to believe that the theoretical formulas will not hold when the range of L/d is extended to the critical length. However, more comprehensive tests should be made.

From the present meager data available, there seems to be little choice between Equations [5], [6], and [10]. Equations [5] and [10] are undoubtedly more accurate than [6], which, as previously stated, was intended only as a hyperbolic curve approximating the envelope represented by Equation [5]. However, the simplicity with which Equation [6] can be used in making computations is very desirable. When Z is replaced by $\pi^4/16$ and the proper values for E and $1/m$ are substituted for the material used, an equation of the type [6a] is obtained, which can be expressed as

$$\frac{t}{d} = \left(\frac{p\ L/d}{\text{constant}}\right)^{2/5} = X^{2/5} \qquad [6b]$$

where the constant for any particular material is given by

$$2.28\ E\left(\frac{m^2}{m^2 - 1}\right)^{3/4}$$

For steel tubes where $E = 30 \times 10^6$ lb. per sq. in. and $1/m = 0.3$, the constant takes the value 73.4×10^6 as given in Equation [6a].

When the design conditions have been stated and p, L, and d are known, X can be evaluated and the correct thickness determined from the relation

$$\log \frac{t}{d} = \frac{2}{5} \log X$$

or from the curve, Fig. 7.

Equations [5] and [10] have the great inconvenience that they cannot be solved directly for t. However, once t has been calculated by Equation [6], it is desirable to use them as a check on the collapsing pressure. As already stated, their use involves finding the number of lobes n which cause the collapsing pressure to be a minimum for a given t, L, and d.

It can be shown that the relation

$$n = \sqrt[4]{\frac{7.06}{\left(\frac{L}{d}\right)^2 \frac{t}{d}}} \qquad [12]$$

determines approximately the required value of n in Equation [5]. Since n represents the number of lobes, the integral number nearest to the value of n given by Equation [12] should be used. Methods for finding the required value of n in Equation [10] have also been developed.

The exact values of n obtained by the use of Equation [12] are given in Table 1, together with the integral values of n by Equations [5] and [10], and the number of lobes obtained by experiment.

The discrepancies in integral values of n in Table 1 are more apparent than real, since n is determined for a minimum value of p at a point where the variation of p with n is small. Substituting either value of n in the formulas will be found to give approximately the same value of p.

The only case where neither Equation [5] nor Equation [10] gave the correct number of lobes is model No. 1000D1. This is as yet unexplained.

Application to Practice

Example 1. Required: To design the shell of a closed cylindrical steel tank, working under full vacuum.

Given: $D = 10$ ft., $L = 12$ ft., $P = 14.7$ lb. per sq. in. No stiffeners or supports except the ends. Take $F = 4$, $E = 30 \times 10^6$ lb. per sq. in., and $1/m = 0.3$.

Solution:

$p = 4 \times 14.7 = 58.8$ lb. per sq. in. (say, 60 lb.)
$d = 120$ in. (approximately)
$L = 144$ in.
$L/d = 144/120 = 1.2$

Since $E = 30 \times 10^6$ lb. per sq. in., and $1/m = 0.3$, the constant in Equation [6b] becomes

$$\text{constant} = 2.28 \times 30 \times 10^6 \left(\frac{1}{0.91}\right)^{3/4} = 73.4 \times 10^6$$

$$\frac{t}{d} = \left(\frac{p\,L/d}{73.4 \times 10^6}\right)^{2/5} = \left(\frac{60 \times 1.2}{73.4 \times 10^6}\right)^{2/5}$$

$$= (0.9809 \times 10^{-6})^{2/5}$$

From Fig. 7, $t/d = 0.00393$, whence $t = 0.47$ in. Analytically, from formula $t/d = (X)^{2/5}$,

$\log t/d = {}^2/_5 \times \log (0.9809 \times 10^{-6}) = 0.4(3.99162 - 10)$

$t/d = 0.003950$

whence

$t = 0.00395 \times 120 = 0.474$ in.

Check by Equations [5] and [10].

From Equation [12],

$$n = \sqrt[4]{\frac{7.06}{\left(\frac{L}{d}\right)^2 \frac{t}{d}}} = \sqrt[4]{\frac{7.06}{(1.2)^2 \times 0.00395}} = \sqrt[4]{1241}$$

$$= 5.94$$

$n = 6$

Substituting in Equation [5] and assuming $Z = \frac{\pi^4}{16}$,

$$p = 2E\frac{t}{d}\left[\frac{Z}{n^4(n^2-1)}\left(\frac{d}{L}\right)^4 + \frac{1}{3}\frac{m^2}{m^2-1}\left(n^2-1\right)\frac{t^2}{d^2}\right]$$

$$p = 2 \times 30 \times 10^6 \times 0.003950\left[\frac{\frac{\pi^4}{16}}{1296 \times 35} \times \frac{1}{(1.2)^4} + \frac{1.1}{3} \times 35 \times (0.00395)^2\right]$$

$$= 237{,}000\ (0.0000647 + 0.0002002)$$

$p = 237{,}000 \times 0.0002649 = 62.8$ lb. per sq. in.

A similar substitution in Equation [10] gives

$p = 65.6$ lb. per sq. in.

Since $t/d = 0.00395$, we have, by Equation [1],

$$p_e = 2\frac{m^2}{m^2-1}E\left(\frac{t}{d}\right)^3$$

$$= 66 \times 10^6 \times 0.06163 \times 10^{-6}$$

$$= 4.07 \text{ lb. per sq. in.}$$

By Fig. 2, the multiplier M for $L/d = 1.2$ from curve C is 16.6.

$$p = Mp_e = 16.6 \times 4.07 = 67.6 \text{ lb. per sq. in.}$$

It must be remembered that this method gives only a rough check when t/d differs appreciably from 0.003, for which the curve C of Fig. 2 is drawn. For higher values of t/d this method gives collapsing pressures which are too high.

Example 2. Required: To determine the thickness of the cylindrical inner shell of a jacketed heater, reinforced by stiffening rings spaced to suit local conditions.

Given: $D = 6$ ft., $L = 2$ ft., $P = 150$ lb. per sq. in. Take $F = 6$. The material of the shell and stiffening rings is nickel alloy, for which $E = 26 \times 10^6$ and $1/m = 0.3$.

Solution:

$p = 6 \times 150 = 900$ lb. per sq. in.
$d = 72$ in. (approximately)
$L = 24$ in.
$L/d = 24/72 = 0.33$
$E = 26 \times 10^6$ lb. per sq. in.
$1/m = 0.3$

Using Equation [6b]

$$\text{constant} = 2.28 \times 26 \times 10^6\left(\frac{1}{0.91}\right)^{6/4} = 63.6 \times 10^6$$

$$\frac{t}{d} = \left(\frac{pL/d}{63.6 \times 10^6}\right)^{2/5} = \left(\frac{900 \times 0.33}{63.6 \times 10^6}\right)^{2/5} = (4.67 \times 10^{-6})^{2/5}$$

From Fig. 7, $t/d = 0.0074$, whence $t = 0.53$ in. Analytically, from formula $t/d = (X)^{2/5}$,

$\log t/d = {}^2/_5 \log (4.67 \times 10^{-6}) = 0.4(4.66932 - 10)$

$t/d = 0.00737$

whence

$t = 0.00737 \times 72 = 0.53$ in.

Check by Equations [5] and [10].

From Equation [12],

$$n = \sqrt[4]{\frac{7.06}{\left(\frac{L}{d}\right)^2 \frac{t}{d}}} = \sqrt[4]{\frac{7.06}{0.1089 \times 0.00737}} = \sqrt{8796} = 9.68$$

$n = 10$

Substituting in Equation [5], we get

$p = 954$ lb. per sq. in.

Substituting in Equation [10], we get

$p = 1086$, for $n = 9$

and $p = 1149$, for $n = 10$

By Equation [1], $p_e = 57.2 \times 10^6 \times (0.00737)^3 = 22.9$ lb. per sq. in.

The multiplier from Fig. 2 for $L/d = 0.33$ from curve C is 61, whence

$$p = Mp_e = 22.9 \times 61 = 1397 \text{ lb. per sq. in.}$$

As stated under Example 1, the collapsing pressure thus obtained is too high, because the t/d ratio greatly exceeds 0.003 for which curve C is drawn.

To calculate the required moment of inertia of the stiffening rings, assuming they are of the same material as the shell, we have, from Equation [11],

$$I = \frac{0.37 \times (36)^3 \times 24 \times 900}{26 \times 10^6} = 14.34 \text{ in.}^4$$

After selection of a type, as in Fig. 5, the necessary scantlings for the rings can be determined by application of the rules there given.

For example, suppose a channel frame is desired for riveted construction. The American standard 5-in. channel C-8 has the required scantlings, thus: Area of section, 2.63 sq. in.; width of flange, 1.885 in.; moment of inertia, 8.8 in.^{4} We consider a strip of the shell plating equal in width to the flange of the channel to work with the channel as a portion of the stiffener; it is therefore reckoned effective in calculating the moment of inertia of the ring as a whole. (See *B*, Fig. 5.) The centroidal axis of this compound section is shifted from the center of the web of the channel toward the shell a distance of 0.761 in., while the total moment of inertia of the compound section becomes 14.358 in.^{4}, distributed as follows:

I of channel about new axis $= 10.323$ in.^{4}
I of shell about new axis $= 4.035$ in.^{4}
I of compound section $= 10.323$ in.$^4 + 4.035$ in.^{4}
$= 14.358$ in.^{4}

Conclusion

In the last analysis, the acceptability of any formula or procedure used by engineers for design purposes rests largely upon the degree of exactitude with which results can be predicted. To permit the final selection of a suitable formula or formulas for the strength of vessels under external pressure and the insertion of the correct constants and coefficients, it will be necessary to accumulate many times more data than are available at present.

This can be accomplished only by the active cooperation of all who have designed, built, used, and tested structures of this kind.

The submission of complete data by which Table 1 might be filled out for each such example or installation would enable analysis of these data and preparation of a definite code to proceed at once, with hope of a satisfactory conclusion in the not distant future.

Discussion

[A discussion of this paper jointly with the one by T. McL. Jasper and J. W. W. Sullivan, from R. G. Sturm, will be found in the discussion of the latter paper, immediately following.]

Ernest F. Miller.[4] This appears to be the first attempt to evaluate the effect of circumferential reenforcement of the shell. The writer's interest is its direct application to the design of vacuum apparatus, particularly steam condensers. Until very recently condensers of medium and large sizes have been made of cast iron, and in a large majority of cases, the wall thickness determined by the casting requirements was sufficient to render the problem of collapse to be of little importance.

Many condensers are today being fabricated from steel plate, a process that permits the use of the minimum wall thickness determined by the theory of stability.

It is necessary in the construction of medium and large condensers to provide intermediate support for the cooling tubes. These supports may be utilized to reenforce the shell and to reduce the L/d ratio to small values.

The adaptation of formula [11] to the design of reenforcing rings is a distinct contribution. The degree of support obtained by circumferential bracing in relation to the ideal has heretofore been considered as the relation to a support of infinite rigidity. It is gratifying to find that this is not the case.

The restriction of limiting the total variation in radius to one shell thickness seems to be rather severe for commercial practice. In one design with which the writer is familiar the diameter is 24 ft. and the wall thickness is $^3/_4$ in. The external pressure is one atmosphere. This thickness was determined with an ample factor of safety so that greater discrepancies should be permissible.

There are two problems in the design of condensers that the writer wishes to present for consideration. One problem is the discontinuity of the cylindrical shape at the steam inlet. Here the cylinder becomes tangent to or joins a flat surface. To reduce the possibility of collapse, it has been a practice to reinforce the flat surfaces so that the bending moment due to the pressure loading approaches zero at the junction of the flat and the cylinder. The other problem is that of supporting the weight of a horizontal condenser by feet attached to the shell. No doubt the structure is reenforced more than necessary at these points because of a fear that the radial components of the load will initiate a collapse.

The authors promise that such problems as these may be adequately handled in the near future. It is hoped that this may be a small contribution to a work so well undertaken.

D. S. Jacobus.[5] The authors should be commended for the care and skill with which they conducted their experiments and for presenting rational rules for the design of certain types of vessels under collapsing pressure. Recommendations for the relative strength of the reenforcements, the bringing out of the fact that very stiff reenforcements may weaken the shell, and the specifying of the allowable tolerance in the diameter add much to the knowledge of the subject. The proof that the law of geometric symmetry holds if care is taken to make the proportionate amount of out-of-roundness the same in the model as in the full-sized vessel is a very notable feature, and taken all in all the paper is a most valuable contribution in a field where data are much needed.

The conclusion is reached that, to permit the final selection of a suitable formula or formulas for the strength of vessels under external pressure with correct constants and coefficients, it will necessitate the accumulation of more data than are available at present. As stated in the preamble of the paper, the lack of adequate design formulas led to the formation of the A.S.M.E. Special Research Committee on the Strength of Vessels Subjected to External Pressure. There is a need of more comprehensive formulas of the sort for inclusion in the A.S.M.E. Boiler Code. It is hoped that the committee will be in a position to recommend such formulas without an undue amount of delay.

D. B. Rossheim,[6] F. G. Kleiber,[7] and C. D. Read.[8] The authors are to be complimented on their paper on the stability phase of this problem which finds almost daily application in the design of vacuum and jacketed vessels, boiler flues, etc. With the work of von Sanden, Günther, von Mises, Southwell, and Cook available for many years, it is surprising that so many engineers adhere to old empirical formulas, which while known to be safe within certain limits, usually err greatly on large-diameter vessels with bracing rings spaced at intervals much smaller than the vessel diameter.

This company has designed large towers (21 ft. in diameter)

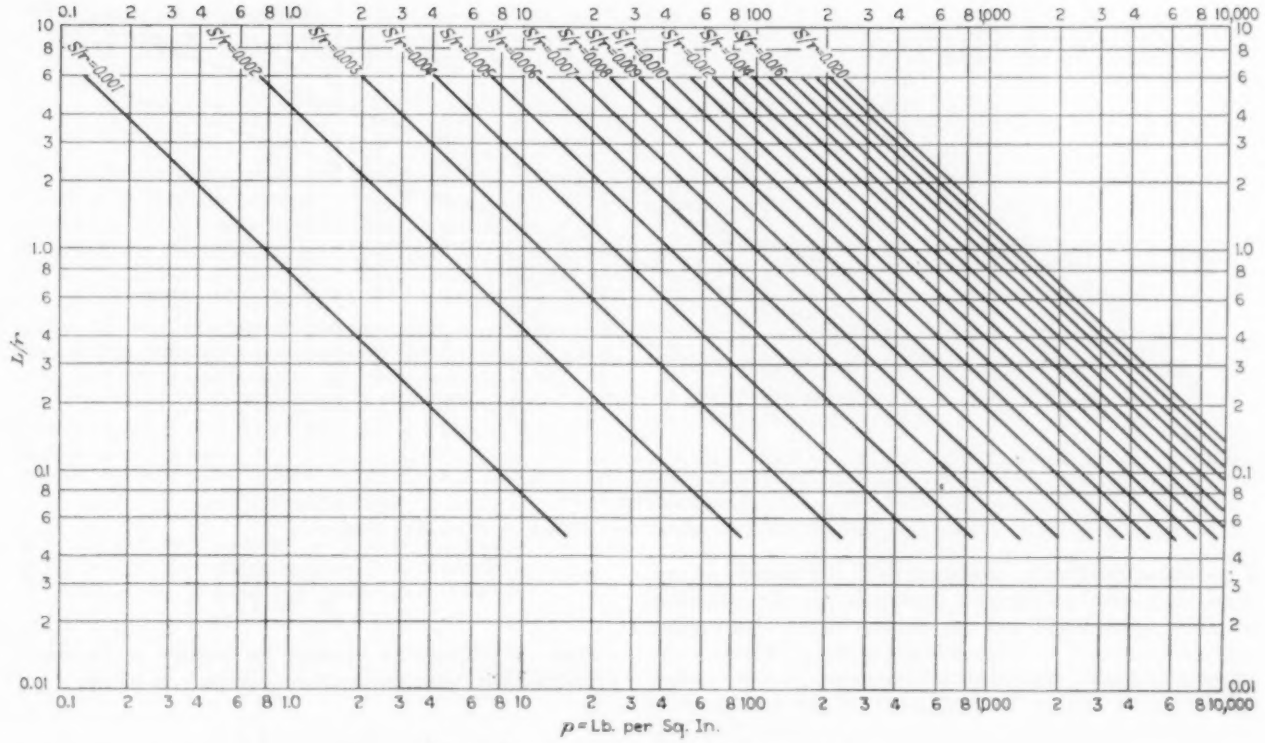

FIG. 8 GRAPH A—SOUTHWELL'S EQUATION [6]

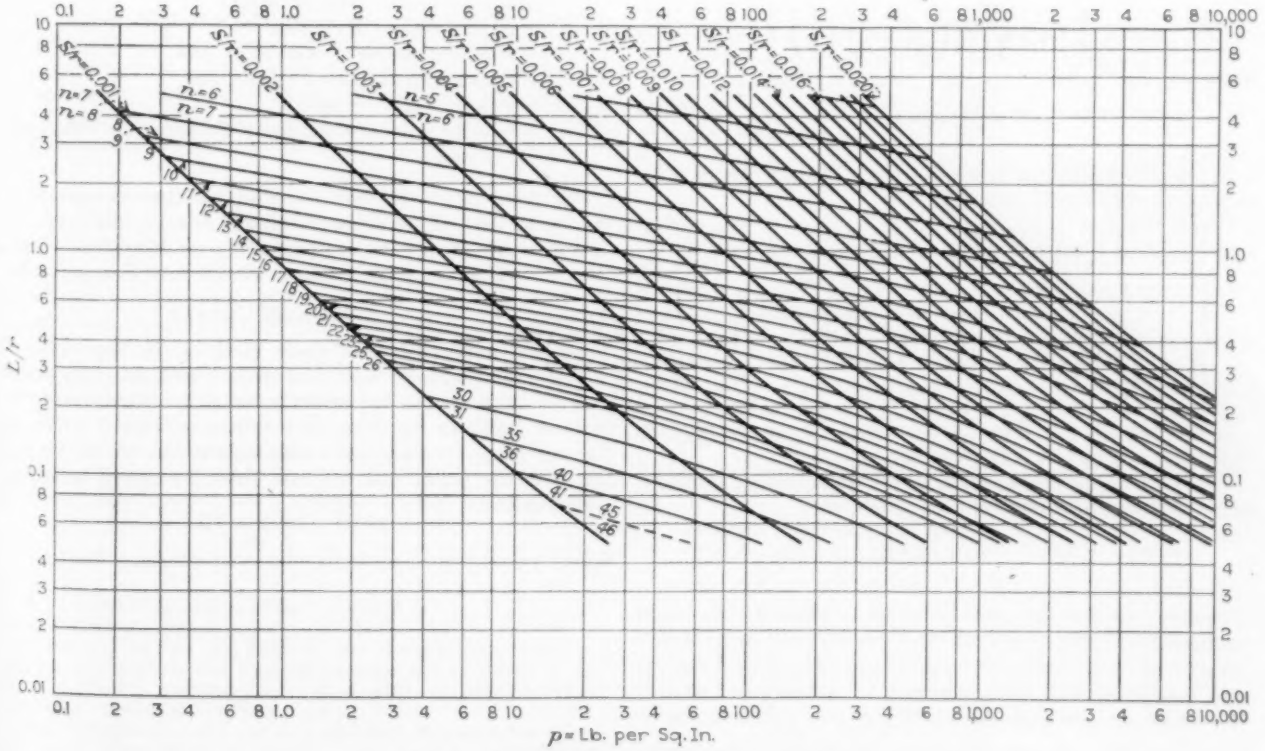

FIG. 9 GRAPH B—VON MISES' EQUATION [10]

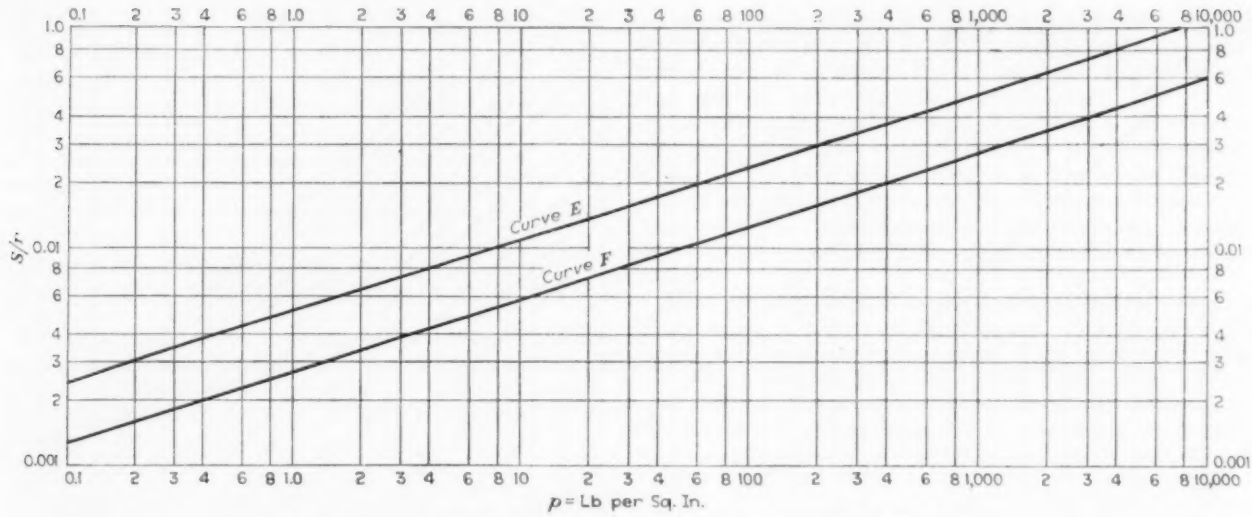

FIG. 10 CURVE E, BRYAN'S EQUATION; CURVE F, STEWART'S EQUATION

of considerable height in accordance with the formula of von Mises, with entire satisfaction. Vessels of this size containing hot inflammable liquid and gas involve considerable expense and hazard, so that to insure absolute safety in operation and economy in design, much time has been spent in investigating and developing data on the many phases of this subject. Also to accelerate calculations and design of such vessels, it has been necessary to compile tables and graphs of the various formulas and equations, which for the most part are somewhat awkward and involve trial and error methods of solution. Three of these curves are presented as Figs. 8, 9, and 10.

Graph A is the approximate Southwell equation for collapse of a short, thin tube under external radial pressure, as follows:

$$p = \frac{32}{9} E \frac{S^2}{Ld} \sqrt[4]{\left[\frac{Z}{36}\left(\frac{m^2}{m^2-1}\right)^3\left(\frac{S}{d}\right)^2\right]}$$

where

$$Z = \frac{\pi^4}{16} \text{ (Co·k)}$$

In this case a family of curves of constant S/r are plotted with an abscissa of p and an ordinate of L/r.

Graph B is von Mises' equation for collapse of thin closed cylinders under equal unit radial and end pressure, as follows:

$$p = \left\{ \frac{\frac{E}{n^2}}{\left[1+\left(\frac{n}{\pi}\frac{L}{r}\right)^2\right]^2}\frac{S}{r} + \frac{n^2}{12}\left[1+\left(\frac{\pi}{n}\frac{r}{L}\right)^2\right]^2 \frac{m^2E}{m^2-1}\left(\frac{S}{r}\right)^3 \right\} \frac{1}{1+\frac{1}{2}\left(\frac{\pi}{n}\frac{r}{L}\right)^2}$$

In this case a family of curves of constant S/r are plotted with an abscissa of p and an ordinate of l/r.

Curve E is the Bryan equation for the collapse of an infinitely long, thin tube under external load, as follows:

$$p = {}^1/_4 \frac{m^2E}{m^2-1}\left(\frac{S}{r}\right)^3$$

Curve F is Stewart's equation for collapse of commercial lap-welded steel tubes under external pressure, as follows:

$$p = 50.2 \times 10^6 \left(\frac{S}{D}\right)^3$$

Nomenclature:

- p = collapsing pressure (lb. per sq. in.)
- E = Young's modulus = (28×10^6)
- S = thickness of cylinder or tube wall
- r = mean radius of cylinder or tube
- d = mean diameter of cylinder
- D = outside diameter of cylinder or tube
- L = length of unsupported ring or tube
- $1/m$ = Poisson's ratio = (0.3)
- n = number of lobes resulting in the minimum collapsing pressure.

The three discussers have compiled the greater part of a treatise on this subject which is believed to cover many phases to which little or no attention has been given heretofore. This will be in shape for presentation in the near future.

AUTHORS' CLOSURE

Additional tests made at the U. S. Experimental Model Basin since the paper was prepared have given results that should be included. These are shown in a new graph for Fig. 2 and in additions to Table 1. [NOTE: The new graph mentioned has been substituted for the former Fig. 2 of the paper, and the new Table 1 is given herewith —EDITOR.]

APM-53-17b

The Collapsing Strength of Steel Tubes

By T. McLEAN JASPER[1] and JOHN W. W. SULLIVAN,[2] MILWAUKEE, WIS.

In this paper the authors present a method for determining the collapsing strength of steel tubes on the basis of the physical and elastic properties of the metal in the tube, and the dimensions, out-of-roundness, and variation in thickness of the tube. This method applies to long, short, thick, or thin tubes. It was developed by considering the collapse of tubes in terms of compressive stress rather than external pressure, by reevaluating the work of other investigators, and from experimental results of the authors. Its application to the determination of the collapsing strength of commercial tubes is shown by illustrative examples.

I—INTRODUCTION

THE object of this paper is to present a method for determining the collapsing strength of steel tubes on the basis of the physical and elastic properties of the steel in the tube, the tube dimensions, and the out-of-roundness and variation in thickness of the tube. The collapsing strength can be determined in terms of (*a*) the maximum compressive stress in the tube walls at the moment of collapse, or (*b*) the external pressure on the tube at the moment of collapse. This method applies to tubes that are sometimes designated as "long," "short," "thick," or "thin."

The physical and elastic properties of the steel used in the construction of tubes which are of importance in determining the collapsing strength of tubes are the yield point, modulus of elasticity, and Poisson's ratio. The tube dimensions which are of importance in determining the collapsing strength consist of the length, diameter, and thickness. The out-of-roundness also affects the pressure necessary to develop collapse.

In order to arrive at a method for determining the collapsing strength of steel tubes, an investigation was made of the factors that influence the collapsing strength of the tubes, and tests were performed in which the effects of these factors were evaluated.

In addition, a study of the experimental work and theoretical considerations of other investigators on the collapsing strength of steel tubes was made.

The method for determining the collapsing strength of steel tubes which is presented in this paper, however, has been derived largely from experimental results. Theoretical considerations have been relied upon only in so far as they have been substantiated by experimental evidence.

The application of this method to the determination of the collapsing strength of commercial tubes is indicated in this paper by illustrative examples.

II—FACTORS THAT AFFECT THE COLLAPSING STRENGTH OF A STEEL TUBE

As a result of the experimental work of the present and previous investigations (1, 2)[3] the following factors have been found to influence the collapsing strength of a steel tube.

- *a* Ratio of length of tube to diameter, L/D
- *b* Ratio of diameter of tube to wall thickness, D/T
- *c* Variations in thickness
- *d* Yield point of the steel in the tube
- *e* Elastic constants of the steel in the tube, represented by the modulus of elasticity and Poisson's ratio
- *f* Variations in roundness
- *g* Method of manufacturing the tube.

In this section the influence of these factors on the collapsing strength of steel tubes will be presented in a general way, and in subsequent sections will be discussed in detail.

As the ratio L/D of length of tube to diameter of tube increases up to about 8, the collapsing strength decreases; above 8 the collapsing strength is practically unaffected by this ratio. For the purposes of this paper, tubes having an L/D ratio of less than 8 will be considered as "short" tubes, and those having an L/D ratio of 8 or over as "long" tubes.

When the ratio of diameter to wall thickness, D/T, increases, the collapsing strength decreases; the actual relationship between this ratio and the collapsing strength being also affected by the yield point of the steel in the tube for the lower D/T ratios. Tubes having lower D/T ratios are sometimes designated "thick" tubes, and those having higher ratios, "thin" tubes. The dividing line between the lower and higher D/T ratios, which separates the thick and thin tubes, is governed by the yield point of the steel in the tubes, as will be subsequently discussed.

Variations in thickness below the average thickness tend to weaken the tube and adversely affect the collapsing strength; whereas variations above the average thickness, under special conditions, may strengthen the pipe and tend to increase the collapsing strength.

The yield point of the steel in the tube has a limiting effect on the collapsing strength for the lower D/T ratios.

The elastic constants of the steel in the tube, represented by the modulus of elasticity and Poisson's ratio, affect the collapsing strength at the higher D/T ratios. But the effect upon the collapsing strength of variations in these constants, for the several types of steel used in tubes, is small.

Variations in the diameter of the tube produce out-of-roundness which tends to lower the collapsing strength.

The method of manufacturing the tube influences the collapsing strength in so far as it affects the roundness and uniformity of thickness of the tube. Methods of manufacturing which tend to increase or decrease the yield point of the steel also have an influence on the collapsing strength of thick tubes.

III—ANALOGY BETWEEN THE COLLAPSE OF A LONG TUBE AND THE FAILURE OF A LONG COLUMN

In this section there will first be discussed the equations of Sturm and Timoshenko for determining the collapsing strength of steel tubes, the curve of Euler for determining the collapsing strength of steel columns, and experimental results on the collapse of tubes and columns. A comparison will then be made of the collapse of a long tube and the failure of a long column on the

[3] Numbers in parentheses are those of references given in section X of the paper.

basis of the theoretical considerations of Sturm and Euler and the experimental results on tubes and columns.

a Sturm's and Timoshenko's Equations for Determining the Collapsing Strength of Long Tubes

On the basis of the elastic constants and tube dimensions the following equations have been developed by Sturm (3) and Timoshenko (4), respectively, for determining the collapsing strength of long steel tubes.

Sturm's Equation:

$$P = \frac{2}{3} E \frac{t^3}{D^3}\left[\frac{N^4 - N^2 + a^4K^2 + a^2K(2N^2 - m)}{N^2(1 - m^2)}\right] \quad \ldots [A]$$

where P = collapsing pressure, lb. per sq. in.
E = modulus of elasticity of steel, taken as 30,000,000 lb. per sq. in. in this investigation, because it is appropriate to the metal used in the experimental work
t = thickness of tube, inches
D = outside diameter of tube, inches
N = number of lobes in which the tube collapses, taken as 2 for long tubes
$K = \pi^2R^2/L^2$, where R = outside radius of tube, inches, and L = length of tube, inches
a = a parameter for end conditions, taken as 1 for long tubes; and
m = Poisson's ratio, taken as 0.260, which is appropriate for the class of steel used in the tubes.

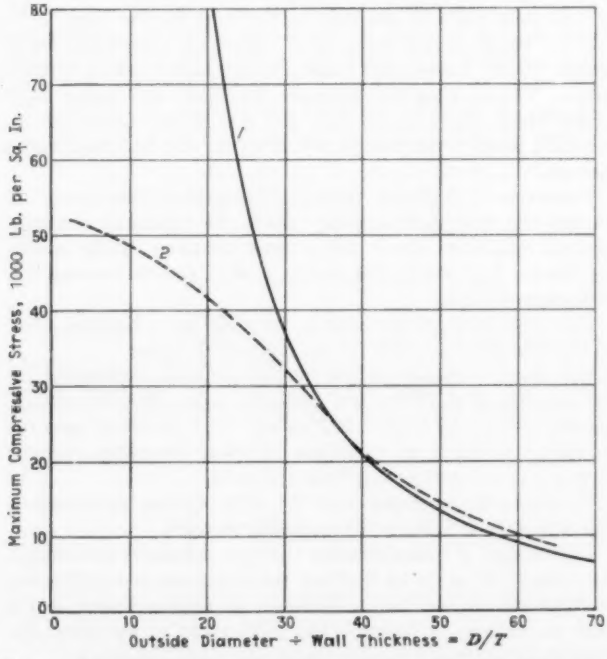

Fig. 1 Curves Showing the Relation Between Maximum Compressive Stress at Collapsing Pressure and D/T, for A. O. Smith Arc-Welded Pipes

1—Calculated from Sturm's equation.
2—Plotted from experimental results.
(Yield point of steel, 52,000 lb. per sq. in.)

For the long tubes tested in the present investigation, this equation reduces to

$$P = 5{,}360{,}000 \frac{t^3}{D^3}(12 + K^2 + 7.74K)$$

where $K = 0.000488\ R^2$.

Timoshenko's Equation:

$$P = \frac{Et^3}{4(1 - m^2)R^3} \quad \ldots [B]$$

where the meanings of the terms are as previously indicated for Sturm's equation. Sturm's and Timoshenko's equations give practically the same values of collapsing pressure for long tubes.

By means of the following Equation [C] the maximum compressive stress in the tube at the collapsing pressure may be determined (5).

$$S = \frac{2PR_1^2}{R_1^2 - R_2^2} \quad \ldots [C]$$

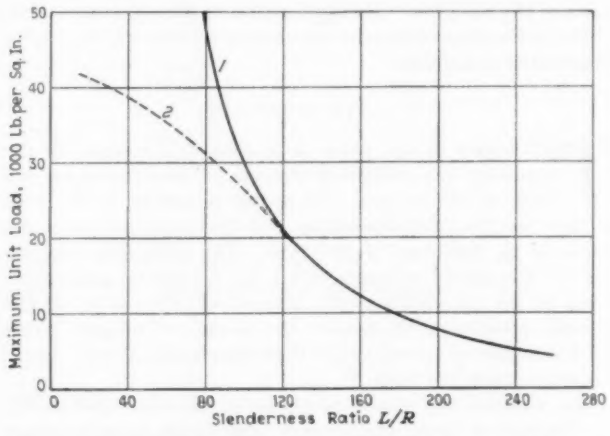

Fig. 2 Relation Between Maximum Unit Load and Slenderness Ratio for Tetmajer's Mild-Steel Columns With Pivoted Ends

1—Calculated from Euler's equation.
2—Plotted from experimental results on Tetmajer's columns.
(Yield point of steel, 39,200 lb. per sq. in.)

where S = maximum compressive stress (at inner surface of tube), lb. per sq. in.
P = collapsing pressure, lb. per sq. in.
R_1 = outer radius of tube, inches, and
R_2 = inner radius of tube, inches.

The theoretical collapsing strength of long steel tubes having various D/T ratios can be obtained from Sturm's Equation [A] and Equation [C]. If the collapsing strengths thus obtained are plotted against the D/T ratios of the corresponding long tubes, a curve results of the form indicated in Fig. 1. This curve will hereinafter be referred to as Sturm's curve. In Fig. 1 there are also plotted the experimental results of one brand of commercial tubes tested in the present investigation. (In Appendix No. 1 there are described the methods and apparatus used in measuring the specimens for out-of-roundness and variations in thickness, and the apparatus and procedure employed in the collapsing tests.)

It is evident in Fig. 1 that Sturm's curve and the curve of experimental results are in agreement for the higher D/T ratios but not for the lower ones. The explanation of this fact is that at the higher D/T ratios the collapsing strength of a steel tube is controlled by one set of factors, whereas at the lower ratios it is controlled by another set, as will be shown later in section IV.

b Euler Curve for Determining the Collapsing Strength of Long Steel Columns Pivoted at Both Ends

In Fig. 2 there is plotted the curve calculated from Euler's

equation for determining the collapsing strength of a long steel column pivoted at both ends. The maximum unit load that may be withstood by the column is plotted against the slenderness ratio; the former being the ratio of total load to cross-sectional area, and the latter being the ratio of length of the column to the least radius of gyration of the cross-section. There are also plotted the experimental results of Tetmajer's mild-steel columns with pivoted ends (6).

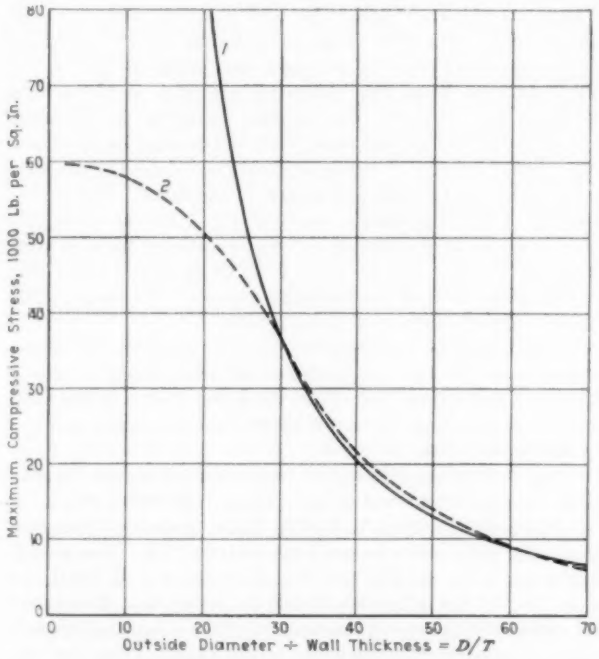

FIG. 3 RELATION BETWEEN MAXIMUM COMPRESSIVE STRESS AT COLLAPSING PRESSURE AND D/T, FOR CARMAN'S SEAMLESS COLD-DRAWN TUBES

1—Calculated from Sturm's equation.
2—Plotted from experimental results.
(Yield point of steel, 59,600 lb. per sq. in.)

It is evident in Fig. 2 that Euler's and Tetmajer's curves are in agreement for the higher slenderness ratios, but not for the lower ones. As in the case of the steel tubes represented in Fig. 1, the collapsing strength of the steel columns is governed by one set of factors at the higher slenderness ratios, while at the lower ratios it is governed by another set.

c COMPARISON OF THE COLLAPSE OF LONG STEEL TUBES AND THE FAILURE OF LONG STEEL COLUMNS PIVOTED AT BOTH ENDS

Only long tubes ($L/D \geq 8$) will be considered in this comparison. The collapse of short tubes will be discussed in a subsequent section. In comparing the collapse of long steel tubes with the failure of long steel columns pivoted at both ends, the ratio D/T of the tubes is analogous to the slenderness ratio of the columns. Hence thin tubes may be compared to columns having higher slenderness ratios, and thick tubes to columns having lower slenderness ratios.

In Figs. 1 and 2 it is evident that the theoretical curves of Sturm and Euler conform to the experimental results on thin tubes and columns having large slenderness ratios. It would therefore appear that the elastic properties of the steel and the ratio D/T control the collapsing strength of thin tubes, and that the elastic properties of the steel and the slenderness ratio L/R control the collapsing strength of columns having large slenderness ratios and which are pivoted at both ends.

For thick tubes and columns having small slenderness ratios, however, the theoretical curves of Sturm and Euler do not conform to the experimental results. In Figs. 1 and 2 it is apparent that the collapsing strengths of thick tubes and columns having small slenderness ratios approach the yield point of the steel as the ratios D/T and L/R decrease. It would therefore appear that the yield point of the steel in these structures controls the collapsing strength. The effect of yield point will be discussed further in the following section.

In the cases of steel columns and thin and thick long steel tubes, failure results from buckling. The slightest degree of eccentricity in the loading of a column lowers the stress at which buckling begins; while in a tube that is subjected to external pressure, out-of-roundness lowers the pressure at which collapse occurs. Also variation in the thickness of a column or tube affects the stress at which failure occurs.

From the foregoing considerations it may be concluded that the collapse of a long steel tube under external pressure is analogous to the failure of a long steel column under a compressive load.

The analogy between the collapse of a tube and the failure of a column is discussed because the relationship between the theoretical considerations and experimental evidence is so well established for column failure.

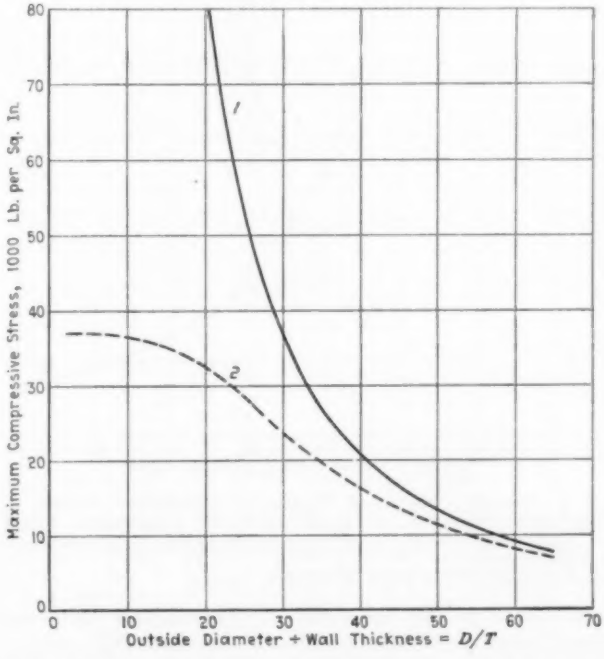

FIG. 4 RELATION BETWEEN MAXIMUM COMPRESSIVE STRESS AT COLLAPSING PRESSURE AND D/T, FOR STEWART'S LAP-WELDED PIPES

1—Calculated from Sturm's equation.
2—Plotted from experimental results.
(Yield point of steel, 37,000 lb. per sq. in.)

IV—FUNDAMENTAL RELATIONSHIP BETWEEN (*a*) THE COLLAPSING STRENGTH OF A LONG STEEL TUBE AND (*b*) THE RATIO D/T, THE ELASTIC CONSTANTS, AND THE YIELD POINT OF THE STEEL

This fundamental relationship is based upon the experimental work of three independent investigations by Carman (2), Stewart (1), and the A. O. Smith Corporation on the collapsing strength of long steel tubes, that is, tubes having an L/D ratio of 8 or over.

a Carman's Experimental Results

In Fig. 3 there are plotted results of Carman's tests on 21 cold-drawn seamless steel tubes. These tubes were 1 in. to 3 in. in diameter, 0.014 in. to 0.065 in. thick, and 7.6 to 14.1 diameters long. The D/T ratios of these tubes ranged from 42.8 to 68.7. The dimension ratios and collapsing strengths of these tubes are listed in Table 1.[4] These tubes were carefully selected and machined to the desired dimensions, and consequently the out-of-roundness and variation in thickness were exceedingly small. The average yield point of the steel in these tubes was 59,600 lb. per sq. in.

The curve of experimental results in Fig. 3 is drawn through the experimental points at the higher D/T ratios and extrapolated back to the yield point through the lower D/T ratios.

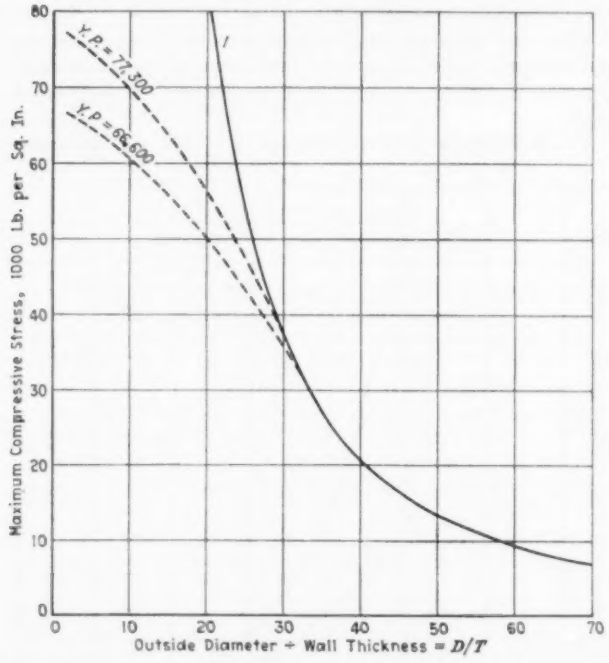

Fig. 5 Relation Between Maximum Compressive Stress at Collapsing Pressure and Ratio D/T, for Commercial Tubes

Note: Tubes are 8 or more diameters in length and of uniform roundness and thickness.
1—Calculated from Sturm's equation.

It is evident in this figure that the experimental curve and Sturm's curve are in close agreement at the higher D/T ratios.

b Stewart's Experimental Results

In Fig. 4 there are plotted the results of Stewart's tests on 256 lap-welded steel tubes. These tubes were 3 in. to 13 in. in diameter, 0.11 in. to 0.51 in. thick, and over 8 diameters long. The D/T ratios ranged from 12.3 to 63.0. The average yield point of the steel was 37,000 lb. per sq. in. The dimensions and collapsing strengths of these tubes are listed in Table 2. The average variation in thickness $[(T_{avg.} - T_{min.}) \times 100/T_{avg.}]$ was 12 per cent, while the average out-of-roundness $[(D_{max.} - D_{min.}) \times 100/D_{min.}]$ was 1.4 per cent. These variations were based on measurements made at the collapsed section of the tubes.

The curve of experimental results in Fig. 4 does not conform to Sturm's curve so closely as does the experimental curve in Fig. 3, for the higher D/T ratios. At the lower D/T ratios it is evident that the curve in Fig. 4 approaches the yield point of the steel in the tubes. The lack of agreement between Sturm's curve and the experimental curve in Fig. 4 is due to the out-of-roundness and variation in thickness of the tubes. The quantitative effect of out-of-roundness in reducing the collapsing strength will be discussed in a subsequent section.

[4] See Appendix No. 3 for tables.

c A. O. Smith Corporation's Experimental Results

In Fig. 1 there are plotted the results of A. O. Smith Corporation's tests on 14 arc-welded tubes. These tubes were $8^5/_8$ in. to 16 in. in diameter, 0.25 in. to 0.38 in. thick, and over 8 diameters long. The D/T ratios ranged from 34.3 to 61.5, and the average yield point of the steel was 52,000 lb. per sq. in. The dimension ratios and collapsing strengths of these tubes are listed in Table 3. The average variation in thickness[5] of these tubes was 2.5 per cent, while the average out-of-roundness was 0.77 per cent. These variations were based on measurements made at the collapsed section of the tubes. The general direction of the experimental curve in Fig. 1 for the lower D/T ratios was further established by eight additional tests on tubes having D/T ratios of 24.4 to 25.9. The results of these tests are not classified with the foregoing group of 14 because of the slightly different method of manufacture.

As mentioned in the foregoing section, the curve of experimental results in Fig. 1 is in agreement with Sturm's curve at the higher D/T ratios, but not at the lower ones. At the lower ratios, the experimental curve approaches the yield point of the steel in the tubes.

In Fig. 5 there are plotted the results of A. O. Smith Corporation's tests on 4 seamless tubes. These tubes were $8^5/_8$ in. to 9 in. in diameter, 0.40 in. to 0.50 in. thick, and over 8 diameters long. The D/T ratios ranged from 18.0 to 21.5. The average yield point of the steel in two of these tubes was 77,300 lb. per sq. in., and in the other two, 66,600 lb. per sq. in. The dimension ratios and collapsing strengths of these tubes are shown in Table 4. The average variation in thickness of the first two was 4.8 per cent, and of the second two, 11 per cent, while the average out-of-roundness of the first two was 0.23 per cent and of the second two, 0.27 per cent.

The experimental results of these tubes at the lower D/T ratios lie in a curve drawn similarly to the experimental curves in Figs. 1 and 3, thus indicating that at the lower D/T ratios the experimental curve approaches the yield point of the steel in the tubes.

d Fundamental Relationship Between the Collapsing Strength of Long Steel Tubes and the Factors Controlling This Strength

From a consideration of Sturm's equation and of the experimental curves in Figs. 1 and 3, it is evident that Sturm's curve approximately defines the collapsing strength of long steel tubes at the higher D/T ratios. As Sturm's curve is based upon the elastic properties of the steel and the dimensions of the tube, it follows that the elastic constants and the D/T ratio are the controlling factors in determining the collapsing strength of tubes having the higher D/T ratios.

The elastic constants are represented by the modulus of elasticity and Poisson's ratio. The effect upon the collapsing strength of variations in these elastic constants, for the several types of steel used in tubes, is small. The controlling factors in determining the collapsing strength of long steel tubes having the higher D/T ratios therefore reduce to merely the ratio D/T itself.

Since the maximum stress in the tube at the collapsing pressure varies directly as the collapsing pressure for a given ratio

[5] The variation in thickness was measured at the collapsed section of the tube, and is equal to $[(T_{avg.} - T_{min.}) \times 100/T_{avg.}]$.

D/T, it follows that the ratio D/T controls the collapsing pressure of tubes having the higher D/T ratios.

Referring to Figs. 1, 3, 4, and 5, it is evident that the maximum stress in the tubes at the collapsing pressure approaches the yield point of the steel in the tubes, as the ratio D/T decreases. It also appears that the higher the yield point the greater the maximum stress, at the lower D/T ratios. Thus, for a ratio $D/T = 25$, the yield point and maximum stress of the tubes represented in Figs. 1, 3, 4, and 5 are set forth in the order of increasing maximum stress in Table 5. The effect of the yield point on the maximum stress becomes more pronounced as the ratio D/T decreases.

On the basis of Table 5 and the curves in Figs. 1, 3, 4, and 5, it appears that for steel tubes having the lower D/T ratios, increasing the yield point raises the maximum stress that may be withstood by the tubes under external pressure. Since the maximum stress varies directly with the collapsing pressure for a given ratio D/T, it follows that for long tubes having the lower D/T ratios, the yield point of the steel and the ratio D/T are the controlling factors in determining the collapsing pressure of the tubes. In developing the foregoing relationships, the following assumptions have been made:

1 The tubes consist of homogeneous steel, and are uniformly round and uniformly thick
2 The yield point of the steel in compression is assumed to be equal to the yield point in tension
3 For very low values of the ratio D/T, the collapsing strength approaches the ultimate strength of the steel in the tube.

The fundamental relationship between (*a*) the collapsing strength of a long steel tube and (*b*) the D/T ratio, the elastic constants, and the yield point of the steel, for tubes of steel having various yield points, is set forth in Fig. 6.

From the foregoing discussion it is concluded that the controlling factors in determining the collapsing strength of long steel tubes are: (1) the elastic constants and the ratio D/T for tubes having the higher D/T ratios; and (2) the yield point of the steel in the tube and the ratio D/T for tubes having the lower D/T ratios.

V—FUNDAMENTAL RELATIONSHIP BETWEEN (*a*) THE COLLAPSING STRENGTH OF A SHORT STEEL TUBE AND (*b*) THE RATIOS L/D AND D/T, THE ELASTIC CONSTANTS, AND THE YIELD POINT OF THE STEEL

In the foregoing section the fundamental relationship between the collapsing strength of a long steel tube and the factors that control this strength was presented. In this section the effect of the ratio L/D of length of tube to diameter as an additional factor in controlling the collapsing strength will be considered. It has been shown that for steel tubes having a ratio L/D of 8 or more the collapsing strength is practically unaffected by this ratio (1) (2). This section will therefore concern tubes having a ratio L/D of less than 8.

No tests on short tubes were performed by A. O. Smith Corporation, as the results of an investigation on short tubes by Carman provided sufficient data to enable the effect of the ratio L/D on the collapsing strength to be determined. Carman's work on short tubes was selected as a basis for determining the effect of the ratio L/D on account of the great care exercised in preparing the specimens and in performing the collapsing tests.

Before discussing the effect of the ratio L/D on the collapsing strength of short tubes, a review will be made of the factors that affect the collapsing strength of such tubes in order that Carman's data may be properly evaluated. These factors are as follows:

1 Ratio of length of tube to diameter of tube, L/D
2 Ratio of diameter of tube to wall thickness, D/T
3 Variations in the thickness of the tube
4 Yield point of the steel in the tube
5 Elastic constants of the steel in the tube, represented by the modulus of elasticity and Poisson's ratio
6 Variations in the diameter of the tube, and
7 Method of manufacturing the tube.

On account of the care with which Carman had his specimens machined, the effect of variations in the diameter and thickness on the collapsing strength of the tube may be considered as negligible. Since the effect of variations in the elastic constants of commercial steels on the collapsing strength of steel tubes is

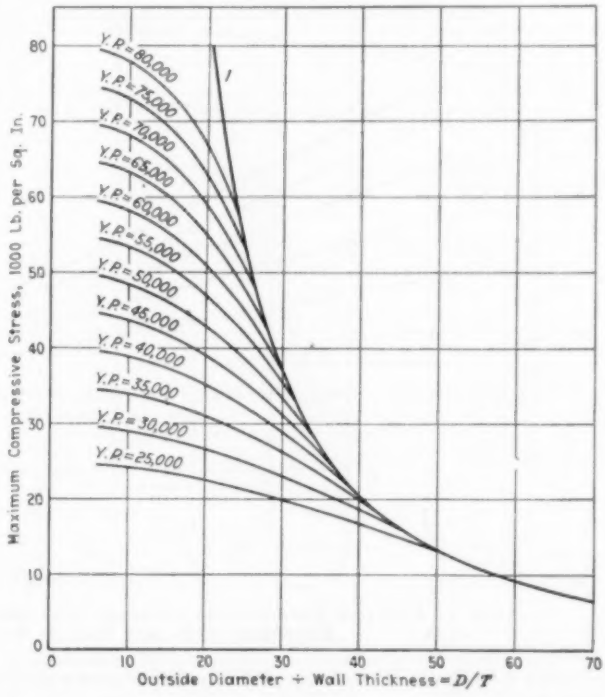

FIG. 6 RELATION BETWEEN MAXIMUM COMPRESSIVE STRESS AT COLLAPSING PRESSURE AND RATIO D/T, FOR HOMOGENEOUS STEEL PIPE HAVING VARIOUS YIELD-POINT VALUES

1—Calculated from Sturm's equation.

small, the fifth factor may be considered as constant. All of Carman's steel tubes were made in the same way and from the same quality of material; consequently the effect of the method of manufacture may also be considered as constant. Accordingly, there remain for consideration the effects of only three factors on the collapsing strength of Carman's short steel tubes, namely, the ratio of length of tube to diameter, L/D, the ratio of diameter to thickness, D/T, and the yield point of the steel in the tube.

a APPLICATION OF CARMAN'S DATA TO STURM'S EQUATION

The effect of the ratio L/D on the collapsing strength of short tubes was investigated by applying Carman's experimental data to Sturm's equation for determining the collapsing strength of steel tubes. These data cover tubes having an L/D ratio of 1.74 to 6.09. In order to determine the effect of the L/D ratio on the collapsing strength of tubes on the border line between short tubes and long tubes, additional data were used on

tubes having an L/D ratio of 7.60 to 8.08. These data are set forth in Table 6.

In applying Sturm's equation to short tubes, the term N (the number of lobes into which the tube collapses) is the only unknown variable. It is entirely logical that N should be represented by either a whole or compound number. In order to evaluate this term, the foregoing data on the collapsing pressure of short tubes were substituted in Sturm's equation, and N was determined for several L/D ratios. The results of these determinations were plotted in a series of intermediate curves, of which Fig. 7 represents the final result. In Fig. 7 the value of N is plotted against the ratio L/D for various D/T ratios. On the basis of the value of N shown in Fig. 7, the collapsing strengths of short tubes having L/D ratios of $1^1/_2$ to 7 were calculated. The results of these calculations are shown in Table 7.

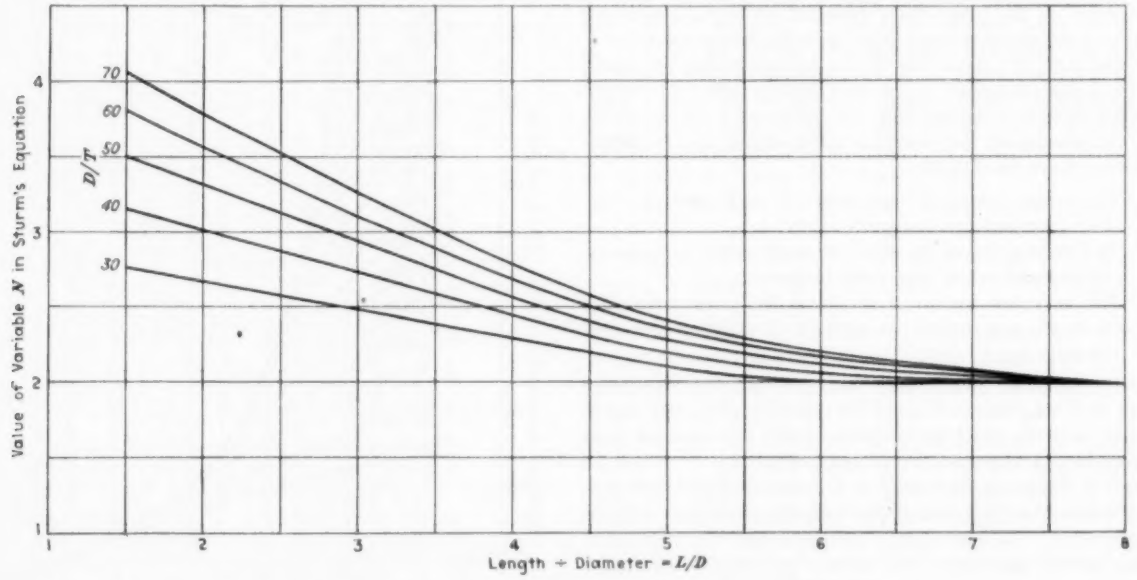

FIG. 7 RELATION BETWEEN THE VARIABLE N IN STURM'S EQUATION AND THE RATIO OF LENGTH OF TUBE TO DIAMETER (L/D), FOR VARIOUS RATIOS OF DIAMETER TO THICKNESS (D/T)

b FUNDAMENTAL RELATIONSHIP BETWEEN THE COLLAPSING STRENGTH OF SHORT STEEL TUBES AND THE FACTORS THAT CONTROL THIS STRENGTH

On the basis of the determination of the collapsing strength of short steel tubes obtained by substituting the proper value of N in Sturm's equation, and on the basis of the experimental data on short tubes, the collapsing strengths of short steel tubes were plotted against the D/T ratios for various L/D ratios, as shown in Fig. 8. The collapsing strength was determined by solving Sturm's equation for collapsing pressure, and then substituting this value of pressure in the following formula.

$$S = \frac{PD}{2T} \quad \text{[D]}$$

where S = maximum compressive stress in the tube, lb. per sq. in.
P = collapsing pressure of the tube, lb. per sq. in.
D = outside diameter of the tube, inches
T = thickness of the tube, inches.

NOTE: The simplified formula [D] may be used in place of the fundamental formula [C], given in section III, for D/T ratios of 32 or more without incurring an error greater than 3 per cent.

From Fig. 8 it is concluded that the collapsing strength of short steel tubes is controlled by the elastic properties and the L/D and D/T ratios for the higher D/T ratios; and by the yield point of the steel and the L/D and D/T ratios for the lower D/T ratios.

Since the collapsing pressure varies directly with the collapsing strength, it follows that these relationships also apply to the collapsing pressure.

In order that the information contained in Fig. 9 may be used more readily, the curves have been replotted for the individual L/D ratios, in Figs. 9 to 15.

As in the case of the long tubes discussed in the previous section, the following assumptions apply to the fundamental relationship between the collapsing strength of short steel tubes and the factors that control this strength, namely:

1 The tubes are made of homogeneous steel, and are uniformly round and uniformly thick.

2 The yield point of the steel in compression is assumed to be equal to the yield point in tension.

3 For very low values of the ratio D/T, the collapsing strength approaches the ultimate strength of the steel in the tube.

c EFFECT OF ENDS ON THE COLLAPSING STRENGTH OF SHORT STEEL TUBES

The parameter a in Sturm's equation concerns the end conditions of the tube. The experimental data used in developing the effect of the ratio L/D on the collapsing strength of short tubes were derived from simply supported tubes, for which $a = 1$.

In determining the collapsing strength of short tubes with ends, the value of a might conceivably be increased somewhat. It is suggested that further tests might be made which would indicate the value of a to be used for vessels having ends of a certain degree of fixity.

However, it is considered that designs based on the curves shown in Fig. 8 will always be on the side of safety.

VI—EFFECT OF OUT-OF-ROUNDNESS ON THE COLLAPSING STRENGTH OF STEEL TUBES

The experimental data obtained from A. O. Smith Corporation's tests on tubes did not reveal the effect of out-of-roundness on the collapsing strength of the tubes. The degree of out-of-

roundness in some of the tubes was too small to be evaluated; and in others the effect of out-of-roundness appeared to be repressed by the method of manufacturing the tube. Consequently Stewart's data (1) on the collapse of long tubes were selected to reveal the effect of out-of-roundness on the collapsing strength.

a Effect of Out-of-Roundness in Reducing the Collapsing Strength of Steel Tubes, as Indicated by Theoretical Considerations

An investigation of the effect of out-of-roundness on the basis of theoretical considerations was first made, which later served as a guide for interpreting Stewart's data. The effect of out-of-roundness as indicated by theoretical considerations, however, did not conform quantitatively to the experimental evidence. It did, however, conform qualitatively to the experimental evidence, in so far as it indicated that the effect of out-of-roundness in reducing the collapsing strength of steel tubes increases as the ratio D/T of diameter to thickness increases.

Because of the lack of quantitative agreement between the effect of out-of-roundness based upon theoretical considerations and that indicated by the experimental evidence, the latter was used to evaluate the effect of out-of-roundness in reducing the collapsing strength of steel tubes.

A study of the effect of out-of-roundness based upon theoretical considerations was made by means of Timoshenko's analysis of an elliptical ring submitted to uniform pressure (7). The results of this calculation are presented in Fig. 16.

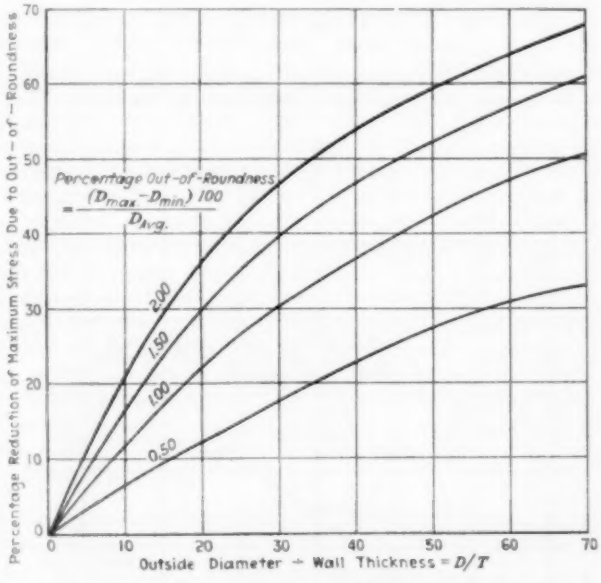

Fig. 16 Showing Effect of Out-of-Roundness in Reducing Maximum Stress in Tube at Collapsing Pressure, as Indicated by Theoretical Considerations

In this figure the percentage reduction of stress in the tube at the collapsing pressure (due to out-of-roundness) is plotted against the ratio of outside diameter to wall thickness, D/T, for various percentages of out-of-roundness. The percentage of out-of-roundness is determined by dividing the difference between the maximum and minimum outside diameters by the average outside diameter and multiplying this result by 100.

It is evident that the effect of out-of-roundness in reducing the collapsing pressure (as derived from the foregoing theoretical considerations) increases as the ratio D/T increases (see Fig. 16). It should be noted, however, as will subsequently be shown, that as the ratio D/T increases and the collapsing strength becomes controlled by the elastic properties of the tube rather than by the yield point of the steel in the tube, the effect of out-of-roundness decreases.

b Application of Stewart's Data to the Determination of the Effect of Out-of-Roundness in Long Steel Tubes

Stewart's data are not ideally suited to an investigation on the effect of out-of-roundness on account of wide variations in the thickness of his specimens. The difference between the collapsing strength of his tubes and that of perfect tubes consequently represents the effects of variations in both roundness and thickness. These data were not sufficiently complete to enable the effects of variations in thickness and roundness on the collapsing strength to be readily separated.

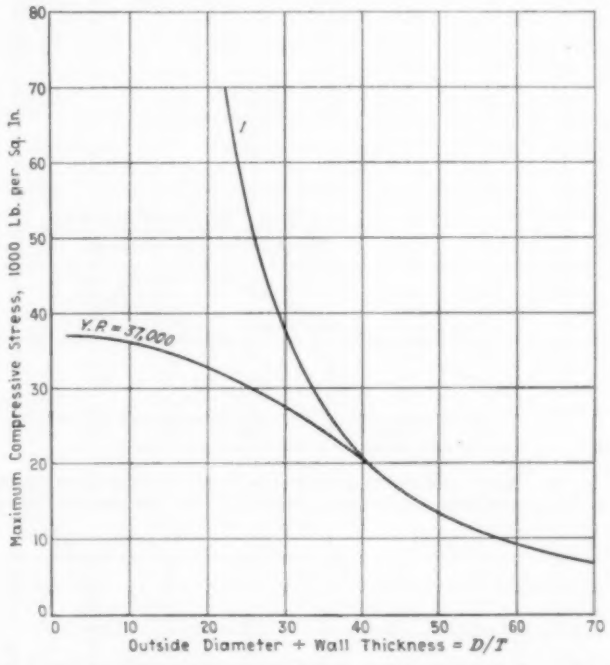

Fig. 17 Relation Between Maximum Compressive Stress at Collapsing Pressure and D/T, for Homogeneous Tubes of Steel Having a Yield Point of 37,000 Lb. per Sq. In.
1—Calculated from Sturm's equation.

However, on the basis of calculations made with these data, it is clearly indicated that the effect of the variations in thickness prevalent in these specimens is in large measure subordinate to the effect of variations in roundness in reducing the collapsing strength, and that the out-of-roundness has a much greater effect than the variation in thickness prevalent in Stewart's tubes.

Since the effects of variations in roundness and thickness are difficult to separate, the total effects of both variations were considered to be a safe evaluation of the maximum effect of out-of-roundness.

The determination of the effect of out-of-roundness presupposes a knowledge of the collapsing strength of perfect tubes, that is, homogeneous tubes of uniform roundness and thickness. The collapsing strength of tubes of steel having the same yield point as the steel in Stewart's tubes, namely, 37,000 lb. per sq. in., is indicated in Fig. 17. This curve is derived on the basis of the fundamental relationship between (*a*) the collapsing strength of long steel tubes and (*b*) the ratio D/T, the elastic constants, and the yield point of the steel, which relationship

is set forth in Fig. 6. In Fig. 17 the maximum compressive stress in the tube at the collapsing pressure is plotted against the ratio D/T of diameter to thickness. As discussed in a previous section, at the lower D/T ratios, the curve marked "Y. P. = 37,000" determines the collapsing strength; while at the higher D/T ratios the curve calculated from Sturm's equation determines the collapsing strength.

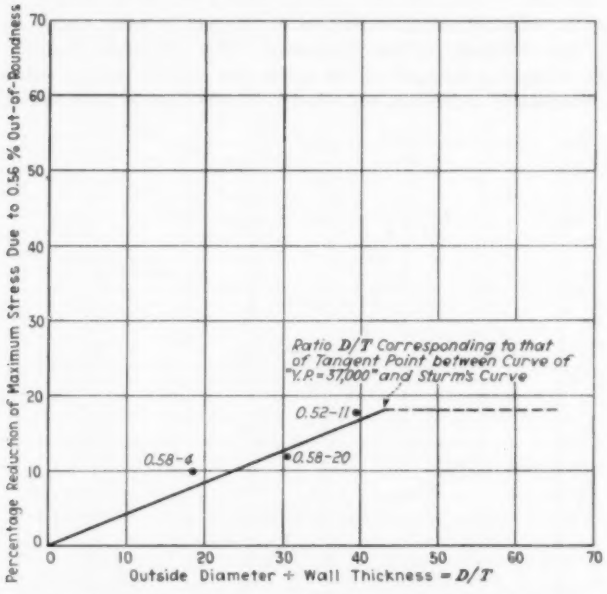

FIG. 18 SHOWING EFFECT OF 0.56 PER CENT OUT-OF-ROUNDNESS IN REDUCING THE COLLAPSING STRENGTH OF STEWART'S TUBES

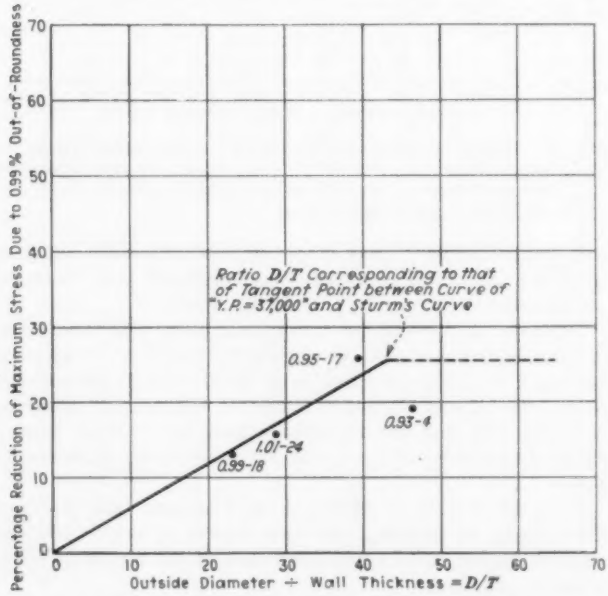

FIG. 19 SHOWING EFFECT OF 0.99 PER CENT OUT-OF-ROUNDNESS IN REDUCING THE COLLAPSING STRENGTH OF STEWART'S TUBES

The maximum stresses in Stewart's tubes were calculated by means of formula [D], Section V, and are set forth in Table 8. The maximum stresses in perfect tubes, having the same D/T ratio as Stewart's tubes, were read off the proper curve in Fig. 17, and are listed in Table 8.

The percentage of out-of-roundness in Stewart's tubes varied from less than 0.25 to more than 2.00. In order to evaluate the effect of this range of out-of-roundness the data were classified into zones of the following percentages, as shown in Table 9: 0.25–0.75, 0.75–1.25, 1.25–1.75, and 1.75–2.25. The average effect of each of these zones in reducing the collapsing strength was plotted in a series of intermediate curves shown in Figs. 18–21.

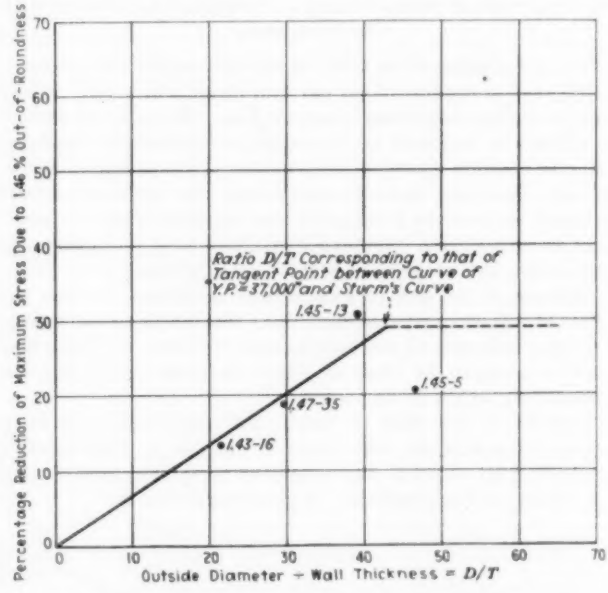

FIG. 20 SHOWING EFFECT OF 1.46 PER CENT OUT-OF-ROUNDNESS IN REDUCING THE COLLAPSING STRENGTH OF STEWART'S TUBES

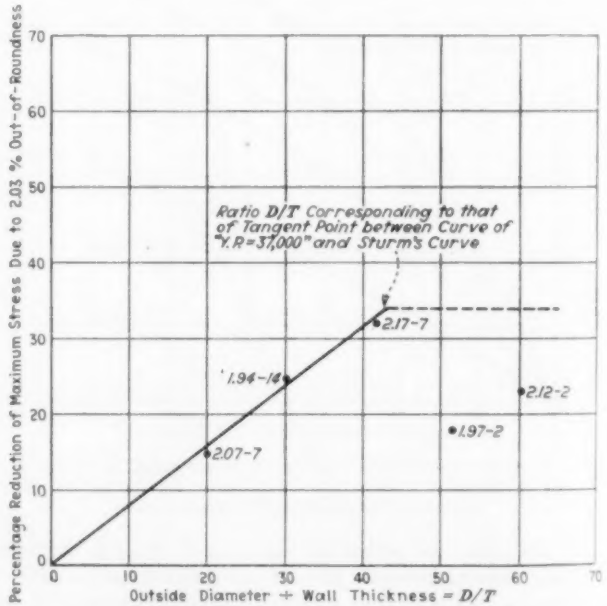

FIG. 21 SHOWING EFFECT OF 2.03 PER CENT OUT-OF-ROUNDNESS IN REDUCING THE COLLAPSING STRENGTH OF STEWART'S TUBES

In Figs. 18–21 the percentage reduction of stress in Stewart's tubes at the collapsing pressure is plotted against the ratio D/T for percentages of out-of-roundness ranging from 0.56 to 2.03.

The numbers accompanying the plotted points indicate first,

the average percentage of out-of-roundness of, and, second, the number of tubes represented by, the point: thus, in Fig. 18 the point having the coordinates of 9.9 per cent reduction in stress and $D/T = 18.5$ represents four tubes whose average out-of-roundness is 0.58 per cent, and whose average D/T ratio and average percentage reduction in stress are indicated by its coordinates.

In Figs. 19, 20, and 21 there are plotted the data on tubes having D/T ratios between 45 and 65. While there are not enough data at these higher ratios to evaluate quantitatively the effect of out-of-roundness, it is nevertheless evident that this effect decreases after attaining a maximum in the vicinity of $D/T = 40$. From a study of the factors that affect the collapsing strength of tubes, it has been concluded that this maximum is located at the point of tangency between the curve of the yield point of the steel in the tubes and the curve calculated from Sturm's equation. These curves and their tangent point are shown in Fig. 17. (In interpreting Fig. 17, it should be noted that the average yield point of the steel in Stewart's tubes is 37,000 lb. per sq. in.) In other words, the maximum effect of any given percentage of out-of-roundness occurs at the ratio D/T at which the yield point of the steel in the tube ceases to control the collapsing strength, and beyond which the collapsing strength is controlled only by the elastic properties of the steel and the tube dimensions. This ratio D/T is 43 for Stewart's tubes.

Since there are insufficient data available to evaluate quantitatively the effect of out-of-roundness at the higher D/T ratios, a horizontal broken line is drawn to indicate that the effect of out-of-roundness beyond the ratio $D/T = 43$ does not increase.

For purposes of design, the effect of out-of-roundness, in reducing the collapsing strength of tubes having D/T ratios greater than that of the tangent point, may safely be taken as that indicated by the ordinate of the horizontal broken line corresponding to the given out-of-roundness.

The curves shown in Figs. 18 to 21 were consolidated into the lower set of curves in Fig. 22. In the upper part of Fig. 22 there are drawn the curves showing the collapsing strength of two sets of perfect tubes having various D/T ratios, the steel in one set having a yield point of 35,000 lb. per sq. in., and that in the other of 75,000 lb. per sq. in. It is evident in Fig. 22 that (*a*) as the ratio D/T increases up to the tangent point, the percentage effect of out-of-roundness in reducing the collapsing strength also increases; and (*b*) the percentage effect of out-of-roundness in reducing the collapsing strength decreases for tubes having higher D/T ratios as the yield point of the steel in the tubes increases.

c Comparison of the Effect of Out-of-Roundness Based Upon Theoretical Considerations and That Indicated by the Experimental Results

A comparison of Figs. 16 and 22 indicates that the percentage effect of out-of-roundness based upon theoretical considerations is greater than that indicated by the experimental results. A small part of the discrepancy arises from the fact that the effect of out-of-roundness indicated by the experimental evidence is diminished by the variation in thickness, more specifically by the thicker portions of the tube.

d Effect of Out-of-Roundness in a Short Steel Tube

The foregoing data on the effect of out-of-roundness in reducing the collapsing strength of steel tubes were obtained from long tubes, that is, tubes having a ratio of length to diameter (L/D) of 8 or over. The data available on short tubes were not sufficient to reveal the effect of out-of-roundness on the collapsing strength of these tubes. However, it is believed that the effect of out-of-roundness in short tubes does not exceed that in long tubes because of the supporting action of the ends, and consequently the effect in long tubes may be regarded as the safe maximum which the effect of out-of-roundness in short tubes does not exceed.

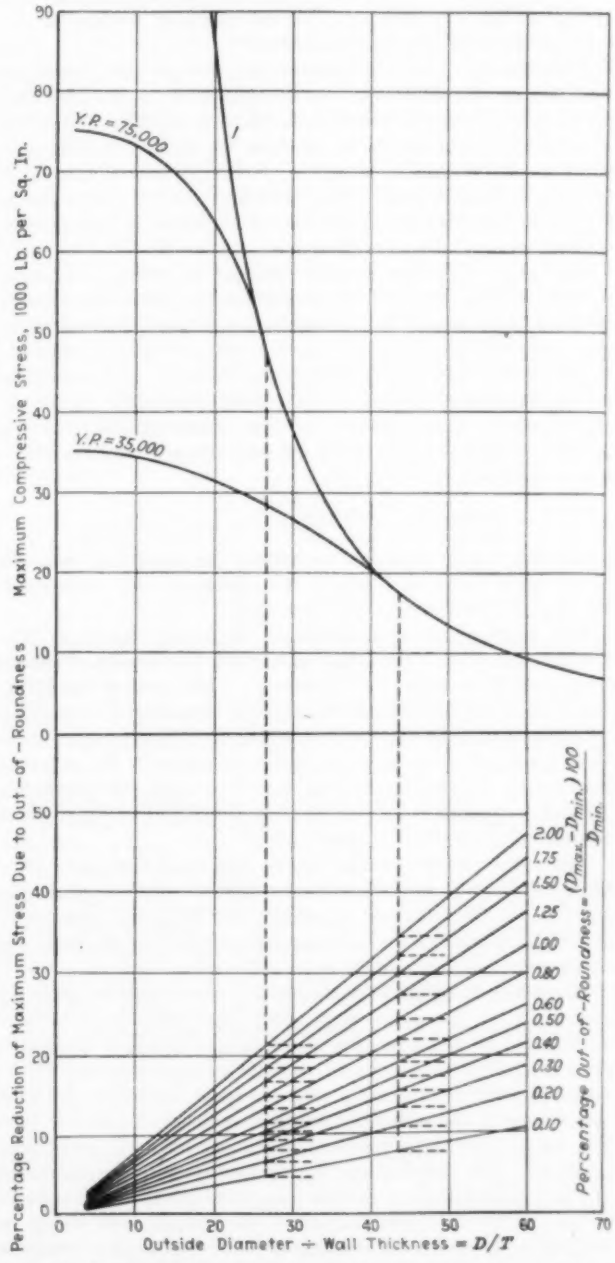

Fig. 22 Showing Effect of Out-of-Roundness of Steel Tubes in Reducing Maximum Compressive Stress at Collapsing Pressure, for Various D/T Ratios, With Particular Reference to Steels Having Yield-Point Values of 35,000 and 75,000 Lb. per Sq. In.

1—Calculated from Sturm's equation.

Since all short tubes in which the stress condition is of importance have closed ends, vessels may be considered as short tubes if their L/D ratios are less than 8, and as long tubes if their L/D ratios are 8 or over.

VII—EFFECT OF OTHER FACTORS ON THE COLLAPSING STRENGTH OF STEEL TUBES

a Variation in Wall Thickness

The variation in wall thickness of the tubes tested by A. O. Smith Corporation did not appear to affect the collapsing strength. The average of the variations in thickness $[(T_{avg.} - T_{min.}) \times 100/T_{min.}]$ of the collapsed sections of the tubes plotted in Fig. 1 was 2.5 per cent.

The data on Carman's tubes do not include the percentage variation in wall thickness. On account of the care with which his specimens were selected and machined, it is probable that the variation in thickness was so small as not to have a noticeable effect on the collapsing strength. A comparison of the curve of the collapsing strength of his tubes and Sturm's curve, shown in Fig. 3, indicates that the effect of variation in thickness in Carman's tubes may be neglected.

The data on Stewart's tubes indicate an average variation in wall thickness between the average and minimum thicknesses of about 12 per cent. As discussed in the section VI on the effect of out-of-roundness, these data are not sufficiently complete to enable the effects of variations in thickness and roundness on the collapsing strength to be readily separated. However, the out-of-roundness prevalent in these tubes appears to have a greater effect in reducing the collapsing strength than the variation in thickness.

b Method of Manufacturing the Tube

The method of manufacture affects the collapsing strength of a tube in so far as it affects the roundness and thickness of the tube and the yield point of the steel.

The average out-of-roundness of the tubes plotted in Fig. 1 is 0.77 per cent. According to Fig. 22, this degree of out-of-roundness (for a tube of steel having a yield point of 52,000 lb. per sq. in.) should produce a maximum reduction in collapsing strength of 18.2 per cent.[6] It is evident in Fig. 1, however, that the experimental curve is not below Sturm's curve, and that this degree of out-of-roundness does not appear to affect the collapsing strength. The explanation of this lack of effect seems to concern the method of manufacture.

The tubes plotted in Fig. 1 were cold-sized externally after being welded. It is believed that this cold sizing represses the effect of out-of-roundness in reducing the collapsing strength of the tubes, on the basis of the reasoning presented in the following paragraphs.

When the sizing press is closed, the tube is almost perfectly round. After the press is released, the tube may become slightly out of round on account of small changes in the elastic recovery, which are produced by slight variations in wall thickness. If uniform external pressure is again applied to the tube (as is done in the collapsing tests), it is believed that the tube will regain its nearly complete roundness before it eventually collapses. The fact that the slight out-of-roundness in the tubes of Fig. 1 does not affect the collapsing strength therefore appears to be due to the beneficial effect of external cold sizing in tending to preserve the roundness under subsequent compression.

This external cold sizing also increases the yield point of the metal in compression, and therefore tends to increase the collapsing strength of tubes having the lower D/T ratios.

[6] This value is obtained by noting that in Fig. 1 the tangent point between the experimental curve and Sturm's curve would theoretically lie at about $D/T = 37.5$, and that in Fig. 22, at $D/T = 37.5$, 0.77 per cent out-of-roundness would produce a reduction in collapsing strength of about 18.2 per cent.

VIII—DETERMINATION OF THE COLLAPSING STRENGTH OF A STEEL TUBE BY MEANS OF THE FUNDAMENTAL RELATIONSHIPS BETWEEN THE COLLAPSING STRENGTH AND THE FACTORS THAT AFFECT THIS STRENGTH

In this section illustrative examples will be presented of the determination of the collapsing strength of long and short tubes, both thick and thin, made of steel of various yield points.

It is believed that on the basis of the following procedure the collapsing strength of any commercial steel tube can be determined from its dimensions, the yield point of the steel, and its degree of out-of-roundness.

a Collapsing Strength of a Long, Thick Steel Tube (Having a Small D/T Ratio)

Let it be assumed that this tube is 8 or more diameters long, has a D/T ratio of 25, a yield point of steel of 35,000 lb. per sq. in., 1 per cent out-of-roundness, and a negligible variation in thickness. The collapsing pressure of this tube will be found from the following procedure.

1 Determine the maximum stress in the tube at the collapsing pressure by consulting Fig. 6. Follow the curve marked "Y. P. = 35,000" until the ratio $D/T = 25$ is reached. At this point read off the maximum stress of 28,800 lb. per sq. in. This is the maximum stress that can be withstood by a homogeneous tube of uniform roundness and thickness, having the aforementioned physical properties.

2 Determine the amount by which the maximum stress should be reduced on account of 1 per cent out-of-roundness by consulting Fig. 22. Note that the ratio $D/T = 25$ is less than the tangent-point ratio $D/T = 43.5$, between the curve marked "Y. P. = 35,000" and Sturm's curve. Hence the percentage reduction of maximum stress may be read from the intersection of the ordinate $D/T = 25$ with the 1 per cent out-of-roundness curve, and is found to be 13.9 per cent.

3 Solve for the collapsing pressure of the tube by substituting in the proper one of the following formulas. Use formula [E] for tubes having a D/T ratio of 32 or over, and [F] for D/T ratios of less than 32.

$$P = \frac{(100 - A)}{100} \frac{ST}{R_1} \quad \text{[E]}$$

$$P = \frac{(100 - A)}{100} \frac{S(R_1^2 - R_2^2)}{2R_1^2} \quad \text{[F]}$$

where P = collapsing pressure of the tube, lb. per sq. in.
A = percentage reduction of the maximum stress due to out-of-roundness
S = maximum compressive stress at the collapsing pressure of a tube with no out-of-roundness, lb. per sq. in.
T = thickness of the tube, inches
R_1 = outside radius of the tube, inches
R_2 = inside radius of the tube, inches.

Using formula [F], the collapsing pressure is found to be 1900 lb. per sq. in.

b Collapsing Strength of a Long, Thin Steel Tube (Having a Large D/T Ratio)

Let it be assumed that this tube is 8 or more diameters long, has a D/T ratio of 50, a yield point of steel of 35,000 lb. per sq. in., 1 per cent out-of-roundness, and a negligible variation in thickness. According to the steps outlined in the previous example:

1 Determine the maximum stress in the tube from Fig. 6 by locating the intersection of the curve marked "Y. P. =

35,000" and the ordinate $D/T = 50$. This stress is found to be 13,400 lb. per sq. in.

2 Determine the reduction in maximum stress due to out-of-roundness by consulting Fig. 22. Note that the ratio $D/T = 50$ is greater than the tangent-point ratio $D/T = 43.5$ for steel having a yield point of 35,000 lb. per sq. in., and consequently the percentage reduction is determined by the intersection of the ordinate $D/T = 50$ with the horizontal broken line drawn from the intersection of the tangent-point ratio $D/T = 43.5$ with the 1 per cent curve. The percentage reduction in stress is found to be 24.2.

3 Solve for the collapsing pressure of the tube by substituting in formula [E]. The collapsing pressure is found to be 406 lb. per sq. in.

c COLLAPSING STRENGTH OF A SHORT, THICK STEEL TUBE (HAVING A SMALL D/T RATIO)

Let it be assumed that this tube is 4 diameters long, has a D/T ratio of 20, a yield point of steel of 60,000 lb. per sq. in., 0.80 per cent out-of-roundness, and a negligible variation in thickness.

1 Determine the maximum stress in the tube by consulting Fig. 12 for $L/D = 4$. The maximum stress is determined by the intersection of the curve marked "Y. P. = 60,000" with the ordinate $D/T = 20$, and is found to be 54,200 lb. per sq. in.

2 Determine the reduction in maximum stress due to out-of-roundness by consulting Fig. 22. Note that the ratio $D/T = 20$ is less than the tangent-point ratio $D/T = 38.7$ between the curve marked "Y. P. = 60,000" and the curve of $L/D = 4$. Accordingly, the percentage reduction is determined by the intersection of the ordinate $D/T = 20$ with the 0.80 per cent out-of-roundness curve, and is found to be 9.9 per cent.

3 Solve for the collapsing pressure of the tube by substituting in formula [F]. The collapsing pressure is found to be 4640 lb. per sq. in.

d COLLAPSING STRENGTH OF A SHORT, THIN STEEL TUBE (HAVING A LARGE D/T RATIO)

Let it be assumed that this tube is 4 diameters long, has a D/T ratio of 55, a yield point of steel of 60,000 lb. per sq. in., 0.80 per cent out-of-roundness, and a negligible variation in thickness.

1 Determine the maximum stress in the tube by consulting Fig. 12. The maximum stress is determined by the intersection of the curve marked "Y. P. = 60,000" with the ordinate $D/T = 55$, and is found to be 22,200 lb. per sq. in.

2 Determine the reduction in maximum stress due to out-of-roundness by consulting Fig. 22. Note that the ratio $D/T = 55$ is greater than the tangent point ratio $D/T = 38.7$, for steel having a yield point of 60,000 lb. per sq. in., and consequently the percentage reduction is determined by the intersection of the ordinate $D/T = 55$ with the horizontal broken line drawn from the intersection of the tangent-point ratio $D/T = 38.7$ with the 0.80 per cent curve. The percentage reduction in stress is found to be 19.2 per cent.

3 Solve for the collapsing pressure of the tube by substituting in formula [E]. The collapsing pressure is found to be 652 lb. per sq. in.

IX—CONCLUSIONS

The method for determining the collapsing strength of steel tubes presented in this paper was developed from the following considerations.

1 The collapsing strength of a steel tube is affected by the following factors:

a Ratio of length of tube to diameter, L/D
b Ratio of diameter of tube to wall thickness, D/T
c Variations in thickness
d Yield point of the steel in the tube
e Elastic constants of the steel in the tube, represented by the modulus of elasticity, and Poisson's ratio
f Variations in roundness
g Method of manufacturing the tube.

2 The collapsing pressure of long steel tubes (having an L/D ratio of 8 or over) is controlled by the elastic properties and the ratio D/T for the higher D/T ratios; and by the yield point of the steel and the D/T ratio for the lower D/T ratios.

3 The collapsing pressure of short steel tubes (having an L/D ratio of less than 8) is controlled by the elastic properties and the L/D and D/T ratios for the higher D/T ratios; and by the yield point of the steel and the L/D and D/T ratios for the lower D/T ratios.

4 The effect of out-of-roundness in reducing the collapsing pressure of steel tubes increases as the ratio D/T increases, up to the tangent point of the curve of the yield point of the steel in the tube and the curve calculated from Sturm's equation; beyond this point the effect of out-of-roundness does not increase as the ratio D/T increases. The effect of out-of-roundness in reducing the collapsing pressure decreases, for tubes having higher D/T ratios, as the yield point of the steel in the tube increases.

EXPERIMENTAL WORK OF A. O. SMITH CORPORATION ON THE COLLAPSING STRENGTH OF STEEL TUBES

(*a*) *Method of Testing Tubes for Collapsing Pressure.* The experimental method employed for determining the collapsing pressure of tubes is essentially that used by Stewart, which it is believed was very well thought out by him (1). It consisted of subjecting the outside of the tube to gradually increasing uniform hydrostatic pressure until the tube was permanently deformed through collapse. The rate of expulsion of air from the inside of the tube was measured to indicate the approach of collapse. The maximum pressure attained was the collapsing pressure. It was read off two calibrated gages by two observers so as to minimize instrumental and observational errors. The lower of the two pressures was taken as the collapsing pressure.

The tubes tested were selected at random and were representative of commercial tubes.

Before testing the tube, thickness and roundness measurements were taken over a zone within which it was expected that collapse would occur. After testing the tube a section was cut through the collapsed portion and the thickness of the collapsed section measured. By these means the roundness and thickness of the collapsed section were accurately determined.

(*b*) *Description of Roundness-Measuring Apparatus.* The roundness of the tube is measured by means of the apparatus shown diagrammatically in Fig. 23. The tube *P* is revolved on the rollers *R* and upon rollers at the other end of the tube which are not shown in the figure. Differences in outside diameter from point to point on the periphery are determined by the gage *G*. The gage is attached to the upper arm *UA* through the holder *H*. The upper arm is rigidly connected to the lower arm *LA* through the post *V*. A counterweight *W* maintains

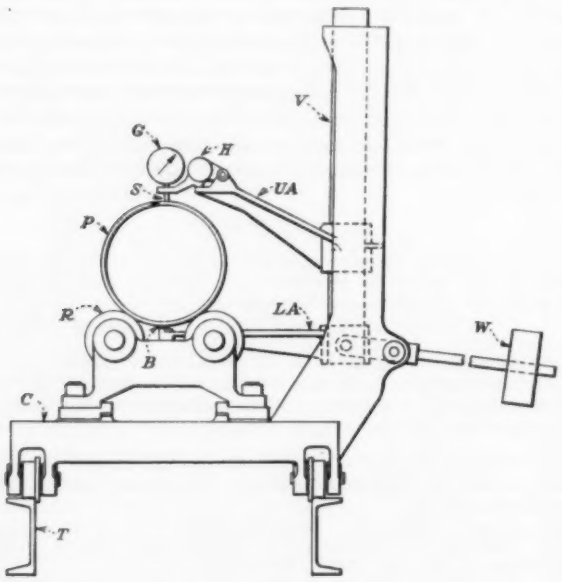

FIG. 23 APPARATUS FOR MEASURING ROUNDNESS OF PIPE

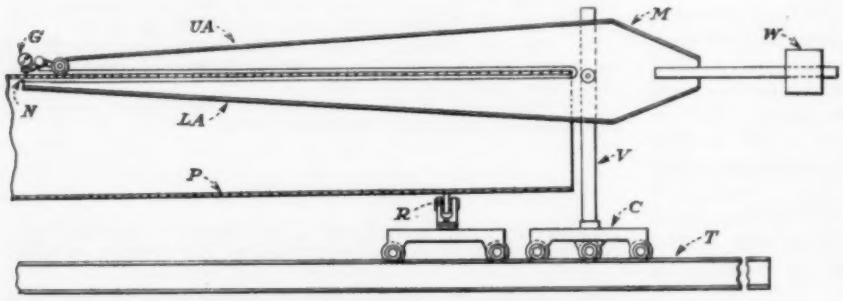

FIG. 24 APPARATUS FOR MEASURING THICKNESS OF PIPE

the lower arm in contact with the tube at *B*, which is diametrically opposite the gage *G*.

The upper arm is adjustable on the post, so that tubes of various diameters can be measured.

In order to measure roundness at intervals along the tube, the apparatus is mounted on the carriage *C* and run along the tracks *T*. The gage reads to 0.001 in.

(*c*) *Description of Thickness-Measuring Apparatus.* The wall thickness of the tube *P* is measured by means of the apparatus shown diagrammatically in Fig. 24. One half of the tube *P* is supported by the rollers *R* and the other half, which is not shown in the figure, by rollers at the other end of the tube. The measuring device *M* is rolled along the track *T* to the point at which a thickness measurement is desired, so that the upper arm *UA* is on the outside and the lower arm *LA* is on the inside of the tube. The measuring knob *N* is held in contact with the inner wall by the counterweight *W*. The wall thickness in thousandths of an inch is indicated on gage *G*.

The arms of the measuring device are adjustable on the vertical post *V*, so that the thickness can be measured for tubes of various diameters.

The carriage *C* enables the measuring device to be rolled back and forth along one half of the tube. The thickness of the other half is determined after the tube is reversed.

The wall thickness at various points on the periphery is measured after the tube is revolved on the rollers *R*.

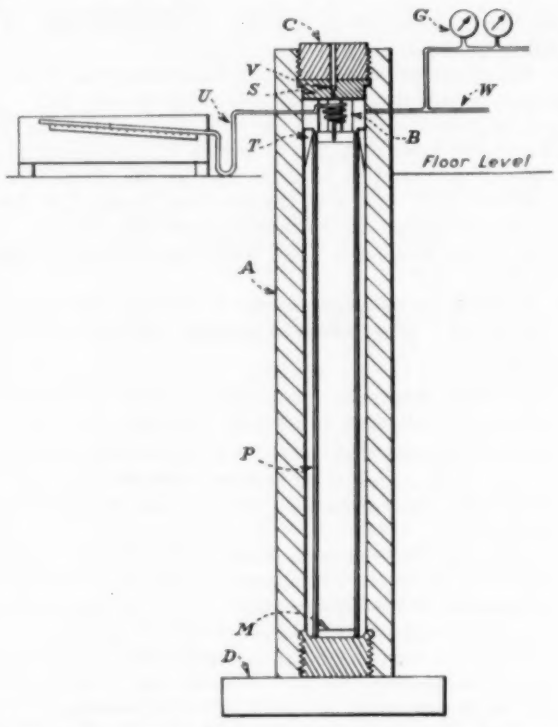

FIG. 25 APPARATUS FOR DETERMINING THE COLLAPSING PRESSURE OF PIPE

(*d*) *Description of Apparatus for Determining the Collapsing Pressure of Tubes.* The apparatus for determining the collapsing pressure of tubes is shown diagrammatically in Fig. 25. The pressure chamber *A* consists of an upright steel cylinder closed at the lower end, and resting on a concrete base *D* 13 ft. below the floor level. The chamber extends 3 ft. 3 in. above the floor level. Tubes 12 ft. long and up to 17 in. in outside diameter can be tested in this apparatus.

The screw cover *C* and secondary cover *S* are removable, so that the tube *P* may be lowered into place. Water under pressure is delivered to the chamber through the inlet *W*. Air between the tube and inner wall of the chamber is released through the valve *V*. The wooden blocks *B* and wedges *T* hold

the tube in place. The fittings required to make the apparatus watertight are not shown. Gages G indicate the pressure on the tube to the nearest five pounds per square inch for the lower ranges of pressure, and to the nearest ten pounds per square inch for the higher ranges.

Before a tube is tested, the ends are closed with the plugs M. A hole in the upper plug connects the inside of the tube with the right arm of the U-tube U. This tube is partially filled with water, and its left arm is open to the atmosphere. The function of the U-tube is to indicate the approach of collapse of the tube by revealing the rate at which the volume of expelled air changes with respect to pressure. At the approach of collapse, the amounts of air expelled increase for equal increments of pressure. The slightly inclined part of the left arm of the U-tube is adjustable, so that the expulsion of very small amounts of air can be detected. When collapse occurs, the water in the U-tube is forcibly ejected, and at the same time the pressure on the tube drops rapidly.

Appendix No. 2

WORK OF PREVIOUS INVESTIGATORS ON THE COLLAPSING STRENGTH OF STEEL TUBES

In the following discussion no attempt is made to evaluate the work of previous investigators. Their work is discussed only in relation to the development of the method of determining the collapsing strength of tubes which is presented in the paper.

(*a*) *Stewart.* In Stewart's investigation of the collapsing strength of commercial lap-welded steel tubes, the following factors were considered to have an influence on the collapsing strength of the tubes (1) (8).

1 Diameter of the tube
2 Length of tube between transverse joints or end connections tending to hold it to a circular form
3 Thickness of the wall
4 Deviation of the tube from perfect roundness
5 Physical properties of the material out of which the tube is made
6 Method of manufacturing the tube, in so far as it affects the uniformity of dimensions of the tube.

The empirical formulas for determining the collapsing strength of tubes that were developed in this investigation were based on the relationship between the collapsing pressure and the ratio of thickness to diameter (T/D). As a result of the investigation of the effect of the length of the tube upon the collapsing strength, it was concluded that the length has no practical influence on the collapsing pressure so long as it is not less than about six diameters. The extensive out-of-roundness measurements made in this investigation indicate that out-of-roundness was considered to have an influence on the collapsing strength of tubes. In the discussion of the physical properties of the steel in the tubes there were mentioned the yield point and ultimate strength. The method of manufacturing the tubes was considered to have an influence on the roundness and variation in thickness of the tubes.

Of the foregoing factors, the influence of the ratios L/D and T/D on the collapsing strength of lap-welded steel tubes were evaluated quantitatively.

(*b*) *Cook.* In Cook's investigation of the collapsing strength of "solid drawn" short, thin steel tubes, the ratios L/D and T/D and variation in thickness were considered to be important factors in determining the collapsing strength of steel tubes (9). On the basis of this investigation it was believed that the ratio L/D, above which the collapsing strength is unaffected by increase in length, probably varied from 13 to 18.

(*c*) *Carman.* In Carman's investigation of the collapsing strength of cold-drawn short steel tubes, the ratios L/D and T/D, out-of-roundness, and variations in thickness were considered to be important factors in determining the collapsing strength of steel tubes (2). From the results of this investigation it is evident that for steel tubes having an L/D ratio of 8 or more, the collapsing strength is practically unaffected by this ratio. In a previous investigation by Carman and Carr, the relationship between the collapsing strength of long, thin seamless tubes and the ratio T/D was indicated in the form of an Equation (11).

(*d*) *Southwell.* In Southwell's mathematical analysis of the collapse of short, thin tubes, an equation was developed for determining the collapsing pressure which took into consideration the dimensions of the tube, the modulus of elasticity, and Poisson's ratio (10).

(*e*) *Sturm.* Sturm's equation for determining the collapsing pressure of steel tubes has already been discussed in detail, so far as the dimensions of the tube, the modulus of elasticity, and Poisson's ratio are concerned.

Discussion

R. G. Sturm.[7] As Messrs. Jasper and Sullivan have pointed out, there are two distinct limitations upon the strength of thin shells under external pressure. One is that of purely elastic instability, and the other is that of instability resulting from the plastic yield of the material of which the shell is made. The first limiting condition is reached when the elastic distortions of the structure become relatively large under a slight increase in load. The other is reached when the strains in the material increase very rapidly with a slight increase in load. This is purely a case of plastic action, and the first signs of failure are indicated by the ordinary static-stress relationships. Between these two cases lies the range which cannot be figured by formulas for either case, because a combination of both actions really takes place.

Dr. H. M. Westergaard has divided the field of elastic action into three general classes:[8] orthostatic action, as in ordinary beams or tension members; astatic action, as in very long and thin columns or thin tubes; heterostatic action, as in crooked columns, columns with transverse loads, or thin tubes under similar conditions.

The field of heterostatic action in connection with the collapse of shells includes cases of partial hydrostatic pressure or concentrated loads resulting from supports and of concentrated or distributed loads resulting from appurtenances attached to the shell. Both papers show that their authors recognize this action.

Another classification of the actions of a shell subjected to external pressure may be made on the basis of the type of loads applied. In each general classification of loading just mentioned the loads may be applied in a number of ways. The buckling loads or pressures may be radial, axial, or a combination of both, thereby giving rise to biaxial buckling. The first type of loading is represented by that of a fire-tube boiler or a long pipe under partial vacuum. The shells referred to in the paper by Messrs. Saunders and Windenburg were subjected to both radial and axial pressure, uniform pressure being applied to both the sides and ends of the cylinders tested. This case is exemplified by the loading to which a submarine is subjected when it is submerged. A third case is that in which the end thrust is maintained and the radial pressure is removed. This case is exem-

[1] S is calculated by means of the following formula:

$$S = \frac{PD}{2T}$$

$$P = \frac{2}{3}\frac{Et^3}{D^3}\left[\frac{N^4 - N^2 - k^2 + k(2N^2 - m)}{N^2(1 - m^2)}\right]$$

$$S = \frac{E}{3}\frac{t^2}{D^2}\left[\frac{N^4 - N^2 + k^2 + k(2N^2 - m)}{N^2(1 - m^2)}\right]$$

See Section IIIa for explanation of terms.

plified by the action of short, thin tubular struts subjected to end loads.

The effect of end conditions upon the elastic instability is of great importance for short tubes, but is practically negligible for long tubes. A separate classification of tubes according to end conditions is necessary for each of the subdivisions previously mentioned.

The tests made by Jasper and Sullivan covered the range of plastic action and extended into the range of elastic action of long, nearly hinged ended tubes, in which case the end thrust is not a significant factor. The tests made by Saunders and Windenburg were in the elastic range of short, practically fixed-ended tubes, in which case the end thrust is a controlling factor in collapse. It may be seen, then, that while the results presented in these two papers appear to be quite different, they each fit into the particular parts of the general behavior of tubes indicated by a general theory of the elastic and plastic behavior of tubes under external pressure.

D. S. JACOBUS.[9] This is a valuable paper, and the authors should be complimented on the complete way in which they have analyzed and correlated the experimental data and for making additional experiments where most needed. The results will be useful in rationalizing the tube sizes for use under external pressure.

REID T. STEWART.[10] This paper makes free use of the results

of an extensive investigation of the collapsing properties of bessemer-steel lap-welded tubes published by the writer in 1906 Transactions of this Society. The purpose was to produce a dependable formula that could be readily used to determine the probable collapsing pressures of commercial tubes as then manufactured. The undertaking was meant to be of the most practical nature, but the writer spent much time in an effort to apply theory to the problem. In the end, however, he was obliged to resort to empiricism.

The authors of this paper seem to consider seriously the effects of the out-of-roundness of the tubes as reported by the writer. He is somewhat surprised at this, as he abandoned all idea of incorporating out-of-roundness in a formula after studying some 5000 experimental graphs made in this investigation. If the out-of-roundness had been elliptical in cross-section for a length of at least six diameters, the problem might have been comparatively simple. But most of the tubes were out of round in the most complex manner, not approximating even remotely to the theoretical elliptical section. Then, too, the characteristics of two adjacent sections are sometimes very different. The short diameter of one may roughly be at right angles to that of its neighbor, thus tending to lessen the weakness that would be caused by each alone. Many of the tubes did not fail at the place of greatest departure from roundness.

Even should a dependable formula be devised for the effects of out-of-roundness, which is not at all likely at present, of what possible use could it be in a commercial sense? The writer has spent many years in measuring, in a specially equipped laboratory, the out-of-roundness of tubes. With this experience in mind, it is inconceivable how any manufacturer of tubes could be persuaded to adopt a system of testing for out-of-roundness applicable to commercial tubes that are intended to resist collapsing pressures. This statement is made in view also of hundreds of comparatively recent tests on seamless-steel tubes manufactured for well casing. The results of these tests show, even to a more marked degree, the impracticability of considering out-of-roundness in the selling and buying of steel tubes. Of course, the writer is limiting his statements to out-of-roundness as found in legitimate manufacture and not to tubes that become unduly out of round due to subsequent rough handling.

Regarding the customary variations of thickness in the tube wall, as found in commerce, the less that engineers talk about the matter the better it will be for all concerned. Tubes of homogeneous material invariably fail at the thinnest part when subjected to internal fluid pressure. But this is not at all the case for similar tubes subjected to external fluid pressure. Both the results of tests reported by the writer in 1906 and those of recent tests on seamless-steel tubes, so far as he has worked over the results, show that the "axis of collapse" is not noticeably related to the thinnest portion of the tube wall. Its consideration has no place in engineering calculations.

Formulas based upon the theory of elasticity, such as Sturm's, given prominence in this paper, are generally useless for industrial calculations. The writer has been applying collapse formulas for about 25 years and does not recall a single instance in which such formulas were applicable, because of their limitation to the relatively thin walls, in which he was not concerned. Simple empirical formulas based directly upon actual tests of

commercial tubes, both welded and seamless, are entirely satisfactory for all cases of thickness divided by outside diameter greater than 0.023, which corresponds to the author's manner of expressing it of D/t less than 43, which covers the entire commercial range that the writer thus far has experienced.

In view of the foregoing, the writer cannot accept the authors' method of calculating the collapsing pressures of steel tubes, because he believes the procedure, in the light of present knowledge, is impracticable. It is not apparent just how the authors constructed the curves in Fig. 6 marked Y.P. 25,000 to 80,000, all of which are tangent to curve 1 calculated by Sturm's equation.

This chart is stated to apply to pipe that is perfectly round and uniformly thick. Presumably this chart is based upon Carman's tests on 21 cold-drawn steel tubes, 1 to 3 in. in diameter, which were machined in order to make their diameters and wall thickness uniform.

Unfortunately Carman did not test specimens cut from the same tubes, with the customary variations in diameter and wall thickness, in order to determine the direct relation of properties of the actual commercial to the machined perfect tubes. The authors therefore go to the writer's report of 1906 on an entirely different product, manufactured by an entirely different process—namely, bessemer-steel lap-welded tubes, 3 to 12 in. in diameter—for correction data on out-of-roundness to apply to calculations on the perfect tubes. In view of the numerous tests that the writer has made to date, both on welded and seamless steel tubes, the meagerness of Carman's data, and the inapplicability of the writer's out-of-round data, the authors' methods of calculating collapsing pressures seems to be ill-advised and unwarranted.

Near the bottom of the first column of the twelfth page there is the statement: "When the sizing press is closed, the tube is almost perfectly round. After the press is released, the tube may become slightly out of round on account of small changes in the elastic recovery, . . . If uniform external pressure is again applied (as is done in the collapsing tests), it is believed that the tube will regain its nearly complete roundness before it eventually collapses." The writer would like to ask the authors on what principles of mechanics this belief of theirs is based. Those who know their mechanics will agree, the writer feels sure, that this belief is entirely false, as uniform pressure was not applied by the sizing press in rounding up the tube, as inferred by the authors. In rounding up the tube the high portions would of necessity be subjected to great pressure, while the low portions at the same time would be subjected to very little or no pressure.

Only thus could the tube be squeezed into roundness. When subjected afterward to an external fluid pressure, which of course is uniformly distributed, any out-of-roundness in the tube will not decrease, as stated by the authors, but will increase. If the authors belief were correct, a tube could not possibly collapse. It would keep round all the while as the fluid pressure increased and would begin to fail only when the compression strength of the steel was reached, when the wall thickness would begin to increase and continue to increase with increase of fluid pressure.

GILBERT COOK.[11] A survey of the investigations which have been carried out in the subject of the collapse of tubes by external pressure reveals the comparatively small part which elastic theory has played in the framing of formulas and rules for practical design. The majority of experimenters in this field in former years have been content to devise empirical formulas to represent the results of their tests, a procedure which was, however, inevitable in the absence of an adequate theory. The disadvantage of an empirical formula is that its application must be limited to the conditions of the tests upon which it is based, and it gives no indication of the effect of any change in those conditions. While therefore it has been known that variations in thickness and imperfections of shape must affect the collapsing pressure of a tube, it has not been possible to predict the extent of their influence.

The mathematical theory of the stability of a cylindrical tube of uniform thickness was first worked out by Bryan in 1888, and he gave the formula [B] quoted by the authors. Previous to this, as long ago as 1875, Unwin had pointed out the analogy that existed between the collapse of a tube and the failure of a column under a compressive load, and obtained by this means a formula differing from [B] only in the numerical coefficient. The more complete theory given by Southwell covered the short as well as the long tube, and although the utility of Southwell's formula for the ordinary conditions of practice was diminished by the uncertainty regarding a numerical constant, it was the first successful attempt to indicate the manner in which the three variables of length, diameter, and thickness were concerned in the problem of collapse. The writer has demonstrated experimentally the accuracy of the formula for the particular end conditions for which the value of the constant was known.

It is interesting to observe that Southwell pointed out that the effect of the length of a tube, in so far as elastic stability was concerned, depended upon its relation to the quantity $\sqrt{(D^3/T)}$. It is not strictly correct to regard simply the L/D ratio as the criterion for a long or short tube. It is a convenience to do so, and may in normal circumstances be sufficiently accurate, but it is analogous to taking the slenderness ratio of a column as the ratio of length to transverse width, and ignoring the shape of the cross-section. It is probable that where elastic breakdown rather than instability is the cause of collapse, the effect of length is quite different, and should be expressed in terms of $\sqrt{(DT)}$. In either case the thickness cannot be entirely ignored in any true representation of the conditions.

The authors have made considerable use of a formula by Sturm. An account of the derivation of this formula does not appear to have been published, and it would be interesting to know in what way it is superior to that of Southwell.

Unfortunately the theory of elasticity has very little to say about the effect of variations in shape and thickness, which is the main theme of the author's paper. Experiment alone can, at present, give any reliable information in this important matter, and the authors have performed a most useful service in the careful analysis they have made of existing data. There are, however, one or two statements which call for comment. In Section II it is stated that "Variations in thickness below the average thickness tend to weaken the tube and adversely affect the collapsing strength; whereas variations above the average thickness, under special conditions, may strengthen the pipe and tend to increase the collapsing strength." The meaning of this paragraph is obscure, as the definition of "average" implies variations both above and below.

The explanation given for the effect described by the authors in Section VII (*b*) does not appear to be sound. For a given perimeter, the figure of greatest area is the circle. In order therefore that a tube initially out of round should become circular there must be an increase in area, and accordingly the work done by the external pressure would be negative, which is clearly impossible. Reverting to the column analogy, it is equivalent to the assertion that a column initially bent may become straight under the application of a compressive load. Is it not more likely that the yield point of the material has been underestimated?

[11] Professor, King's College, London, England.

CYRIL O. RHYS.[12] The general method followed in investigating pressures and stresses in tubes when about to collapse makes considerable use of the analogy between the failure of a column and the collapse of a tube. For a column, it is shown that Euler's equation,

$$\text{Max. unit load} = \frac{F}{A} = E\,\pi^2\,\frac{R^2}{L^2} \quad \ldots\ldots [1]$$

where

F = total load on column
A = cross-sectional area of column
E = Young's modulus
L = length of column
R = least radius of gyration of cross-section

agrees with experiment for long columns, but diverges from observed results for short ones. This is of course because Euler's equation is based on failure by bending, and short columns fail by direct crushing. Taking Tetmajer's experimental results for short columns, it is shown, in Fig. 2 of the paper, that these can be combined with Euler's equation so as to give a smooth curve, representing the relation between maximum unit load and slenderness ratio L/R. In the foregoing no allowance is made for eccentric loading.

Very much the same procedure is followed, in the paper, for tubes. Substituting the equation of Sturm or Timoshenko for that of Euler, and the results of pipe tests for Tetmajer's experiments, curves such as that of Fig. 2 are plotted showing the relation between maximum compressive stress and the ratio D/T or outside diameter ÷ wall thickness. The tubes are supposed to be straight, round, and of uniform thickness. Variations in these properties are allowed for by other charts such as Fig. 16 and Fig. 22. Equations [E] and [F] show how chart readings are combined to calculate collapsing pressures for various cases.

Returning to the column analogy, for short columns, the load which will produce rupture is fA, if f is the ultimate compressive stress, or

$$\frac{F}{A} = f \quad \ldots\ldots [2]$$

This can be combined with the Euler equation in the form

$$\frac{F}{A} = \frac{f}{1 + \dfrac{fL^2}{E\pi^2R^2}} \quad \ldots\ldots [3]$$

which is true for both long and short columns, since, when L/R is large, the 1 can be neglected and Euler's equation results, and when L/R is small the term containing it can be neglected, leaving [2].

Equation [3] is the well-known Gordon equation much used in column design. It is plotted on Fig. 26, accompanying this discussion, as well as the curve representing Euler's equation and Tetmajer's results. As will be seen, Gordon's equation is somewhat on the safe side, some allowance being thus made for unpredictable eccentricities in loading.

Using Gordon's equation as an analogy, an equation of the same general type as [3] can be applied to the collapsing of tubes. For very thick tubes, the collapsing pressure can be expressed by equation [C] of the paper in the form

$$P = \frac{K^2 - 1}{2K^2}\,S \quad \ldots\ldots [4]$$

[12] Mechanical Engineer, Standard Oil Development Company, Linden, N. J.

where $K = R_1/R_2$. Combining this with Timoshenko's equation [B] in the paper, to get a form like [3], there results,

$$P = \frac{\dfrac{K^2 - 1}{2K^2}\,S}{1 + \dfrac{2S(1 - m^2)}{E} \cdot \dfrac{K(K + 1)}{(K - 1)^2}} \quad \ldots\ldots [5]$$

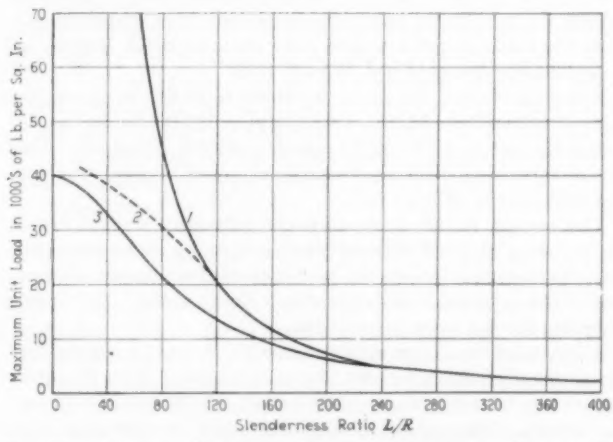

FIG. 26 MAXIMUM UNIT LOAD VERSUS SLENDERNESS RATIO L/R FOR STEEL COLUMNS WITH HINGED ENDS

(1, Euler's equation; 2, Tetmajer's experiments; 3, Gordon's equation.)

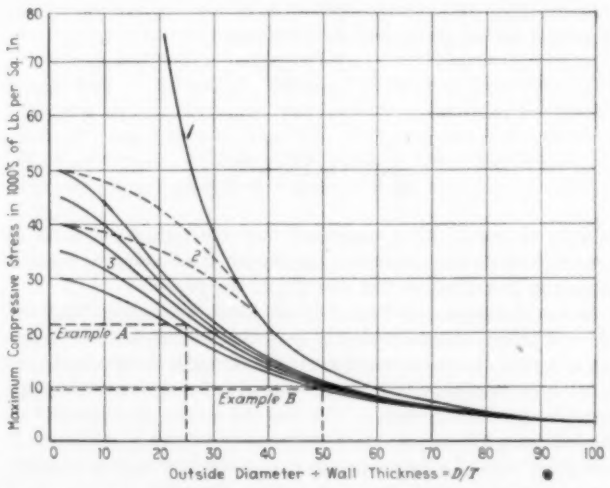

FIG. 27 RELATION BETWEEN MAXIMUM COMPRESSIVE STRESS AND RATIO D/T AT COLLAPSING PRESSURE

(1, from Timoshenko's equation; 2, from experimental results; 3, from analogy with Gordon's equation.)

This is true for thick or thin tubes. For a thick tube or K very large, $K\,\dfrac{(K + 1)}{(K - 1)^2}$ approaches unity. The quantity $\dfrac{2S(1 - m^2)}{E}$ is very small, and the equation reduces to [4]. For a very thin tube or K approaches 1, the second term in the denominator gets very large, the 1 can be neglected, and Timoshenko's equation results.

Fig. 27 of this discussion shows maximum compressive stress at collapsing pressure plotted against ratio D/T, for steel pipe having various yield-point values. As will be seen, the curves plotted from Equation [5] give safer values than the curves composed of the results of tests combined with Timoshenko's equation. This makes some allowance for the reduction due to out-of-roundness and other factors. The difference between the

solid and dotted curves meeting at (0,40), for instance, varies roughly with D/T, as does reduction in stress due to out-of-roundness shown in Fig. 22 of the paper.

As an illustration of this, if we take example *a* on the twelfth page of the paper, the maximum compressive stress given there is 28,800 lb. per sq. in. This has to be reduced by 13.9 per cent on account of 1 per cent out-of-roundness, leaving 25,000 lb. per sq. in. Using Fig. 27 of this discussion, there is obtained 21,500 lb. per sq. in. using curves plotted from Equation [5]. Had the out-of-roundness been 2 per cent, 21,500 lb. per sq. in. would have been obtained in each case.

For example *b* of the paper the stress is 13,400 lb. per sq. in. This is reduced by 24.2 per cent, giving 10,200 lb. per sq. in. Using the curve of Fig. 27, the stress is 9600 lb. per sq. in. This would correspond with a percentage of out-of-roundness of 1.25 per cent instead of 1 per cent.

Comparison is not made with the extremely short tubes of examples *c* and *d*. For these Sturm's equation no longer agrees with Timoshenko's equation, and time does not permit, at present, of the application of the Gordon formula analogy to Sturm's equation for the proper conditions.

From what has been shown, however, it would appear that for tubes of ordinary lengths, the curves plotted from Equation [5] on Fig. 27 of this discussion would be very suitable for practical design. The collapsing pressures could be computed from Equation [5]. Tables of $\frac{(K^2-1)}{K^2}$ and $K\frac{(K+1)}{(K-1)^2}$ would reduce the work to a minimum.

In checking over the examples *a*, *b*, *c*, and *d* of the paper, the tube radii are not given, and the relations

$$\frac{T}{R_1} = \frac{2T}{D}$$

$$\frac{R_1^2 - R_2^2}{2R_1^2} = \frac{2T}{D}\left(1 - \frac{T}{D}\right)$$

have to be used. It is suggested that the right-hand sides of these equations be substituted for the left-hand sides, at present appearing in Equations [E] and [F] of the paper.

In the discussion by Prof. Gilbert Cook it is stated that the effect of length should probably be stated in terms of the quantity $\sqrt{(DT)}$. In an investigation of the strength of vacuum drums it has been necessary to find an expression for the critical length between reinforcing rings. This has led to the development of the following theory, which is believed to be new. Although it may form part of a future paper, it is given here as it is of interest in connection with Professor Cook's discussion.

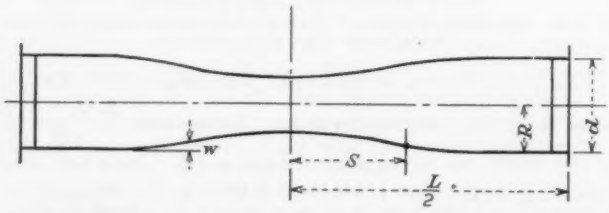

FIG. 28 COLLAPSE OF TUBE OR DRUM BETWEEN REINFORCING RINGS

Fig. 28 represents a length of tube or drum between reinforcing rings. Supposing the rings to be rigid and sufficiently strong to resist the external pressure, it is still possible for the tube to collapse, as indicated in the figure, by bending in the plane of the paper.

Using some well-known bending relations (see "Applied Elasticity," Timoshenko and Lessells, Chap. VI), we are led to the differential equation

$$\frac{d^4w}{ds^4} + 4n^4w = 0$$

and its solution $w = e^{-ns}(a \sin ns + b \cos ns)$ ..... [6]

where s = distance measured from a mid-section of the tube, L = length of the tube, w = deflection, and n = the quantity $\sqrt[4]{\frac{3(1-m^2)}{R_2t_2}}$. R = tube radius, t = thickness, and m = Poisson's ratio.

Differentiating [6] gives the slope anywhere, or,

$$\frac{dw}{ds} = ne^{-ns}[(a-b)\cos ns - (a+b)\sin ns]$$

This is 0 when $s = 0$, from which $a = b$, and it is also 0 when $s = L/2$ or $\sin Ln/2 = 0$. The least root of this is given by $Ln/2 = -\pi$, or $n = 2\pi/L$.

Substituting the expression for n, with Poisson's ratio taken as 0.3,

$$L = 4.9\sqrt{(Rt)} = 3.46\sqrt{(dt)}$$

which is of exactly the form indicated by Professor Cook. L is apparently the critical length below which the tube can only collapse as a ring collapses. Applications of the formula to a number of existing structures show the distance between reinforcing rings to be from $^1/_2$ to $^2/_3$ of L, as calculated above.

GEORGE C. PRIESTER.[13] The authors present a very practical method of determining the stress and the collapsing strength of steel tubes. The writer is pleased to note that the authors have regarded the collapsing strength of a steel tube to be due to two causes depending on the ratio of the diameter of the tube to its thickness. When this ratio is small, the failure is due to local deformations where the unit stress has exceeded the yield point of the material; when this ratio is large, the failure is an elastic failure similar to the failure of a long column. To make use of the analogous buckling phenomenon of columns in determining the collapsing strength of tubes is therefore both rational and logical.

The presentation of sufficient data to calculate the strength of a steel tube of any reasonable length, size, and thickness is a valuable contribution to engineering literature.

H. E. SAUNDERS[14] AND D. F. WINDENBURG.[15] Attention is called to an apparent inconsistency in the paper. Equation [A], due to Sturm, is used for obtaining the collapsing pressures of tubes shorter than the critical length.

For the shorter lengths, the number of lobes into which the circumference of the tube divides itself at the time of collapse is greater than two. Theoretically, the number of lobes N will be integral, and the tube will collapse into that number of lobes which makes the collapsing pressure a minimum. Experimentally, the lobes are not always of equal length, especially when these lengths are measured after collapse.

It is easily possible to obtain the value of N, which will make Equation [A] a minimum by differentiating with respect to N, equating the result to zero, and solving for N. Whence,

---

[13] Professor of Materials of Engineering, University of Minnesota, Minneapolis, Minn.

[14] Senior Assistant to Officer in Charge, U. S. Experimental Model Basin, Navy Yard, Washington, D. C.

[15] Assistant Physicist, U. S. Experimental Model Basin, Navy Yard, Washington, D. C.

$$N = \sqrt{\frac{\pi a}{\frac{L}{R}}} \times \sqrt[4]{\frac{\pi^2 a^2}{\frac{L^2}{R^2}} - m} \quad [7]$$

$$= \sqrt{\frac{\pi a}{2\frac{L}{D}}} \times \sqrt[4]{\frac{\pi^2 a^2}{4\frac{L^2}{D^2}} - m} \quad [7a]$$

In the paper the value of N is determined from existing experimental data. Quoting: "In order to evaluate this term [N], the foregoing data on the collapsing pressure of short tubes were substituted in Sturm's equation, and N was determined for several L/D ratios. The results of these determinations were plotted in a series of intermediate curves, of which Fig. 7 represents the final result. In Fig. 7 the value of N is plotted against the ratio L/D for various D/t ratios. On the basis of the value of N shown in Fig. 7, the collapsing strengths of short tubes having L/D ratios of $1^1/_2$ to 7 were calculated."

The Fig. 7 referred to shows distinctly separate curves for D/t ratios of 30, 40, 50, 60, and 70. From these curves, it is seen that N depends upon t/D, increasing as D/t increases for a constant value of the length-diameter ratio L/D. However, Equation [7a] shows that, in Sturm's equation, N is a function of L/D only and is independent of t/D. That is, according to this equation, two tubes of the same length and diameter will collapse in the same number of lobes, even though one tube is very thin and the other very thick. Evidently, then, Sturm's equation will not predict the correct number of lobes, and hence it cannot safely be used for calculating the collapsing pressures of short tubes. This is especially significant, since the equations developed by Southwell and von Mises give the correct number of lobes in practically every case.

Under Figs. 1, 3, 4, and 5, it is stated that curve 2 (broken line) is "plotted from experimental results." Actually the range of D/T values in the experiments quoted by no means covers the range for which curve 2 is drawn, with the exception of Fig. 4. It would be illuminating to have the experimental spots indicated in the figures. Furthermore, to be exact, there should be a series of curves No. 1 for various L/D ratios.

The choice of the term "collapsing strength," which has been used extensively throughout the paper to denote calculated unit stress at collapse, seems rather unfortunate. It is suggested that some more definite or descriptive term be substituted for it.

With regard to the last paragraph of Section IV and other similar paragraphs, it is felt that the limiting boundaries for the regions controlled by various factors should be more definitely given, if the paper is to be of the maximum benefit to the designer.

It would be instructive to have the reasons behind the statement in section V that "it is entirely logical that N should be represented by either a whole or a compound number." If N is calculated from a formula, it will rarely come out an integral value; on the other hand, why should a column collapse in a fractional number of bays?

Under section VI*a*, it should be pointed out that variation from circular section within the region of one lobe is the controlling feature in premature collapse. Any analysis based upon the behavior of an elliptical ring is almost sure to break down when the number of lobes is greater than two.

HENRY FOWLER.[16] In section VII of the paper, an average variation in wall thickness of 2.5 per cent (for tubes tested by A. O. Smith Corporation) is said to have no effect on the collapsing strength of the tubes; and in Section VI, an average variation in wall thickness of 12 per cent (Stewart's data) is assumed to be of considerably less account than an out-of-roundness figure varying from 0.52 per cent to 2.17 per cent.

While this assumption may be of value in determining the absolute maximum effect due to out-of-roundness, and in this way provide a factor of safety for design purposes, the writer does not think that it is justifiable to state that variation in wall thickness can be left out of account.

For example, using the method set out in the paper, a calculation for a tube with, say, 2 per cent out-of-roundness will indirectly cover any variation in wall thickness coming within ordinary manufacturing tolerances, but any greater variation will not be covered; and a calculation for a perfectly round tube will give an optimistic value for the pressure that can be withstood, as no allowance is made directly or indirectly for variation in wall thickness.

A. ONO.[17] As stated by the authors, the relation between tubes and struts is very close. This can be seen also in the calculation of the critical stress of a tube wall which fails by inelastic collapsing. As to the inelastic buckling of struts, Dr. Th. von Kármán showed clearly by theory and experiment that the stress in a strut may be found from the stress-strain relation observed in compressing the material of the strut under a stress beyond the elastic limit. A similar consideration may be applied to the case of a tube, and a formula deduced may serve for estimating the collapsing stress. As the deduction is very similar to the case of struts, a brief account of the calculation will be sufficient.

Let us denote the outside radius by r and the thickness of the wall by t, respectively. If the tube is truly circular, and the thickness is small as compared with the diameter, the stress is equal to pr/t, p being the intensity of the fluid pressure. If the pressure becomes high, the wall, which is assumed to be infinitely long for the present, undergoes collapsing with an additional bending stress. Denoting the distance from the neutral axis by η, the bending stress is approximately given by the following equation:

$$\sigma = H\eta\left(\frac{1}{\rho} - \frac{1}{r}\right)$$

where H stands for the constant $m^2E/m^2 - 1$ (E the modulus of elasticity and m the reciprocal of Poisson's ratio). Different values of H should be taken for the positive and the negative sides of η, as the stress-strain relation is not the same.

The bending moment per unit length of the tube is $M = \int \sigma\eta d\eta$ taken over a section of the wall. Introducing the foregoing expression for the stress, and using the condition that $\int \sigma d\eta = 0$, we obtain in the same way as in the case of a strut

$$M = \frac{Kt^3}{12}\left(\frac{1}{\rho} - \frac{1}{r}\right)$$

where

$$\frac{1}{\sqrt{K}} = \frac{1}{2}\left(\frac{1}{\sqrt{H}} + \frac{1}{\sqrt{H_1}}\right)$$

H and H_1 refer to the positive and the negative parts of η, respectively.

With this expression for the bending moment, the calculation of the critical pressure may be performed. (See Timoshenko, "Applied Elasticity.") The result of the calculation is, obviously, as follows:

$$p = \frac{K}{4}\frac{t^3}{r^3}$$

[16] Assistant to Vice-President (Research and Development), London Midland and Scottish Railway Company, Derby, England.

[17] Professor, Institute of Strength of Material, Kyushu Imperial University, Fukuoka, Japan.

Accordingly, with $S = pr/t$, the critical stress is given by the formula:

$$S = \frac{K}{4}\frac{t^2}{r^2}$$

This formula gives the critical stress in a long cylindrical tube under a right condition. Any defect such as out-of-roundness, local weakness of material, etc., may of course reduce the critical stress. So the deviation of a test result from the theoretical value may be taken as a sign of imperfection existing in some points.

Authors' Closure

The aim of the paper was twofold: (1) to gather theoretical and experimental material on the collapse of cylinders and endeavor to put it together in a manner which might be useful in the analysis of structures subjected to collapse; and (2) to differentiate in a practical manner between the influence of the physical properties and elastic properties of steel on the behavior of cylinders under external pressure. Had the latter not been aimed at, considerable difficulty would have resulted in dealing with tubes made of steels of widely varying yield points, so as to bring them under a rational analysis. In the use of available data there has been no desire to depreciate the work of other investigators nor to duplicate it except to coordinate it, but rather to recognize and use the careful work which has been done by others. The authors are therefore extremely grateful that such a mass of good experimental data was available for this purpose.

It is not presumed that this paper is anything but a stepping stone to a more complete analysis of the behavior of cylinders subjected to collapsing loads. Nor is it presumed that all of the ideas presented are free from controversy, but to the best of the authors' belief at the present time, the essential ones are. It might be appropriate here to state that the authors have applied the methods outlined to the design of large autoclaves under collapsing pressures and have followed the behavior of such equipment under test to the point of being exceedingly well gratified. The field of the very slender cylinder has been studied also from the experimental angle, and it is hoped that this will yield to an extension of the same general treatment which was applied to the less slender cylinder. This will be presented eventually as a supplement to this paper. There are many data available on slender cylinders which have not been used because they fall mainly outside of the range of D/T ratios presented in the paper. Particularly is this true of the valuable work done by Professor Cook of King's College, London,[18] which is being used for the extension of the method of analysis here applied.

It is believed by the authors that the mathematical treatment of a problem needs tests to supplement it; and that when tests of several investigators can be used which fall into line in a rational manner, a satisfaction is lent to the problem which otherwise could not be obtained. However, this particular problem in its entirety can be only partially analyzed by the available mathematical set-up; and to apply mathematics to the whole range of the problem would seem to be impracticable at the present time.

The derivation of Sturm's equation has not been produced because its author is preparing it for a Doctor's thesis to be presented at the University of Illinois. It is hoped that it will be available to those interested within the very near future. The development of this formula will therefore not be discussed.

Mr. Sturm has introduced the term "plastic yield" in his discussion. The authors have not been able to adjust themselves to such a term. It is believed that at or below the appropriate curves shown for a steel of definite physical properties and with definite dimensions of a tube, no plastic action is possible in the material. In the action of a tube under collapse the possibility of elastic buckling is freely admitted; and except for very stiff tubes the point at which buckling starts is well below the yield point of the material. It is believed that plastic yielding does not occur until the yield point of the material is reached. The authors are quite in agreement with Mr. Sturm's statement of Dr. Westergaard's conception of the division of the field of elastic action.

The authors are grateful to Professor Cook for drawing their attention to the fact that Bryan is responsible for the formula which was labeled as Timoshenko's. In 1913 Professor Cook pointed out that no universal formula had been found to cover the entire range of the behavior of tubes under collapse, and that it was unlikely that such a formula could be devised which would be sufficiently simple to be of practical value.[19] The authors are in entire agreement with him on this point, and the resort to curves has been made in recognition of this fact. Professor Cook also draws attention to the value of bringing mathematical studies into direct application by the use of actual tests. Such tests not only clarify the mathematical results, but also can be used (and have been used by the authors) to draw attention to the degree of perfection available in commercial tubes of today.

Referring to that part of Section II which is quoted in Professor Cook's discussion, "variations in thickness below the average thickness" concern the thin portions of a commercial tube, and "variations above the average thickness" concern the thick portions. In a uniformly round tube subjected to external pressure, the circumferential stress will attain a maximum at the thin portions, and the tube will collapse at a lower pressure than if it were both round and uniformly thick. In an out-of-round tube, the circumferential stress may or may not attain a maximum at the thin portions, depending upon the locations of these portions with respect to the greater diameter of the tube. If the thin portions are at the extremities of this diameter, the circumferential stress will attain a maximum at these points. However, if the thick portions of the tube are at the extremities of the greatest diameter, the circumferential stress may not always attain a maximum at these points, although the bending moment is greatest at these points, but rather at other points where the bending moment is less. Whether or not the circumferential stress will attain a maximum in the thick portions of the tube will depend upon the relative thickness of the thick and thin portions and the respective bending moments at both the thin and thick portions.

With reference to the first part of Professor Cook's closing paragraph, on the possibility of an out-of-round tube's becoming more round under collapsing loads, there can be a serious difference of opinion. This possibility was considered by the authors in conjunction with the test results obtained on tubes which were sized in a die that was as perfectly round as it could be made. In carrying out the sizing operations the portions of the pipe which were slightly thinner were strained a larger amount, and the yield point stress at those points raised above the value it would attain in the thicker portions. The greater amount of elastic recovery at the thinner portions therefore produced a slightly greater curvature at these portions. On subsequent reloading in the testing apparatus, the authors believe the following to be the explanation of the recovery of roundness. As the load was gradually applied, the bending moment at the thinner portions was slightly less than at the thicker portions; but the stress at the former was greater than at the latter, and therefore the curvature of the thinner portions tended to decrease and approach the roundness assumed by the tube when the sizing dies were closed. As the load continually increased there was of course no opportunity

[19] "The Resistance of Tubes to Collapse," British Association Rep. (Birmingham) (1913), pp. 213–224.

for further elastic recovery, and the tube eventually collapsed. This seems to be confirmed by the test results as indicated in Fig. 1.

With reference to the last part of Professor Cook's closing paragraph, the tubes tested for collapse by the authors were tested for physical properties after they had been completely fabricated, so that the reported yield points represent the values in the tubes when tested in collapse.

Messrs. Saunders and Windenburg, in their discussion of lobes, state, "Theoretically, the number of lobes N will be integral, and the tube will collapse into that number of lobes which makes the collapsing pressure a minimum." The authors are in agreement with the latter part of this statement, but not with the former part.

Theoretically, the number of lobes will not necessarily be integral, as the lobing is not a discontinuous function of collapsing stress; if it were, the number of symmetrical lobes would abruptly change from one whole number to the next.

The tube will have a natural lobing tendency, and the maximum collapsing pressure that a tube can sustain will be controlled by this natural tendency. It is quite possible that the natural length of a lobe may not divide into the periphery of the pipe an even number of times, and at least there may result one hybrid lobe which represents a whole natural lobe and part of another. This is shown by the unsymmetrical forming of lobes.

The authors have taken the experimental data for short tubes and assumed for each set of dimensions that the value of N is an unknown quantity. Solving for this unknown quantity in Sturm's equation will result in the curves for N which are given in Fig. 7. Fig. 7 was interpolated for values of N, and these latter values were then substituted in Sturm's equation to provide stress values for Fig. 8. Fig. 8 is directly applicable to tube-strength analysis under collapsing pressure when the yield point of the steel, L/D, and D/T are known; and from this figure the collapsing stress can be determined.

It is not clear to the authors how Messrs. Saunders and Windenburg arrive at the conclusion that "Equation [7*a*] shows that, in Sturm's equation, N is a function of L/D only and is independent of t/D." Presumably, in the partial differentiation of Sturm's equation the ratio t^3/D^3 is considered to be constant. But if it is so considered, the deduction, made by Messrs. Saunders and Windenburg that "according to this equation, two tubes of the same length and diameter will collapse in the same number of lobes, even though one tube is very thin and the other very thick," is incorrect. In the partial differentiation t^3/D^3 was made a constant, and this implies that while this ratio is kept constant N will vary only with L/D according to the mathematics shown.

Concerning Sir Henry Fowler's discussion, the authors wish to state that the question of thickness is not considered to have no effect on the collapsing strength. It is believed, however, with the present methods of pipe making (which use fairly uniform thicknesses of steel), that this factor is very much less effective than the question of out-of-roundness, and can be neglected for all practical purposes. This conclusion was reached after a considerable study of tubes which were very round, but in which the thickness difference in the tubes was the maximum tolerance allowed in the plates purchased for tube making.

It is gratifying to read the kind remarks of Dr. Jacobus and Professor Priester.

Professor Ono and Mr. Rhys have both been very helpful in their discussions in clarifying the analogy which the authors have drawn between columns and tubes.

In his reference to Gordon's formula, Mr. Rhys has suggested a more conservative series of curves for tubes. The authors believe, however, that while Gordon's formula is a reliable consideration for columns because of the difficulty in avoiding eccentric loading in service, it does not strictly apply to tubes under collapse. In the very principles applied to tube making, this degree of eccentricity (which is represented by out-of-roundness) need not be present in modern methods of manufacture. The degree of out-of-roundness found in commercial tubes today is very small. In order to get information on out-of-roundness the authors had to study data on tubes made by old tube-manufacturing methods. These methods have been so much improved that today the importance of out-of-roundness is reduced to a minor position. Nevertheless, an evaluation of out-of-roundness in tubes has been made in this paper; and can be applied to processes of manufacture which demand it. The effect of out-of-roundness becomes increasingly important in studying large vessels under collapsing loads, such as autoclaves and the like.

Concerning Professor Stewart's discussion, the authors believe that his generalizations on commercial tubes and on the impracticability of evaluating the effect of out-of-roundness and variations in thickness would be more helpful if they were substantiated by specific test results on modern tubes.

In 1906 he made a splendid contribution to the study of the collapse of tubes and revealed the superiority of the prevailing methods of manufacturing tubes over those existing in 1858 when Professor William Fairbairn published his investigation on riveted tubes.[20] Professor Stewart's tests, however, were made on tubes which were more out-of-round and had greater variations in thickness than is commercially necessary at the present time. It is therefore logical to suppose that his results can be bettered by those on commercial tubes of today.

While industry is approaching nearer to the ideal in tube manufacturing, it is helpful to have some kind of calibration to reveal what this ideal is, and to demonstrate how near commercial tubes can come to this ideal. Professor Carman's tubes were machined to nearly perfect roundness and uniform thickness; and the test results are shown in Fig. 3. Although these tubes cannot be classed as commercial, reference is made to Fig. 1 for tubes selected at random which were made commercially to the extent of over 1,000,000 tons within the past few years. The correlation of results between Carman's almost perfect tubes (Fig. 3) and those shown in Fig. 1 will indicate the degree of perfection possible in commercial tubes at the present time. A close study of the experimental curves in Figs. 1 and 4 will show particularly in the elastic range of the curves the degree to which modern manufacturing methods have progressed toward the ideal tube.

It is believed that the technical points raised by Professor Stewart are covered in the author's remarks bearing on Professor Cook's, Sir Henry Fowler's, and Mr. Rhys's discussions.

Spiral Springs

A New Theory Regarding Their Stress, Strain, and Energy Functions

By J. A. VAN DEN BROEK,[1] ANN ARBOR, MICH.

The paper presents a new theory relative to the stress, strain, and energy functions of spiral springs. This theory differs from the current one in that it takes into account the large deformations implied in the action of spiral springs. In the light of the theory, definite recommendations are made with reference to the design and mounting of spiral springs. It is suggested that springs may be loaded in such a manner as to eliminate all locally overstressed points as well as all friction between leaves. No grease or graphite, therefore, need be employed and the efficiency of spiral springs may thus be increased: (1) By the utilization of space otherwise occupied by a lubricant, from 10 to 20 per cent; (2) by the elimination of all friction between leaves, from 20 to 40 per cent; and (3) by the elimination of locally overstressed points, from 40 to 100 per cent.

FOR a number of years the author has been giving a discussion of spiral springs before his classes at the University of Michigan. He was aware that his analysis differed from those of Föppl, Morley, and Castigliano, and while writing a chapter on Resilience for his text "Elastic Energy Theory" (John Wiley & Sons, Inc., 1931) this disagreement became all the more apparent. Hence this paper is presented with a view to offering opportunity for discussion. The same arguments used in his class work and as given in the text just referred to, are more or less followed in the present discussion. The problem, however, is dealt with in more detail. Furthermore a rational application of the theory to practical problems in design is suggested.

A distinction is made between four essentially different conditions of loading of spiral springs, which include most of those of practical importance at the present time. These four loading conditions are discussed separately under cases I, II, III, and IV.

After having established what appears to be the most desirable condition of loading of the spiral spring, practical means of obtaining it are considered in the light of the theory.
